201 West 103rd Street,
Indianapolis, Indiana 46290

Contents at a Glance

Introduction	xxii
1 Personal Computer Background	1
2 PC Components, Features, and System Design	17
3 Microprocessor Types and Specifications	35
4 Motherboards and Buses	203
5 BIOS	345
6 Memory	413
7 The IDE Interface	503
8 The SCSI Interface	529
9 Magnetic Storage Principles	567
10 Hard Disk Storage	583
11 Floppy Disk Storage	639
12 High-Capacity Removable Storage	671
13 Optical Storage	705
14 Physical Drive Installation and Configuration	771
15 Video Hardware	803
16 Serial, Parallel, and Other I/O Interfaces	871
17 Input Devices	899
18 Internet Connectivity	949
19 Local Area Networking	995
20 Audio Hardware	1045
21 Power Supply and Chassis/Case	1085
22 Printers and Scanners	1143
23 Portable PCs	1205
24 Building or Upgrading Systems	1251
25 PC Diagnostics, Testing, and Maintenance	1287
26 Operating System Software and Troubleshooting	1337
27 File Systems and Data Recovery	1379
28 A Final Word	1423
A Web Site List	1447
B Glossary	1451
C Making the Most Of PartitionMagic and Drive Image	1529
Index	1537

Upgrading and Repairing PCs, 11th Edition

Contents

Introduction xxii

1 Personal Computer Background 1

- Computer History—Before Personal Computers 2
 - Timeline 2
 - Mechanical Calculators 5
 - The First Mechanical Computer 5
 - Electronic Computers 7
- Modern Computers 7
 - From Tubes to Transistors 8
 - Integrated Circuits 9
 - The First Microprocessor 9
- Personal Computer History 11
 - Birth of the Personal Computer 11
- The IBM Personal Computer 12
- The PC Industry 18 Years Later 14

2 PC Components, Features, and System Design 17

- What Is a PC? 18
 - Who Controls PC Software? 18
 - Who Controls PC Hardware? 21
 - PC 9x Specifications 25
- System Types 26
- System Components 29
 - Motherboard 30
 - Processor 31
 - Memory (RAM) 31
 - Case (Chassis) 31
 - Power Supply 32
 - Floppy Disk Drive 32
 - Hard Disk Drive 32
 - CD-ROM Drive 33
 - Keyboard 33
 - Mouse 33
 - Video Card 33
 - Monitor (Display) 34

3 Microprocessor Types and Specifications 35

- Microprocessors 36
- Pre-PC Microprocessor History 36
- Processor Specifications 39
 - Processor Speed Ratings 42
 - Processor Speeds and Markings Versus Motherboard Speed 45
 - Data Bus 50
 - Internal Registers (Internal Data Bus) 51
 - Address Bus 52
 - Internal Level 1 (L1) Cache 53
 - Level 2 (L2) Cache 55
 - Cache Organization 56
 - Processor Modes 58
- SMM (Power Management) 61
- Superscalar Execution 61
- MMX Technology 62
- SSE (Streaming SIMD Extensions) 63
- Dynamic Execution 64
 - Multiple Branch Prediction 64
 - Data Flow Analysis 64
 - Speculative Execution 65
- Dual Independent Bus (DIB) Architecture 65
- Processor Manufacturing 66
- PGA Chip Packaging 70
- Single Edge Contact (SEC) and Single Edge Processor (SEP) Packaging 71
- Processor Sockets 74
 - Socket 1 75
 - Socket 2 76
 - Socket 3 78
 - Socket 4 79
 - Socket 5 80
 - Socket 6 82
 - Socket 7 (and Super7) 82
 - Socket 8 84
 - Socket PGA-370 85

- Zero Insertion Force (ZIF) Sockets 86
 - Processor Slots 87
 - Slot 1 87
 - Slot 2 (SC330) 90
 - CPU Operating Voltages 91
 - Heat and Cooling Problems 93
 - Heat Sinks 94
 - Math Coprocessors (Floating-Point Units) 97
 - Processor Bugs 100
 - Processor Update Feature 100
 - Intel Processor Codenames 102
 - Intel-Compatible Processors (AMD and Cyrix) 103
 - AMD Processors 103
 - Cyrix 105
 - IDT Winchip 106
 - P-Ratings 107
 - P1 (086) First-Generation Processors 108
 - 8088 and 8086 Processors 108
 - 80186 and 80188 Processors 109
 - 8087 Coprocessor 109
 - P2 (286) Second-Generation Processors 109
 - 286 Processors 109
 - 80287 Coprocessor 111
 - 286 Processor Problems 111
 - P3 (386) Third-Generation Processors 112
 - 386 Processors 112
 - 386DX Processors 113
 - 386SX Processors 113
 - 386SL Processors 114
 - 80387 Coprocessor 114
 - Weitek Coprocessors 115
 - 80386 Bugs 115
 - P4 (486) Fourth-Generation Processors 117
 - 486 Processors 117
 - 486DX Processors 120
 - 486SL 121
 - 486SX 122
 - 487SX 123
 - DX2/OverDrive and DX4 Processors 124
 - Pentium OverDrive for 486SX2 and DX2 Systems 126
 - "Vacancy"—Secondary OverDrive Sockets 126
 - 80487 Upgrade 127
 - AMD 486 (5x86) 127
 - Cyrix/TI 486 128
 - P5 (586) Fifth-Generation Processors 129
 - Pentium Processors 129
 - First-Generation Pentium Processor 133
 - Second-Generation Pentium Processor 134
 - Pentium-MMX Processors 137
 - Pentium Defects 138
 - Testing for the FPU Bug 139
 - Power Management Bugs 140
 - Pentium Processor Models and Steppings 141
 - AMD-K5 149
 - Pseudo Fifth-Generation Processors 150
 - IDT Centaur C6 Winchip 150
 - Intel P6 (686) Sixth-Generation Processors 151
 - Pentium Pro Processors 154
 - Pentium II Processors 162
 - Celeron 174
 - Pentium III 181
 - Pentium II/III Xeon 184
 - Pentium III Future 187
 - Other Sixth-Generation Processors 187
 - Nexgen Nx586 187
 - AMD-K6 Series 188
 - 3DNow 191
 - AMD-K7 192
 - Cyrix MediaGX 192
 - Cyrix/IBM 6x86 (M1) and 6x86MX (MII) 193
 - P7 (786) Seventh-Generation Processors 194
 - Merced 195
 - Processor Upgrades 197
 - OverDrive Processors 198
 - OverDrive Processor Installation 198
 - OverDrive Compatibility Problems 199
 - Processor Benchmarks 200
 - Processor Troubleshooting Techniques 201
- ## 4 Motherboards and Buses 203
- Motherboard Form Factors 204
 - Baby-AT 205
 - Full-Size AT 209
 - LPX 210
 - ATX 214
 - Micro-ATX 218
 - Flex-ATX 220

- NLX 222
- WTX 226
- Proprietary Designs 230
- Backplane Systems 231
- Motherboard Components 234
- Processor Sockets/Slots 234
- Chipsets 235
- Intel Chipsets 237
 - Intel Chipset Model Numbers 238
 - Intel's Early 386/486 Chipsets 240
- Fifth-Generation (P5 Pentium Class) Chipsets 241
 - Intel 430LX (Mercury) 242
 - Intel 430NX (Neptune) 242
 - Intel 430FX (Triton) 243
 - Intel 430HX (Triton II) 244
 - Intel 430VX (Triton III) 246
 - Intel 430TX 246
 - Third-Party (Non-Intel) P5 Pentium Class Chipsets 247
- Sixth-Generation (P6 Pentium Pro/Pentium II/III Class) Chipsets 252
 - Intel 450KX/GX (Orion Workstation/Server) 256
 - Intel 440FX (Natoma) 256
 - Intel 440LX 257
 - Intel 440EX 257
 - Intel 440BX 258
 - Intel 440ZX and 440ZX-66 259
 - Intel 440GX 260
 - Intel 450NX 260
 - Intel 810 261
 - Third-Party (non-Intel) P6 Class Chipsets 265
- Super I/O Chips 267
 - Motherboard CMOS RAM Addresses 268
 - Motherboard Interface Connectors 272
- System Bus Functions and Features 276
 - The Processor Bus 277
 - The Memory Bus 281
- The Need for Expansion Slots 281
- Types of I/O Buses 282
 - The ISA Bus 283
 - The Micro Channel Bus 288
 - The EISA Bus 289
 - Local Buses 292
 - VESA Local Bus 294
 - The PCI Bus 299
 - Accelerated Graphics Port (AGP) 310

- System Resources 311
 - Interrupts (IRQs) 312
 - DMA Channels 320
 - I/O Port Addresses 322
- Resolving Resource Conflicts 326
 - Resolving Conflicts Manually 326
 - Using a System-Configuration Template 328
 - Heading Off Problems: Special Boards 332
 - Plug-and-Play Systems 336
- Knowing What to Look For (Selection Criteria) 338
 - Documentation 342
 - Using Correct Speed-Rated Parts 342

5 BIOS 345

- BIOS Basics 346
- BIOS Hardware/Software 347
- Motherboard BIOS 349
 - ROM Hardware 350
 - ROM Shadowing 352
 - Mask ROM 353
 - PROM 353
 - EPROM 355
 - EEPROM/Flash ROM 356
 - ROM BIOS Manufacturers 357
- Upgrading the BIOS 363
 - Where to Get Your BIOS Update 364
 - Determining Your BIOS Version 365
 - Backing Up Your BIOS's CMOS Settings 365
 - Keyboard-Controller Chips 366
 - Motherboard CMOS RAM Addresses 371
 - Replacing a BIOS ROM 375
- CMOS Setting Specifications 375
 - Running or Accessing the CMOS Setup Program 375
 - BIOS Setup Menus 376
 - Maintenance Menu 377
 - Main Menu 377
 - Advanced Menu 379
 - Security Menu 390
 - Power Management Menu 391
 - Boot Menu (Boot Sequence, Order) 394
 - Exit Menu 395
 - Additional BIOS Setup Features 396

Year 2000 BIOS Issues	397
Award	399
AMI	399
Phoenix	400
Plug-and-Play BIOS	400
PnP Device IDs	401
Initializing a PnP Device	408
BIOS Error Messages	409
General BIOS Boot Text Error Messages	410

6 Memory 413

Memory Basics	414
ROM	416
DRAM	418
Cache Memory: SRAM	419
RAM Memory Speeds	424
Fast Page Mode (FPM) DRAM	426
EDO (Extended Data Out) RAM	427
Burst EDO	428
SDRAM	428
Future DRAM Memory Technologies	429
RDRAM	429
DDR SDRAM	435
Physical RAM Memory	435
SIMMs and DIMMs	437
SIMM Pinouts	442
DIMM Pinouts	446
Physical RAM Capacity and Organization	449
Memory Banks	451
RAM Chip Speed	453
Gold Versus Tin	453
Parity and ECC	457
Installing RAM Upgrades	465
Upgrade Options and Strategies	465
Selecting and Installing Motherboard Memory with Chips, SIMMs, or DIMMs	466
Replacing SIMMs and DIMMs with Higher Capacity	467
Adding Adapter Boards	467
Installing Memory	468
Troubleshooting Memory	472
Memory Defect Isolation Procedures	475
The System Logical Memory Layout	477
Conventional (Base) Memory	481
Upper Memory Area (UMA)	481
Extended Memory	494

Preventing ROM BIOS Memory Conflicts and Overlap	495
ROM Shadowing	496
Total Installed Memory Versus Total Usable Memory	497
Adapter Memory Configuration and Optimization	499

7 The IDE Interface 503

An Overview of the IDE Interface	504
Precursors to IDE	504
The ST-506/412 Interface	505
The ESDI Interface	507
The IDE Interface	509
IDE Origins	510
IDE Bus Versions	511
ATA IDE	512
ATA Standards	513
ATA-1 (AT Attachment Interface for Disk Drives)	513
ATA I/O Connector	514
ATA I/O Cable	516
ATA Signals	516
Dual-Drive Configurations	517
ATA Commands	519
ATA-2 (AT Attachment Interface with Extensions)	520
ATA-3 (AT Attachment 3 Interface)	520
Increased Drive Capacity	521
Faster Data Transfer	523
DMA Transfer Modes	524
ATAPI (ATA Packet Interface)	525
ATA/ATAPI-4 (AT Attachment 4 with Packet Interface Extension)	526
ATA/ATAPI-5 (AT Attachment 5 with Packet Interface)	526
Obsolete IDE Versions	527
XT-Bus (8-bit) IDE	528
MCA IDE	528

8 The SCSI Interface 529

Small Computer System Interface (SCSI)	530
ANSI SCSI Standards	532
SCSI-1 and SCSI-2	537
SCSI-3	538
Fast and Fast-Wide SCSI	539
Fast-20 (Ultra) SCSI	539

Fast-40 (Ultra2) SCSI	539
Fast-80 SCSI	540
Wide SCSI	540
Fiber Channel SCSI	540
Termination	540
Command Queuing	540
New Commands	540
SCSI Cables and Connectors	541
SCSI Cable and Connector Pinouts	543
Single-Ended SCSI Cables and Connectors	544
Differential SCSI Signals	547
Expanders	548
Termination	548
SCSI Drive Configuration	549
Start On Command (Delayed Start)	553
SCSI Parity	554
Terminator Power	554
SCSI Synchronous Negotiation	554
Plug-and-Play (PnP) SCSI	555
SCSI Configuration Troubleshooting	556
SCSI Versus IDE	557
SCSI Hard Disk Evolution and Construction	558
Performance	564
SCSI Versus IDE: Advantages and Limitations	564
Recommended SCSI Host Adapters	565

9 Magnetic Storage Principles 567

Magnetic Storage	568
History of Magnetic Storage	568
How Magnetic Fields Are Used to Store Data	569
Magneto-Resistive (MR) Heads	574
Data Encoding Schemes	575
FM Encoding	577
MFM Encoding	577
RLL Encoding	578
Encoding Scheme Comparisons	579
PRML (Partial-Response, Maximum-Likelihood) Decoders	581
Capacity Measurements	581

10 Hard Disk Storage 583

Definition of a Hard Disk	584
Hard Drive Advancements	585
Areal Density	585
Hard Disk Drive Operation	586
The Ultimate Hard Disk Drive Analogy	589
Tracks and Sectors	591
Disk Formatting	594
Basic Hard Disk Drive Components	599
Hard Disk Platters (Disks)	600
Recording Media	601
Read/Write Heads	603
Read/Write Head Designs	604
Head Sliders	607
Head Actuator Mechanisms	608
Air Filters	618
Hard Disk Temperature	
Acclimation	620
Spindle Motors	621
Logic Boards	621
Cables and Connectors	622
Configuration Items	623
The Faceplate or Bezel	623
Hard Disk Features	624
Reliability	624
Performance	627
Shock Mounting	636
Cost	636
Capacity	636
Specific Recommendations	638

11 Floppy Disk Storage 639

Floppy Disk Drives	640
Drive Components	640
Read/Write Heads	640
The Head Actuator	643
The Spindle Motor	644
Circuit Boards	645
The Controller	645
The Faceplate	646
Connectors	646
The Floppy Disk Drive Cable	647
Disk Physical Specifications and Operation	649
How the Operating System Uses a Disk	650
Cylinders	651
Clusters or Allocation Units	651
Diskette Changeline	652

Types of Floppy Disk Drives	653
The 1.44MB 3 1/2-Inch Drive	654
The 2.88MB 3 1/2-Inch Drive	654
The 720KB 5 1/4-Inch Drive	655
The 1.2MB 5 1/4-Inch Drive	656
The 360KB 5 1/4-Inch Drive	657
Analyzing Floppy Disk Construction	657
Floppy Disk Media Types and Specifications	660
Caring for and Handling Floppy Disks and Drives	661
Airport X-ray Machines and Metal Detectors	662
Drive-Installation Procedures	663
Troubleshooting Floppy Drives	664
Common Floppy Drive Error Messages—Causes and Solutions	665
Repairing Floppy Disk Drives	666
Cleaning Floppy Disk Drives	667
Aligning Floppy Disk Drives	668

12 High-Capacity Removable Storage 671

Why Use Removable Drives?	672
Types of Removable Media Drives	673
High-Capacity Floptical Drives	674
21MB Floptical Drives	674
LS-120 (120MB) SuperDisk Drives	675
Bernoulli Drives	676
Zip Drives	676
Jaz Drives	679
SyQuest Drives	680
Removable Drive Letter Assignments	681
Comparing Removable Drives	683
Tape Drives	685
The Origins of Tape Backup Standards	686
The QIC Standards	687
Other High-Capacity Tape Drive Standards	692
Choosing a Tape Backup Drive	696
Tape Drive Installation Issues	698
Tape Drive Backup Software	700
Tape Drive Troubleshooting	701
Tape Retensioning	703

13 Optical Storage 705

What Is a CD-ROM?	706
CDs: A Brief History	706
CD-ROM Technology	707
TrueX/MultiBeam Technology	709
Inside Data CDs	711
What Types of Drives Are Available?	713
CD-ROM Drive Specifications	714
Interface	721
Loading Mechanism	725
Other Drive Features	727
CD-ROM Disc and Drive Formats	728
Data Standard: ISO 9660	730
High Sierra Format	730
CD-DA (Digital Audio)	731
CD-ROM XA or Extended Architecture	731
Mixed-Mode CDs	734
PhotoCD	735
Writable CD-ROM Drives	738
CD-R	738
How to Reliably Make CD-Rs	742
CD-R Software	746
Creating Music CDs	747
Creating Digital Photo Albums	748
Creating a Rescue CD	748
Multiple Session CD-R Drives	748
CD-RW	749
DVD (Digital Versatile Disc)	751
DVD History	751
DVD Specifications	751
Adding a DVD Drive to Your System	753
DVD Standards	754
DVD Standards	755
CD-ROM Software on Your PC	756
DOS SCSI Adapter Driver	757
DOS CD-ROM Device Driver	757
MSCDEX: Adding CDs to DOS	758
Loading CD-ROM Drivers	759
CD-ROM in Microsoft Windows 3.x	760
Optical Drives in Windows 9x and Windows NT 4.0	760
MS-DOS Drivers and Windows 9x	761
Creating a Bootable Disk with CD-ROM Support	762
Making a Bootable CD-ROM for Emergencies	763
Files Needed for a Bootable CD	764

- Caring for Optical Media 767
- Troubleshooting Optical Drives 768
 - Failure Reading a CD 768
 - Failure to Read CD-R, CD-RW Disks in CD-ROM or DVD Drive 768
 - IDE/ATAPI CD-ROM Drive Runs Slowly 768
 - Poor Results When Writing to CD-R Media 769
 - Trouble Reading CD-RW Disks on CD-ROM 769
 - Trouble Reading CD-R Disks on DVD Drive 769
 - Trouble Making Bootable CDs 769

14 Physical Drive Installation and Configuration 771

- Hard Disk Installation Procedures 772
 - Drive Configuration 773
 - Host Adapter Configuration 773
 - Physical Installation 775
- Hard Drive Physical Installation—Step by Step 776
 - System Configuration 778
 - Formatting 779
 - Drive Partitioning with FDISK 782
 - Drive Partitioning with Partition Magic 786
 - High-Level (Operating System) Formatting 787
 - FDISK and FORMAT Limitations 788
- Replacing an Existing Drive 789
 - Drive Migration for MS-DOS Users 790
 - Drive Migration for Windows 9x Users 790
- Hard Disk Drive Troubleshooting and Repair 791
 - Testing a Drive 792
- Installing an Optical Drive 792
 - Avoiding Conflict: Get Your Cards in Order 793
 - Drive Configuration 793
 - External (SCSI) Drive Hook-Up 795
 - Internal Drive Installation 796
 - Ribbon Cable and Card Edge Connector 796
 - SCSI Chains: Internal, External, or Both 798
- Floppy Drive Installation Procedures 801
- Tape Drive Installation Issues 801
 - Internal Installation 802
 - External Installation 802

15 Video Hardware 803

- Video Display Technologies 804
- CRT Monitors 805
- LCD Displays 806
- Flat-Panel LCD Displays 808
- Monitor Selection Criteria 810
 - Monochrome Versus Color 811
 - The Right Size 811
 - Monitor Resolution 813
 - Dot Pitch 815
 - Image Brightness and Contrast (LCD Panels) 815
 - Interlaced Versus Noninterlaced 815
 - Energy and Safety 816
 - Emissions 818
 - Frequencies 819
 - Refresh Rates 819
 - Horizontal Frequency 822
 - Controls 822
 - Environment 823
 - Testing a Display 823
- Video Display Adapters 824
 - Obsolete Display Adapters 825
 - VGA Adapters and Displays 825
 - XGA and XGA-2 827
 - Super VGA (SVGA) 828
 - VESA VGA Standards 829
 - Video Adapter Components 831
 - High-Speed Video RAM Solutions—Older Types 837
 - Current High-Speed Video RAM Solutions 838
 - Emerging High-Speed Video RAM Solutions 838
 - The Digital-to-Analog Converter (RAM-DAC) 839
 - The Bus 839
 - AGP Speeds 841
 - The Video Driver 842
- Video Cards for Multimedia 844
 - Video Feature Connectors (VFC) 844
 - VESA Video Interface Port (VESA VIP) 845
 - Video Output Devices 845
 - Still-Image Video Capture Cards 846
 - Multiple Monitors 846
 - Desktop Video (DTV) Boards 847

- 3D Graphics Accelerators 851
 - Common 3D Techniques 853
 - Advanced 3D Techniques 854
 - APIs (Application Programming Interface) 856
 - Microsoft DirectX 856
 - Troubleshooting DirectX 859
 - 3D Chipsets 859
- Upgrading or Replacing Your Video Card 862
 - Video Card Memory 864
 - TV Tuner and Video Capture Upgrades 865
 - Warranty and Support 865
 - Video Card Benchmarks 865
 - Comparing Video Cards with the Same Chipset 866
- Adapter and Display Troubleshooting 867
 - Troubleshooting Monitors 869
 - Troubleshooting Video Cards and Drivers 870

16 Serial, Parallel, and Other I/O Interfaces 871

- Introduction to I/O Ports 872
- Serial Ports 872
 - UARTs 876
- High-Speed Serial Ports (ESP and Super ESP) 878
- Serial Port Configuration 879
- Testing Serial Ports 880
 - Microsoft Diagnostics (MSD) 880
 - Troubleshooting I/O Ports in Windows 881
 - Advanced Diagnostics Using Loopback Testing 882
- Parallel Ports 883
- IEEE 1284 Parallel Port Standard 884
 - Standard Parallel Ports (SPP) 885
 - Bidirectional (8-bit) Parallel Ports 886
 - Enhanced Parallel Port (EPP) 886
 - Enhanced Capabilities Port (ECP) 887
- Upgrading to EPP/ECP Parallel Ports 887
- Parallel Port Configuration 888
- Linking Systems with Parallel Ports 888
- Parallel to SCSI Converters 890
- Testing Parallel Ports 890

- USB and 1394 (i.Link) FireWire—Serial and Parallel Port Replacements 891
 - USB (Universal Serial Bus) 892
 - IEEE-1394 (Also Called i.Link or FireWire) 896

17 Input Devices 899

- Keyboards 900
 - Enhanced 101-Key (or 102-Key) Keyboard 900
 - 104-Key (Windows 95/98 Keyboard) 902
 - Portable Keyboards 904
 - Compatibility 905
 - Num Lock 906
- Keyboard Technology 907
 - Keyswitch Design 907
 - The Keyboard Interface 910
 - Typematic Functions 911
 - Keyboard Key Numbers and Scan Codes 914
 - International Keyboard Layouts 919
 - Keyboard/Mouse Interface Connectors 920
 - USB Keyboards and Mice 922
 - Keyboards with Special Features 922
- Keyboard Troubleshooting and Repair 926
- Disassembly Procedures and Cautions 928
 - Cleaning a Keyboard 929
 - Replacement Keyboards 930

About the Author

Scott Mueller is president of Mueller Technical Research, an international research and corporate training firm. Since 1982, MTR has specialized in the industry's longest running, most in-depth, accurate and effective corporate PC hardware and technical training seminars, maintaining a client list that includes Fortune 500 companies, the U.S. and foreign governments, major software and hardware corporations, as well as PC enthusiasts and entrepreneurs. His seminars have been presented to thousands of PC support professionals throughout the world.

Scott Mueller has developed and presented training courses in all areas of PC hardware and software. He is an expert in PC hardware, operating systems, and data-recovery techniques. For more information about a custom PC hardware or data recovery training seminar for your organization, contact Lynn at

Mueller Technical Research
21 Spring Lane
Barrington Hills, IL 60010-9009
(847) 854-6794
(847) 854-6795 Fax
Internet: scottmueller@compuserve.com
Web: <http://www.m-tr.com>

Scott has many popular books, articles, and course materials to his credit, including *Upgrading and Repairing PCs*, which has sold more than 2 million copies, making it by far the most popular PC hardware book on the market today. His two hour video titled *Your PC—The Inside Story* is available through LearnKey, Inc. For ordering information, contact

LearnKey, Inc.
1845 West Sunset Boulevard
St. George, UT 84770
(800) 865-0165
(801) 674-9733
(801) 674-9734 Fax

If you have questions about PC hardware, suggestions for the next edition of the book, or any comments in general, send them to Scott via email at scottmueller@compuserve.com.

When he is not working on PC-related books or teaching seminars, Scott can usually be found in the garage working on vehicle performance projects. This year a Harley Road King is taking most of his time, and he promises to finish the Impala next.

Special Thanks to...

Mark Edward Soper is a writer, editor, and trainer who has worked with IBM-compatible PCs since 1984. Mark spent plenty of time in the trenches as a technical support specialist and technical salesman before his first computer-related articles were published in 1988. He has written over 100 articles on a wide variety of topics from scanner upgrades to Web-enabled presentations for major industry publications including *WordPerfect Magazine*, *PCNovice Guides*, *PCToday*, and *SmartComputing*. Since 1992 he has taught thousands of students across the country how to troubleshoot and upgrade their computers, create Web sites, and build basic networks. Mark is a rail fan from way back, and has also had his photos published in *Passenger Train Journal* magazine. You can learn more about Mark at his company's Web site, www.selectsystems.com, and you can write to him at mesoper@selectsystems.com.

Jeff Sloan is the Dimension OEM BIOS development manager for Dell Computers. Prior to Dell, he worked at IBM PC Company for 15 years, the last eight of which were spent in PS/2 BIOS development and the Problem Determination SWAT team. He has a BS in computer science from University of Pittsburgh, 1979, and is currently working on an MS in Software Engineering at Southwest Texas State. Jeff has tech edited numerous Que books.

Joe Curley is an engineering manager at Dell Computer Corporation, working in audio, motion video, and graphics development. Prior to Dell, Joe worked for Tseng Labs, Inc. and was a pioneer in Super VGA graphics development in numerous roles, including general manager for Advanced Systems development. Joe has spoken at several leading industry conferences, including the Windows Hardware Engineering Conference, about topics ranging from I/O bus and PC architecture to graphics memory architecture.

Anthony Armstrong is a development engineer working for Dell Computer Corporation on PC motherboards for the Dimension and Optiplex lines of business. Anthony has previously worked for IBM in the PowerPC reference platform test group and currently has one personal computer-related patent pending. Anthony is a computer engineering graduate of the University of Texas at Austin.

Doug Klippert is an independent contract trainer living in Tacoma, Washington. He is a Microsoft Certified Software Engineer (MCSE) and a Microsoft Certified Trainer (MCT). He is also a Microsoft Office User Specialist, Master in Office 97. Doug has a BA in accounting and an MBA in public administration. He can be reached at doug@klippert.com. Doug has tech edited numerous Que books.

Pete Lenges is a technical software instructor for New Horizons Computer Learning Centers, one of the world's largest training integrators. He is an A+ certified technician with a specialty in Microsoft operating systems as well as an MCT (Microsoft Certified Trainer) and MCP (Microsoft Certified Professional). He currently conducts both hardware and software classes at the Indianapolis facility and also assists in the everyday management of his company's LAN/WAN.

Karen Weinstein is an independent computer consultant living in North Potomac, Maryland. She has had over a decade of experience in PC sales and support. Karen has a BS in business administration from the University of Maryland.

Kent Easley is an assistant professor of computer information systems at Howard College in Big Spring, Texas. He teaches introductory computer science, networking, and programming. He is a Microsoft Certified Professional and supervises the Microsoft Authorized Academic Training Program (AATP) at Howard College. He has experience as a network administrator and as a systems librarian. Kent has tech edited numerous Que books. He can be reached by email at keasley@hc.cc.tx.us.

Ariel Silverstone has been involved in the computer industry for over 15 years. He has consulted nationally for Fortune 1000 firms on the implementation of management information systems and networking systems. He has designed and set up hundreds of networks over the years, including using all versions of NetWare and Windows NT Server. For five years, he has been the chief technical officer for a computer systems integrator in Indiana. While no longer a professional programmer, he is competent in a variety of computer languages, including both low- and high-level languages. He has been a technical reviewer over 20 books, including titles on Windows NT, NetWare, networking, Windows 2000, Cisco routers, and firewalls.

Acknowledgments

This Eleventh Edition is the product of a great deal of additional research and development over the previous editions. Several people have helped me with both the research and production of this book. I would like to thank the following people:

First, a very special thanks to my wife and partner, Lynn. This book continues to be an incredible burden on both our business and family life, and she has to put up with a lot! Apparently I can be slightly incorrigible after staying up all night writing, drinking Jolt, and eating chocolate covered raisins. <g> Lynn is also excellent at dealing with the many companies we have to contact for product information and research. She is the backbone of MTR.

Thanks to Lisa Carlson of Mueller Technical Research for helping with product research and office management. She has fantastic organizational skills that have been a tremendous help in managing all of the information that comes into and goes out of this office.

I must give a special thanks to Jill Byus, Rick Kughen, and Jim Minatel at Que. They are my editorial and publishing team, and have all worked so incredibly hard to make this the best book possible. They have consistently pressed me to improve the content of this book. You guys are the best!

I would also like to say thanks to Mark Soper, who added expertise in areas that I might tend to neglect. Also thanks to all the technical editors who checked my work and questioned me at every turn, as well as the numerous other editors, illustrators, and staff at Que who work so hard to get this book out!

Thanks to all the companies who have provided hardware, software, and research information that has been helpful in developing this book. Thanks to David Means for feedback from the trenches about various products and especially data recovery information.

Thanks to all the readers who have emailed me with suggestions concerning this book; I welcome all your comments. A special thanks to Paul Reid who always has many suggestions to offer for improving the book and making it more technically accurate.

Finally, I would like to thank the more than 10,000 people who have attended my seminars; you may not realize how much I learn from each of you and all your questions! Thanks also to those of you on the Internet and CompuServe forums with both questions and answers, from which I have also learned a great deal.

Tell Us What You Think!

As the reader of this book, *you* are our most important critic and commentator. We value your opinion and want to know what we're doing right, what we could do better, what areas you'd like to see us publish in, and any other words of wisdom you're willing to pass our way.

As the associate publisher for this book, I welcome your comments. You can fax, email, or write me directly to let me know what you did or didn't like about this book—as well as what we can do to make our books stronger.

While I cannot help you with technical problems related to the topics covered in this book, Scott Mueller welcomes your technical questions. The best way to reach him is by email at scottmueller@compuserve.com.

When you write, please be sure to include this book's title and author as well as your name and phone or fax number. I will carefully review your comments and share them with the author and editors who worked on the book.

Introduction

Welcome to *Upgrading and Repairing PCs, Eleventh Edition*. More than just a minor revision, this new edition contains hundreds of pages of new material and extensive updates. The PC industry is moving faster than ever, and this book is the most accurate, complete, and up-to-date book of its type on the market today.

This book is for people who want to upgrade, repair, maintain, and troubleshoot computers or for those enthusiasts who want to know more about PC hardware. This book covers the full range of PC-compatible systems from the oldest 8-bit machines to the latest in high-end 64-bit PC-based workstations. If you need to know about everything from the original PC to the latest in PC technology on the market today, this book is definitely for you.

This book covers state-of-the-art hardware and accessories that make the most modern personal computers easier, faster, and more productive to use. Hardware coverage includes all the Intel and Intel-compatible processors through the latest Pentium III, Celeron, and AMD CPU chips; new cache and main memory technology; PCI and AGP local bus technology; CD-ROM drives; tape backups; sound boards; PC-card and Cardbus devices for laptops; IDE and SCSI interface devices; larger and faster hard drives; and new video adapter and display capabilities.

The comprehensive coverage of the PC-compatible personal computer in this book has consistently won acclaim since debuting as the first book of its kind on the market in 1988. Now with the release of this 11th Edition, *Upgrading and Repairing PCs* continues its role as not only the best-selling book of its type, but also the most comprehensive and complete reference on even the most modern systems—those based on cutting-edge hardware and software. This book examines PCs in depth, outlines the differences among them, and presents options for configuring each system.

Sections of this book provide detailed information about each internal component of a personal computer system, from the processor to the keyboard and video display. This book examines the options available in modern, high-performance PC configurations and how to use them to your advantage; it focuses on much of the hardware and software available today and specifies the optimum configurations for achieving maximum benefit for the time and money you spend. At a glance, here are the major system components, peripherals, technologies, and processes covered in this edition of *Upgrading and Repairing PCs*:

- Pentium III, Pentium II, Celeron, Xeon, and earlier central processing unit (CPU) chips as well as Intel-compatible processors from AMD, Cyrix, and other vendors. The processor is one of the most important parts of a PC, and this book features more extensive and updated processor coverage than ever before.
- The latest processor-upgrade socket and slot specifications, including expanded coverage of Super7 motherboards and Intel's new Socket 370.

- New motherboard designs, including the ATX, WTX, micro-ATX, and NLX form factors. This new edition features the most accurate, detailed and complete reference to PC motherboards that you will find.
- The latest chipsets for current processor families, including all new coverage of the Intel 810 chipset, as well as new members of the 440 chipset family, including the 440ZX, 440GX, and 440NX.
- Special bus architectures and devices, including high-speed PCI (Peripheral Component Interconnect), AGP (Accelerated Graphics Port), and the 100MHz processor bus.
- Bus and system resources that often conflict such as interrupt request (IRQ) lines, Direct Memory Access (DMA) channels, and input/output (I/O) port addresses.
- Plug-and-Play (PnP) architecture for setting system resources automatically, including features such as IRQ steering, which allows you to share the IRQ lines—the resource most in-contention in a modern PC.
- All new coverage of the BIOS, including detailed coverage of BIOS setup utilities, Flash upgradable BIOSes, and Plug-and-Play BIOS. The CD accompanying this book also contains BIOS error codes, beep codes, and error messages for Phoenix, AMI, Award, Microid Research, and IBM BIOSes.
- Greatly expanded coverage of IDE and SCSI includes in-depth looks at hard drive interfaces and technologies, including new IDE specifications such as Ultra ATA/33, Ultra-ATA/66, and the latest on SCSI-3.
- Floppy drives and other removable storage devices such as Zip and LS-120 (SuperDisk) drives, tape drives, and recordable CDs.
- New coverage of drive installation and configuration, including steps for partitioning hard drives, mapping drive letters, and transferring data from an old drive to a new drive.
- Expanded coverage of burgeoning CD technologies, including the newest MultiBeam CD-ROMs. CD-R/CD-RW coverage now includes detailed steps and advice for avoiding buffer under-runs, creating bootable CDs, and selecting the most reliable media.
- Increasing system memory capacity with SIMM, DIMM, and RIMM modules and increasing system reliability with ECC RAM.
- New types of memory, including Synchronous Pipeline Burst cache, EDO RAM, Burst EDO, Synchronous DRAM, and Rambus DRAM.
- Large-screen Super VGA monitors, flat-panel LED displays, high-speed graphics adapters, and 3D graphics accelerators. Includes advice for choosing a 3D accelerator to optimize your system for game play, as well as coverage of 3D technologies, chipsets and APIs.
- Peripheral devices such as sound cards, modems, DVD drives, and network interface cards.
- PC-card and Cardbus devices for laptops.
- Laser and dot-matrix printer features, maintenance, and repair. Also includes all new coverage of scanners and scanning technology.

The Eleventh Edition includes more detailed troubleshooting advice that will help you track down problems with your memory, system resources, new drive installations, BIOS, I/O addresses, video and audio performance, modems, and much more.

This book also focuses on software problems, starting with the basics of how an operating system such as DOS or Windows works with your system hardware to start your system. You also learn how to troubleshoot and avoid problems involving system hardware, the operating system, and applications software.

This book is the result of years of research and development in the production of my PC hardware, operating system, and data recovery seminars. Since 1982, I have personally taught (and still teach) thousands of people about PC troubleshooting, upgrading, maintenance, repair, and data recovery. This book represents the culmination of many years of field experience and knowledge culled from the experiences of thousands of others. What originally started out as a simple course workbook has over the years grown into a complete reference on the subject. Now you can benefit from this experience and research.

What Are the Main Objectives of This Book?

Upgrading and Repairing PCs focuses on several objectives. The primary objective is to help you learn how to maintain, upgrade, and repair your PC system. To that end, *Upgrading and Repairing PCs* helps you fully understand the family of computers that has grown from the original IBM PC, including all PC-compatible systems. This book discusses all areas of system improvement such as floppy disks, hard disks, central processing units, and power-supply improvements. The book discusses proper system and component care; it specifies the most failure-prone items in different PC systems and tells you how to locate and identify a failing component. You'll learn about powerful diagnostics hardware and software that enable a system to help you determine the cause of a problem and how to repair it.

PCs are moving forward rapidly in power and capabilities. Processor performance increases with every new chip design. *Upgrading and Repairing PCs* helps you gain an understanding of all the processors used in PC-compatible computer systems.

This book covers the important differences between major system architectures from the original Industry Standard Architecture (ISA) to the latest in PCI and AGP systems. *Upgrading and Repairing PCs* covers each of these system architectures and their adapter boards to help you make decisions about which kind of system you want to buy in the future, and to help you upgrade and troubleshoot such systems.

The amount of storage space available to modern PCs is increasing geometrically. *Upgrading and Repairing PCs* covers storage options ranging from larger, faster hard drives to state-of-the-art storage devices. In addition, it provides detailed information on upgrading and troubleshooting system RAM.

When you finish reading this book, you should have the knowledge to upgrade, troubleshoot, and repair almost all systems and components.

Who Should Use This Book?

Upgrading and Repairing PCs is designed for people who want a thorough understanding of how their PC systems work. Each section fully explains common and not-so-common problems, what causes problems, and how to handle problems when they arise. You will gain an understanding of disk configuration and interfacing, for example, that can improve your diagnostics and troubleshooting skills. You'll develop a feel for what goes on in a system so that you can rely on your own judgment and observations and not some table of canned troubleshooting steps.

Upgrading and Repairing PCs is written for people who will select, install, configure, maintain, and repair systems they or their companies use. To accomplish these tasks, you need a level of knowledge much higher than that of an average system user. You must know exactly which tool to use for a task and how to use the tool correctly. This book can help you achieve this level of knowledge.

What Is in This Book?

This book is organized into chapters that cover the components of a PC system. There are a few chapters that serve to introduce or expand in an area not specifically component-related, but most parts in the PC will have a dedicated chapter or section, which will aid you in finding the information you want. Also note that the index has been improved greatly over previous editions, which will further aid in finding information in a book of this size.

Chapters 1 and 2 of this book serve primarily as an introduction. Chapter 1, "Personal Computer Background," begins with an introduction to the development of the original IBM PC and PC-compatibles. This chapter incorporates some of the historical events that led to the development of the microprocessor and the PC. Chapter 2, "PC Components, Features, and System Design," provides information about the different types of systems you encounter and what separates one type of system from another, including the types of system buses that differentiate systems. Chapter 2 also provides an overview of the types of PC systems that help build a foundation of knowledge essential for the remainder of the book, and it offers some insight as to how the PC market is driven and where components and technologies are sourced.

Chapters 3–6 cover the primary system components of a PC. Chapter 3, "Microprocessors," goes into detail about the central processing unit, or main processor, including those from Intel, AMD, and other companies. Chapter 4, "Motherboards and Buses," covers the motherboard, chipsets, motherboard components, and system buses in detail. Because the processor and motherboard are perhaps the most significant parts of the PC, Chapters 3 and 4 were a primary focus of mine when rewriting this book. They have received extensive updates and a great deal of new material has been added.

Chapter 5, "BIOS," has a detailed discussion of the system BIOS including types, features, and upgrades. This has grown from a section of the book to a complete chapter, with more

information on this subject than ever before. Be sure to see the exhaustive list of BIOS codes and error messages I've included on the CD-ROM. They're all printable, so be sure to print the codes for your BIOS in case you need them later.

Chapter 6, "Memory," gives a detailed discussion of PC memory, including the latest in cache and main memory specifications. Next to the processor and motherboard, the system memory is one of the most important parts of a PC. Memory is also one of the most difficult things to understand, as it is somewhat intangible and not always obvious how it works. This chapter has received extensive updates in order to make memory technology more understandable, as well as to cover the newest technologies on the market today. Coverage of cache memory has been updated in order to help you understand this difficult subject and know exactly how the different levels of cache in a modern PC function, interact, and affect system performance.

Chapter 7, "The IDE Interface," gives a detailed discussion of ATA/IDE, including types and specifications. This includes coverage of the new Ultra-ATA modes that allow 33MB/sec and 66MB/sec operation. Chapter 8, "The SCSI Interface," includes a discussion of SCSI including the new higher speed modes possible with SCSI-3. The SCSI chapter covers the new Low Voltage Differential signaling used by some of the higher speed devices on the market, as well as the latest information on cables, terminators, and SCSI configurations.

Chapter 9, "Magnetic Storage Principles," details the inner workings of magnetic storage devices such as disk and tape drives. Chapter 10, "Hard Disk Storage," details the function and operation of hard disk drives, while Chapter 11, "Floppy Disk Storage," does the same thing for floppy drives. Chapter 12, "High-Capacity Removable Disk Storage," covers removable storage drives such as SuperDisk (LS-120), Zip, and tape drives. Chapter 13, "Optical Storage," covers optical drives and storage using CD and DVD technology, including CD recorders, rewritable CDs, and other optical technologies. This chapter features extensive updates on DVD as well as all the CD recording technology. Chapter 14, "Physical Drive Installation and Configuration," covers how to install drives of all kinds in a PC system.

Chapter 15, "Video Hardware," covers everything there is to know about video cards and displays. Chapter 16, "Serial, Parallel, and Other I/O Interfaces," covers the standard serial and parallel ports still found in most systems, as well as newer technology such as USB and iLink (FireWire). Chapter 17, "Input Devices," covers keyboards, pointing devices, and game ports used to communicate with a PC. Chapter 18, "Internet Connectivity," covers all the different methods for connecting to the Net. Chapter 19, "Local Area Networking," covers PC-based local area networks in detail. Chapter 20, "Audio Hardware," covers sound and sound-related devices, including sound boards and speaker systems. Chapter 21, "Power Supply and Chassis/Case," is a detailed investigation of the power supply, which still remains the primary cause for PC system problems and failures. Chapter 22, "Printers and Scanners," covers the various types of printers and scanners in detail.

Chapter 23, "Portable PCs," covers portable systems including laptop and notebook systems. It also focuses on all the technology unique and peculiar to portable systems, such as mobile processors, display, battery, and other technologies.

Chapter 24, “Building or Upgrading Systems,” focuses on buying or building a PC-compatible system as well as system upgrades and improvements. This information is useful, especially if you make purchasing decisions, and also serves as a general guideline for features that make a certain compatible computer a good or bad choice. The more adventurous can use this information to assemble their own custom system from scratch. Physical disassembly and assembly procedures are also discussed.

Chapter 25, “PC Diagnostics, Testing, and Maintenance,” covers diagnostic and testing tools and procedures. This chapter also adds more information on general PC troubleshooting and problem determination. Chapter 26, “Operating Systems Software and Troubleshooting,” covers operating system software and troubleshooting. Chapter 27, “File Systems and Data Recovery,” covers file systems and data recovery procedures.

Chapter 28, “A Final Word,” offers closure by tying all the technologies together and providing suggestions on additional places to find information.

What’s New and Special About the Eleventh Edition

Many of you who are reading this have purchased one or more of the previous editions. Based on your letters, emails, and other correspondence, I know that as much as you value each new edition, you want to know what new information I’m bringing you. So here is a short list of the major improvements to this edition:

- As the PC industry continues to move further away from “IBM compatible” thinking and nomenclature, this edition is doing the same. In Chapter 2 I discuss who controls the PC hardware industry and what effect this control has on you.
- The updating of Chapter 3 involved a major reorganization of the chapter and many pages of new coverage. The new organization looks at all the relevant processors (and coprocessors and processor upgrades) in terms of the family of processor they belong to. The coverage of Pentium II, III, and Celeron processors has been strengthened with up-to-date listings of steppings, processors from AMD, Cyrix, and other vendors have been given more coverage. Cutting-edge features such as on-die L2 cache are explained in more detail as well. The latest processor slots and sockets are covered, including Slot 1, Slot 2, Socket 370, and the Super7 socket architecture. I hope you will like the substantial additions of illustrations and photographs that better show items such as socket types, processor features, and markings.
- Chapter 4 takes the new approach of covering the motherboards and the buses found on the motherboards together as one topic. In addition, you will find extensive new coverage of the latest chipsets, which form the basis of all modern motherboards. This chapter includes detailed coverage of the features, capabilities, and limitations of the chipsets in common use today.
- Chapter 5 is a new addition to the lineup that delves into how the drivers in a system work together to act as an interface between the hardware and the operating system software. This chapter also explains ROM chips installed on adapter cards, as well as all the additional drivers loaded when your system starts up. You’ll also find an in-depth look at working with the BIOS Setup utility.

- Chapter 6 has been reorganized to begin by looking at types of memory and how they are installed. All of the more recent types of memory, including SDRAM and RDRAM, are explained in more detail in this edition. You'll also find answers to often-asked questions relating memory speed to processor speed and a more thorough explanation of why error checking is still an important memory feature. This chapter also contains new coverage of RIMMs, continuity modules, and Rambus memory in general.
- Chapter 7 and 8 also contain a great deal of new information. Here, you'll find in-depth coverage of both interfaces, including ATA/66 and SCSI-3.
- Chapters 9 and 10 contain expanded coverage of hard drive mechanics and principles of electromagnetism. Chapter 12 contains the latest information on the SuperDisk drives and investigates problems with other removable formats such as the Iomega Zip "Click of Death" syndrome.
- Chapter 13 contains expanded coverage of CD-R and CD-RW drives, including advice for writing CDs more reliably and creating bootable CDs. This chapter also includes improved coverage of DVD and new MultiBeam technology.
- Chapter 14 walks you through installing drives—hard drives, floppy drives, CD-ROM, magnetic tape—and helps you set map a letter to the drive.
- Chapter 15 includes enhanced coverage of video displays—including flat-panel LEDs—and video cards for gaming and multimedia enthusiasts.
- Chapter 18 contains a greatly expanded coverage of Internet connectivity options, including more coverage of 56K connections, ISDN, DSL, DirecPC, and leased lines.
- Chapter 19 is the perfect primer for those new to networking—at home or in the office. This chapter provides the background you'll need to be productive on a network—whether you're part of a corporate-wide LAN or simply networking a pair of computers at home.
- Chapter 20 helps you optimize your computer's sound output, whether you are a hard-core gamer, a MIDI musician, or if you want to learn about the MP3 format that is revolutionizing the way musical artists distribute music via the Internet.
- Chapters 25 and 26 both have new and different coverage. Much of this is a reflection of newer operating systems such as Windows 98, NT, and Windows 2000. The fact that troubleshooting and configuration tools are less dependent on hardware system vendors (such as IBM or Compaq) and more generally are third-party software tools necessitates a new way to look at setup and testing.
- Chapter 27 takes an in-depth look at the file system, including new examples that explain how FAT16, FAT32, and NTFS work. If you're upgrading to Windows 2000, you'll find that choosing the right file system is an important decision to make up-front. This chapter provides the in-depth background you need to make a sound decision.

Although these are the major changes to the core of the book, every chapter has seen substantial updates. If you thought the additions to the Tenth Anniversary Edition were incredible, wait until you see what I've done with the Eleventh Edition. It is the most comprehensive overhaul this book has seen since I wrote the first edition 11 years ago!

The Eleventh Edition CD-ROM

As if everything included in the printed book isn't enough, this edition contains an all-new CD-ROM. You'll find the new content on this CD to be an indispensable addition to this book. The CD contains

- *Que's edition of PartitionMagic.* Create and manage multiple hard disk partitions with this powerful application. PartitionMagic allows you to create partitions without first backing up your data and deleting existing partitions. PartitionMagic also allows you to create and manage partitions using a native Windows 95/98 and NT executable that operates from within the Windows interface. The best part is that because you can work within the Windows interface from the same drive you are partitioning, you don't have to spend hours reloading your operating system, applications, and data files.

PartitionMagic allows you to switch between FAT and FAT32 file systems with ease. It also enables you to manage multiple operating systems in separate partitions.

PartitionMagic includes support for FAT, FAT32, NTFS, HPFS, and Linux ext2 file systems.

You can use PartitionMagic as a replacement to FDISK or use it to tweak your drive partitioning after completing your drive setup with FDISK. If you decide to change partitioning later, run PartitionMagic and reallocate your partitions.

▶▶ See Appendix C, "Making the Most of PartitionMagic and Drive Image" p. 1529.

- *Que's Edition of Drive Image.* Rest easy knowing your data is secure because you've created compressed backups of your hard drives and stored them safely to your Zip, LS-120 SuperDrive, or CD-R. Drive Image creates a carbon copy of your drive, including all optimizations and configurations, allowing you to make a complete backup you can use to restore your system or make exact duplicates of a system. Drive Image saves all passwords, Registry settings, user profiles, and customizations with the image, saving you hours of down time.

Create compressed hard-disk image files that are about 40 percent smaller than the used space on the drive. You can even create and image of your primary partition, store it to a separate partition, and restore your primary partition in an emergency.

Drive Image supports FAT, FAT32, NTFS, and HPFS file systems, and allows for sector-by-sector copying of data from Windows, Linux, UNIX, and NetWare drives.

▶▶ See Appendix C, "Making the Most of PartitionMagic and Drive Image" p. 1529.

Note

PartitionMagic and Drive Image would cost more than \$100 if purchased separately. The Que Editions of both applications are yours for the price of this book. These are fully licensed products, not demos or timeout versions.

- *A+ Testing Questions from Heathkit.* Study for the A+ exams using 150 training questions from Heathkit Educational Systems, a leader in technical-based education.

The questions appear in an interactive, Windows-based format that allows you to answer questions as if you were taking the actual tests. Use this book to learn the concepts and technologies then use the test questions to sharpen your skills and point out areas in which you need more study.

Note

If you need additional help studying for A+ Certification, see my *Upgrading and Repairing PCs: A+ Certification Study Guide*, also published by Que, ISBN 0-7897-2095-7.

- *Hard Drive Specifications from Blue-Planet.com.* This database contains hard drive specifications for more than 4,000 hard drives from Seagate, Quantum, Western Digital, Maxtor, IBM, and many others. This incredibly useful database puts thousands of drive specifications at your fingertips, and the elegant database design allows you to quickly find and print just the specs you need.

Note

The CD also includes a wealth of legacy PC technical information. See the Technical Reference section on the CD.

Note

If you are a field technician or someone who frequently works on PCs away from your desk, I recommend picking up a copy of *Upgrading and Repairing PCs: Technician's Portable Reference*, also published by Que (ISBN: 0-7897-2096-5). This handy book is filled with many of the tables and technical detail from this book, as well as boiled down versions of these chapters that put crucial details and technical specifications at your fingertips—all in a portable book that fits easily in your toolkit or briefcase.

- *Vendor List Database.* Use Scott Mueller's fully searchable database of vendors to locate addresses, phone numbers, and URLs for all the manufacturers discussed in this book. This keyword searchable database allows you to search for any vendor or product using any keyword. Instead of searching through 70+ pages of vendors, search and extract the data you need.
- *BIOS Codes, Beep Codes, and Error Message.* Find complete listings of BIOS codes, beep codes and error messages from Phoenix, AMI, Award, Microid Research (MR BIOS), and IBM—as well as some of those used by OEM vendors. If you are service technician, you'll find these lists to be an integral part of your troubleshooting arsenal. If you are a private user, I recommend that you print the codes for your BIOS and keep them in a safe place in case you need to troubleshoot BIOS errors.
- *Third-Party Software.* Use Que's extensive library of software, including overclocking, Y2K, and performance benchmarking utilities to tune and optimize your PC.
- *Previous Editions of This Book.* If you're looking for legacy coverage of older technologies, be sure to check the previous editions of this book that are in PDF format on the CD (the Fourth, Sixth, and Tenth Anniversary editions are included in their entirety and are fully printable). Simply use the included Adobe Acrobat Reader software to open and print the pages you need from the selected editions of this book.
- *IBM Personal Computer Family Hardware Reference.* Many of the technologies used in today's PCs originated from the original IBM PC, XT, and AT systems. This chapter serves as a technical reference will prove valuable if you are service technician who is required to work on all types of computers. If you want to learn how the original PC evolved into what you use today, this is an excellent place to start.

A Personal Note

I am so excited about all the new changes in this edition, I can hardly wait for everybody to see it. The last few months before the release of this new edition were more difficult than usual, not only in meeting the deadlines that are required to bring it out on schedule, but also while corresponding with readers and teaching my classes using the previous edition and knowing I had all the great new information written for this edition. This has been more noticeable to me this time around because this is perhaps the most extensive update I have done; there is so much new material added. Well now the wait is over, and this new edition is now available.

When asked what year was his favorite Corvette, Dave McLellan, former manager of the Corvette platform at GM, always said “Next year’s model.” Now with the new Eleventh Edition, next year’s model has just become this year’s model, until next year that is...

During the months leading up to the release of the Eleventh Edition, I and everybody else at Que have worked hard to make this the best edition ever. I am so grateful to everybody who has helped me with this book over the last 11 years as well as all the loyal readers who have been reading this book, many of you since the first edition came out. I have had personal contact with many thousands of you in the seminars I have been teaching since 1982, and all I can say is I enjoy your comments and even criticisms tremendously. Using this book in a teaching environment has been a major factor in its development. Some of you might be interested to know that I originally began writing this book in 1985; back then it was used exclusively in my PC hardware seminars before being published by Que in 1988. In one way or another I have been writing and rewriting this book almost continuously for more than 15 years! In the more than 11 years since it was first published, *Upgrading and Repairing PCs* has proven to be not only the first but absolutely the best book of its kind. With the new Eleventh Edition, it is even better than ever. Your comments, suggestions, and support have helped this book to become the best PC hardware book on the market. I look forward to hearing your comments after you see this exciting new edition.

Scott

Personal Computer Background

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Computer History—Before Personal Computers

Modern Computers

Personal Computer History

The IBM Personal Computer

The PC Industry 18 Years Later

Many discoveries and inventions have directly and indirectly contributed to the development of the personal computer. Examining a few important developmental landmarks can help bring the entire picture into focus.

Computer History—Before Personal Computers

The first computers of any kind were simple calculators. Even these evolved from mechanical devices to electronic digital devices.

Timeline

The following is a timeline of some significant events in computer history. It is not meant to be complete, just a representation of some of the major landmarks in computer development.

- 1617. John Napier creates “Napiers Bones,” wooden or ivory rods used for calculating.
- 1642. Blaise Pascal introduces the Pascaline digital adding machine.
- 1822. Charles Babbage conceives the Difference Engine, and later the Analytical Engine, a true general purpose computing machine.
- 1906. Lee DeForest patents the vacuum tube triode, used as an electronic switch in the first electronic computers.
- 1945. John von Neumann wrote “First Draft of a Report on the EDVAC,” in which he outlined the architecture of the modern stored-program computer.
- 1946. ENIAC was introduced, an electronic computing machine built by John Mauchly and J. Presper Eckert.
- 1947. On December 23, William Shockley, Walter Brattain, and John Bardeen successfully tested the point-contact transistor, setting off the semiconductor revolution.
- 1949. Maurice Wilkes assembled the EDSAC, the first practical stored-program computer, at Cambridge University.
- 1950. Engineering Research Associates of Minneapolis built the ERA 1101, one of the first commercially produced computers.
- 1952. The UNIVAC I delivered to the U.S. Census Bureau was the first commercial computer to attract widespread public attention.
- 1953. IBM shipped its first electronic computer, the 701.
- 1954. A Silicon-based junction transistor, perfected by Gordon Teal of Texas Instruments Inc., brought the price of this component down to \$2.50.
- 1954. The IBM 650 magnetic drum calculator established itself as the first mass-produced computer, with the company selling 450 in one year.
- 1955. Bell Laboratories announced the first fully transistorized computer, TRADIC.
- 1956. MIT researchers built the TX-0, the first general-purpose, programmable computer built with transistors.
- 1956. The era of magnetic disk storage dawned with IBM’s shipment of a 305 RAMAC to Zellerbach Paper in San Francisco.
- 1958. Jack Kilby created the first integrated circuit at Texas Instruments to prove that resistors and capacitors could exist on the same piece of semiconductor material.

- 1959. IBM's 7000 series mainframes were the company's first transistorized computers.
- 1959. Robert Noyce's practical integrated circuit, invented at Fairchild Camera and Instrument Corp., allowed printing of conducting channels directly on the silicon surface.
- 1960. Bell Labs designed its Dataphone, the first commercial modem, specifically for converting digital computer data to analog signals for transmission across its long-distance network.
- 1960. The precursor to the minicomputer, DEC's PDP-1 sold for \$120,000.
- 1961. According to *Datamation* magazine, IBM had an 81.2-percent share of the computer market in 1961, the year in which it introduced the 1400 Series.
- 1964. CDC's 6600 supercomputer, designed by Seymour Cray, performed up to three million instructions per second—a processing speed three times faster than that of its closest competitor, the IBM Stretch.
- 1964. IBM announced System/360, a family of six mutually compatible computers and 40 peripherals that could work together.
- 1964. Online transaction processing made its debut in IBM's SABRE reservation system, set up for American Airlines.
- 1965. Digital Equipment Corp. introduced the PDP-8, the first commercially successful minicomputer.
- 1966. Hewlett-Packard entered the general purpose computer business with its HP-2115 for computation, offering a computational power formerly found only in much larger computers.
- 1970. Computer-to-computer communication expanded when the Department of Defense established four nodes on the ARPAnet: the University of California-Santa Barbara and UCLA, SRI International, and the University of Utah.
- 1971. A team at IBM's San Jose Laboratories invented the 8-inch floppy disk.
- 1971. The first advertisement for a microprocessor, the Intel 4004, appeared in *Electronic News*.
- 1971. The Kenbak-1, one of the first personal computers, advertised for \$750 in *Scientific American*.
- 1972. Hewlett-Packard announced the HP-35 as "a fast, extremely accurate electronic slide rule" with a solid-state memory similar to that of a computer.
- 1972. Intel's 8008 microprocessor made its debut.
- 1972. Steve Wozniak built his "blue box," a tone generator to make free phone calls.
- 1973. Robert Metcalfe devised the Ethernet method of network connection at the Xerox Palo Alto Research Center.
- 1973. The Micral was the earliest commercial, non-kit personal computer based on a microprocessor, the Intel 8008.
- 1973. The TV Typewriter, designed by Don Lancaster, provided the first display of alphanumeric information on an ordinary television set.
- 1974. Researchers at the Xerox Palo Alto Research Center designed the Alto—the first workstation with a built-in mouse for input.
- 1974. Scelbi advertised its 8H computer, the first commercially advertised U.S. computer based on a microprocessor, Intel's 8008.

- 1975. Telenet, the first commercial packet-switching network and civilian equivalent of ARPAnet, was born.
- 1975. The January edition of *Popular Electronics* featured the Altair 8800, based on Intel's 8080 microprocessor, on its cover.
- 1975. The visual display module (VDM) prototype, designed by Lee Felsenstein, marked the first implementation of a memory-mapped alphanumeric video display for personal computers.
- 1976. Steve Wozniak designed the Apple I, a single-board computer.
- 1976. The 5 1/4-inch flexible disk drive and diskette were introduced by Shugart Associates.
- 1976. The Cray I made its name as the first commercially successful vector processor.
- 1977. Tandy Radio Shack introduces the TRS-80.
- 1977. Apple computer introduces the Apple II.
- 1977. Commodore introduces the PET (Personal Electronic Transactor).
- 1978. The VAX 11/780 from Digital Equipment Corp. featured the capability to address up to 4.3 gigabytes of virtual memory, providing hundreds of times the capacity of most mini-computers.
- 1979. Motorola introduces the 68000 microprocessor.
- 1980. John Shoch, at the Xerox Palo Alto Research Center, invented the computer "worm," a short program that searched a network for idle processors.
- 1980. Seagate Technology created the first hard disk drive for microcomputers.
- 1980. The first optical data storage disk had 60 times the capacity of a 5 1/4-inch floppy disk.
- 1981. Adam Osborne completed the first portable computer, the Osborne I, which weighed 24 pounds and cost \$1,795.
- 1981. IBM introduced its PC, igniting a fast growth of the personal computer market.
- 1981. Sony introduced and shipped the first 3 1/2-inch floppy drives and diskettes.
- 1983. Apple introduced its Lisa. The first personal computer with a graphical user interface (GUI).
- 1983. Compaq Computer Corp. introduced their first PC clone that used the same software as the IBM PC.
- 1984. Apple Computer launched the Macintosh, the first successful mouse-driven computer with a GUI, with a single \$1.5 million commercial during the 1984 Super Bowl.
- 1984. IBM released the PC-AT. Several times faster than original PC and based on the Intel 286 chip. This is the computer all modern PCs are based on.
- 1985. CD-ROM was introduced from CDs on which music is recorded.
- 1986. Compaq announced the Deskpro 386, the first computer on the market to use Intel's new 386 chip.
- 1987. IBM introduced its PS/2 machines, which made the 3 1/2-inch floppy disk drive and VGA video standard for IBM computers.
- 1988. Apple cofounder Steve Jobs, who left Apple to form his own company, unveiled the NeXT.

- *1988.* Compaq and other PC-clone makers developed enhanced industry standard architecture, which was better than microchannel and retained compatibility with existing machines.
- *1988.* Robert Morris' worm flooded the ARPAnet. Then 23-year-old Morris, the son of a computer security expert for the National Security Agency, sent a nondestructive worm through the Internet, causing problems for about 6,000 of the 60,000 hosts linked to the network.
- *1989.* Intel released the 486 microprocessor, which contained more than 1 million transistors.
- *1990.* The World Wide Web (WWW) was born when Tim Berners-Lee, a researcher at CERN, the high-energy physics laboratory in Geneva, developed Hypertext Markup Language (HTML).

Mechanical Calculators

One of the earliest calculating devices on record is the Abacus, which has been known and widely used for more than 2,000 years. The Abacus is a simple wooden rack holding parallel rods on which beads are strung. When these beads are manipulated back and forth according to certain rules, several different types of arithmetic operations can be performed.

Math with standard Arabic numbers found its way to Europe in the eighth and ninth centuries. In the early 1600s a man named Charles Napier (the inventor of logarithms) developed a series of rods (later called Napier's Bones) that could be used to assist with numeric multiplication.

Blaise Pascal is normally credited with building the first digital calculating machine in 1642. It could perform the addition of numbers entered on dials and was intended to help his father, who was a tax collector. Then in 1671, Gottfried Wilhelm von Leibniz invented a calculator that was finally built in 1694. His calculating machine could not only add, but by successive adding and shifting, it could also multiply.

In 1820, Charles Xavier Thomas developed the first commercially successful mechanical calculator that could not only add but also subtract, multiply, and divide. After that, a succession of ever improving mechanical calculators created by various other inventors followed.

The First Mechanical Computer

Charles Babbage, a mathematics professor in Cambridge England, is considered by many as being the father of computers because of his two great inventions—each a different type of mechanical computing engine.

The Difference Engine as he called it was conceived in 1812, and solved polynomial equations by the method of differences. By 1822, he had built a small working model of his Difference Engine for demonstration purposes. With financial help from the British government, Babbage started construction of a full-scale model in 1823. It was intended to be steam-powered, and fully automatic, and would even print the resulting tables.

Babbage continued work on it for 10 years, however, by 1833 he had lost interest because he now had an idea for an even better machine, something he described as a general-purpose, fully program-controlled, automatic mechanical digital computer. Babbage called his new machine an Analytical Engine. The plans for the Analytical Engine specified a parallel decimal computer operating on numbers (words) of 50 decimal digits and with a storage capacity (memory) of 1,000 such numbers. Built-in operations were to include everything that a modern general-purpose computer would need, even the all-important conditional function, which would allow instructions to be executed in an order depending on certain conditions, not just in numerical sequence. In modern computers this conditional capability is manifested in the IF statement found in modern computer languages. The Analytical Engine was also intended to use punched cards, which would control or program the machine. The machine was to operate automatically, by steam power, and would require only one attendant.

This Analytical Engine would have been the first true general-purpose computing device. It is regarded as the first real predecessor to a modern computer because it had all the elements of what is considered a computer today. These included

- *An input device.* Using an idea similar to the looms used in textile mills at the time, a form of punched cards supplied the input.
- *A control unit.* A barrel shaped section with many slats and studs was used to control or program the processor.
- *A processor (or calculator).* A computing engine containing hundreds of axles and thousands of gears about 10 feet tall.
- *Storage.* A unit containing more axles and gears that could hold 1,000 50-digit numbers.
- *An output device.* Plates designed to fit in a printing press, used to print the final results.

Alas, this potential first computer was never actually completed because of the problems in machining all the precision gears and mechanisms required. The tooling of the day was simply not good enough.

An interesting side note is that the punched card idea first proposed by Babbage finally came to fruition in 1890. That year a competition was held for a better method to tabulate the U.S. Census information, and Herman Hollerith, a Census Department employee, came up with the idea for punched cards. Without these cards, they had estimated the census data would take years to tabulate, with it they were able to finish in about six weeks. Hollerith went on to found the Tabulating Machine Company, which later became known as IBM.

IBM and other companies at the time developed a series of improved punch-card systems. These systems were constructed of electromechanical devices such as relays and motors. Such systems included features to automatically feed in a specified number of cards from a “read-in” station; perform operations such as addition, multiplication, and sorting; and feed out cards punched with results. These punched-card computing machines could process from 50–250 cards per minute, with each card holding up to 80-digit numbers. The punched cards provided a means of not only input and output, but they also served as a form of memory storage. Punched card machines did the bulk of the world’s computing for more than 50 years and gave many of the early computer companies their start.

Electronic Computers

A physicist named John V. Atanasoff is credited with creating the first true digital electronic computer in 1942, while he worked at Iowa State College. His computer was the first to use modern digital switching techniques and vacuum tubes as the switches.

Military needs during World War II caused a great thrust forward in the evolution of computers. Systems were needed to calculate weapons trajectory and other military functions. In 1946, John P. Eckert, John W. Mauchly, and their associates at the Moore School of Electrical Engineering at the University of Pennsylvania built the first large scale electronic computer for the military. This machine became known as *ENIAC*, the *Electrical Numerical Integrator and Calculator*. It operated on 10-digit numbers, and could multiply two such numbers at the rate of 300 products per second by finding the value of each product from a multiplication table stored in its memory. ENIAC was about 1,000 times faster than the previous generation of electromechanical relay computers.

ENIAC used about 18,000 vacuum tubes, occupied 1,800 square feet (167 square meters) of floor space, and consumed about 180,000 watts of electrical power. Punched cards served as the input and output; registers served as adders and also as quick-access read-write storage.

The executable instructions composing a given program were created via specified wiring and switches that controlled the flow of computations through the machine. As such, ENIAC had to be rewired and switched for each different program to be run.

Earlier in 1945, the mathematician John Von Neumann demonstrated that a computer could have a very simple, fixed physical structure and yet be capable of executing any kind of computation effectively by means of proper programmed control without the need for any changes in hardware. In other words, you could change the program without rewiring the system. Von Neumann's ideas, often referred to as the *stored-program technique*, became fundamental for future generations of high-speed digital computers and were universally adopted.

The first generation of modern programmed electronic computers to take advantage of these improvements appeared in 1947. This group of machines included EDVAC and UNIVAC, the first commercially available computers. These computers included, for the first time, the use of true random access memory (RAM) for storing parts of the program and data that is needed quickly. Typically, they were programmed directly in machine language, although by the mid-1950s progress had been made in several aspects of advanced programming. The standout of the era is the UNIVAC (UNIVersal Automatic Computer), which was the first true general-purpose computer designed for both alphabetical and numerical uses. This made the UNIVAC a standard for business, not just science and the military.

Modern Computers

From UNIVAC to the present, computer evolution has moved very rapidly. The first generation computers were known for using vacuum tubes in their construction. The generation to follow would use the much smaller and more efficient transistor.

From Tubes to Transistors

Any modern digital computer is largely a collection of electronic switches. These switches are used to represent and control the routing of data elements called binary digits (or bits). Because of the on or off nature of the binary information and signal routing used by the computer, an efficient electronic switch was required. The first electronic computers used vacuum tubes as switches, and although the tubes worked, they had many problems.

The type of tube used in early computers was called a *triode* and was invented by Lee DeForest in 1906. It consists of a cathode and a plate, separated by a control grid, suspended in a glass vacuum tube. The cathode is heated by a red-hot electric filament, which causes it to emit electrons that are attracted to the plate. The control grid in the middle can control this flow of electrons. By making it negative, the electrons are repelled back to the cathode; by making it positive, they are attracted toward the plate. Thus by controlling the grid current, you could control the on/off output of the plate

Unfortunately, the tube was inefficient as a switch. It consumed a great deal of electrical power and gave off enormous heat—a significant problem in the earlier systems. Primarily because of the heat they generated, tubes were notoriously unreliable—one failed every couple of hours or so in the larger systems.

The invention of the transistor, or semiconductor, was one of the most important developments leading to the personal computer revolution. The transistor was invented in 1947, and announced in 1948, by Bell Laboratories engineers John Bardeen, Walter Brattain, and William Shockley. The transistor, which essentially functions as a solid-state electronic switch, replaced the much less suitable vacuum tube. Because the transistor was so much smaller and consumed significantly less power, a computer system built with transistors was also much smaller, faster, and more efficient than a computer system built with vacuum tubes.

Transistors are made primarily from the elements silicon and germanium, with certain impurities added. Depending on the impurities added and its electron content, the material becomes known as either N-Type (negative) or P-Type (positive). Both types are conductors, allowing electricity to flow in either direction. However, when the two types are joined, a barrier is formed where they meet that allows current to flow only in one direction when a voltage is present in the right polarity. This is why they are normally called semiconductors.

A transistor is made from placing two P-N junctions back to back. They are made by sandwiching a thin wafer of one type of semiconductor material between two wafers of the other type. If the wafer in-between is made from P-type material, the transistor is designated a NPN. If the wafer in-between is N-type, the transistor is designated PNP.

In an NPN transistor, the N-type semiconductor material on one side of the wafer is called the *emitter* and is normally connected to a negative current. The P-type material in the center is called the *base*. And the N-type material on the other side of the base is called the *collector*.

An NPN transistor compares to a triode tube such that the emitter is equivalent to the cathode, the base is equivalent to the grid, and the collector is equivalent to the plate. By controlling the current at the base, you can control the flow of current between the emitter and collector.

Compared to the tube, the transistor is much more efficient as a switch, and in addition can be miniaturized to microscopic scale. The latest Pentium II and III microprocessors consist of more than 27 million transistors on a single chip die!

The conversion from tubes to transistors began the trend toward miniaturization that continues to this day. Today's small laptop (or palmtop) PC systems, which run on batteries, have more computing power than many earlier systems that filled rooms and consumed huge amounts of electrical power.

Integrated Circuits

The third generation of modern computers is known for using integrated circuits instead of individual transistors. In 1959, engineers at Texas Instruments invented the integrated circuit (IC), a semiconductor circuit that contains more than one transistor on the same base (or substrate material) and connects the transistors without wires. The first IC contained only six transistors. By comparison, the Intel Pentium Pro microprocessor used in many of today's high-end systems has more than 5.5 million transistors, and the integral cache built into some of these chips contains as many as an additional 32 million transistors! Today, many ICs have transistor counts in the multimillion range.

The First Microprocessor

In 1998, Intel celebrated its 30th anniversary. Intel was founded on July 18, 1968, by Robert Noyce, Gordon Moore, and Andrew Grove. They had a specific goal: to make semiconductor memory practical and affordable. This was not a given at the time considering that Silicon chip-based memory was at least 100 times more expensive than the magnetic core memory commonly used in those days. At the time, semiconductor memory was going for about a dollar a bit, whereas core memory was about a penny a bit. Noyce said, "All we had to do was reduce the cost by a factor of a hundred, then we'd have the market; and that's basically what we did."

By 1970, Intel was known as a successful memory chip company, having introduced a 1Kbit memory chip much larger than anything else available at the time. (1Kbit equals 1,024 bits, and a byte equals 8 bits. This chip, therefore, stored only 128 bytes—not much by today's standards.) Known as the 1103 dynamic random access memory (DRAM), it became the world's largest-selling semiconductor device by the end of the following year. By this time Intel had also grown from the core founders and a handful of others to more than 100 employees.

Because of Intel's success in memory chip manufacturing and design, Japanese manufacturer Basicom asked Intel to design a set of chips for a family of high-performance programmable calculators. At the time, all logic chips were custom-designed for each application or product. Because most chips had to be custom designed specific to a particular application, no one chip could have any widespread usage.

Basicom's original design for their calculator called for at least 12 custom chips. Intel engineer Ted Hoff rejected the unwieldy proposal and instead designed a single-chip, general-purpose logic device that retrieved its application instructions from semiconductor memory. As the core of a four-chip set, this central processing unit could be controlled by a program that could essentially

tailor the function of the chip to the task at hand. The chip was generic in nature, meaning it could function in designs other than calculators. Previous designs were hard-wired for one purpose, with built-in instructions; this chip would read a variable set of instructions from memory, which would control the function of the chip. The idea was to design almost an entire computing device on a single chip that could perform different functions, depending on what instructions it was given.

There was one problem with the new chip: Busicom owned the rights to it. Hoff and others knew that the product had almost limitless application, bringing intelligence to a host of “dumb” machines. They urged Intel to repurchase the rights to the product. While Intel founders Gordon Moore and Robert Noyce championed the new chip, others within the company were concerned that the product would distract Intel from its main focus, making memory. They were finally convinced by the fact that every four-chip microcomputer set included two memory chips. As the director of marketing at the time recalled, “Originally, I think we saw it as a way to sell more memories, and we were willing to make the investment on that basis.”

Intel offered to return Busicom’s \$60,000 investment in exchange for the rights to the product. Struggling with financial troubles, the Japanese company agreed. Nobody else in the industry at the time, even at Intel, realized the significance of this deal. Of course it paved the way for Intel’s future in processors. The result was the 1971 introduction of the 4-bit Intel 4004 microcomputer set (the term *microprocessor* was not coined until later). Smaller than a thumbnail and packing 2300 transistors, the \$200 chip delivered as much computing power as the first electronic computer, ENIAC. By comparison, ENIAC relied on 18,000 vacuum tubes packed into 3,000 cubic feet (85 cubic meters) when it was built in 1946. The 4004 executed 60,000 operations in one second, primitive by today’s standards, but a major breakthrough at the time.

Intel introduced the 8008 microcomputer in 1972, which processed eight bits of information at a time, twice as much as the original chip. By 1981, Intel’s microprocessor family had grown to include the 16-bit 8086 and the 8-bit 8088 processors. These two chips garnered an unprecedented 2,500 design wins in a single year. Among those designs was a product from IBM that was to become the first PC.

In 1982, Intel introduced the 286 chip. With 134,000 transistors, it provided about three times the performance of other 16-bit processors of the time. Featuring on-chip memory management, the 286 was the first microprocessor that offered software compatibility with its predecessors. This revolutionary chip was first used in IBM’s benchmark PC-AT.

In 1985 came the Intel386 processor. With a new 32-bit architecture and 275,000 transistors, the chip could perform more than 5 million instructions every second (MIPS). Compaq’s DESKPRO 386 was the first PC based on the new microprocessor.

Next out of the block was the Intel486 processor in 1989. The new chip had 1.2 million transistors and the first built-in math coprocessor. The 486 was some 50 times faster than the original 4004, equaling the performance of powerful mainframe computers.

In 1993, Intel introduced the first Pentium processor, setting new performance standards with up to five times the performance of the Intel486 processor. The Pentium processor uses 3.1 million

transistors to perform up to 90 MIPS—now up to about 1,500 times the speed of the original 4004.

The first processor in the P6 family, called the Pentium Pro processor, was introduced in 1995. With 5.5 million transistors, it was the first to be packaged with a second die containing high-speed memory cache to accelerate performance. Capable of performing up to 300 MIPS, the Pentium Pro continues to be a popular choice for multiprocessor servers and high-performance workstations.

Intel introduced the Pentium II processor in May 1997. Pentium II processors have 7.5 million transistors packed into a cartridge rather than a conventional chip. The Pentium II family was augmented in April 1998, with both the low-cost Celeron processor for basic PCs and the high-end Pentium II Xeon processor for servers and workstations.

Sometime during the year 2000 we expect to see the new P7 processor, code-named Merced.

This will be Intel's first processor with 64-bit instructions, and will spawn a whole new category of operating systems and applications, while still remaining backward-compatible with 32-bit software.

Personal Computer History

The fourth and current generation of modern computer includes those that incorporate microprocessors in their designs. Of course, part of this fourth generation of computers is the personal computer, which itself was made possible by the advent of low cost microprocessors and memory.

Birth of the Personal Computer

In 1973, some of the first microcomputer kits based on the 8008 chip were developed. These kits were little more than demonstration tools and didn't do much except blink lights. In late 1973, Intel introduced the 8080 microprocessor, which was 10 times faster than the earlier 8008 chip and addressed 64K of memory. This was the breakthrough the personal computer industry had been waiting for.

A company called MITS introduced the Altair kit in a cover story in the January 1975 issue of *Popular Electronics*. The Altair kit, considered to be the first personal computer, included an 8080 processor, a power supply, a front panel with a large number of lights, and 256 bytes (not kilobytes) of memory. The kit sold for \$395 and had to be assembled. Assembly back then meant you got out your soldering iron to actually finish the circuit boards, not like today where you can assemble a system of pre-made components with nothing more than a screwdriver.

The Altair included an open architecture system bus called the S-100 bus because it had 100 pins per slot. The open architecture meant that anybody could develop boards to fit in these slots and interface to the system. This prompted various add-ons and peripherals from numerous aftermarket companies. The new processor inspired software companies to write programs, including the CP/M (Control Program for Microprocessors) operating system and the first version of the Microsoft BASIC (Beginners All-purpose Symbolic Instruction Code) programming language.

IBM introduced what can be called its first personal computer in 1975. The Model 5100 had 16K of memory, a built-in 16-line by 64-character display, a built-in BASIC language interpreter, and a built-in DC-300 cartridge tape drive for storage. The system's \$9,000 price placed it out of the mainstream personal computer marketplace, which was dominated by experimenters (affectionately referred to as hackers) who built low-cost kits (\$500 or so) as a hobby. Obviously, the IBM system was not in competition for this low-cost market and did not sell as well by comparison.

The Model 5100 was succeeded by the 5110 and 5120 before IBM introduced what we know as the IBM Personal Computer (Model 5150). Although the 5100 series preceded the IBM PC, the older systems and the 5150 IBM PC had nothing in common. The PC IBM turned out was more closely related to the IBM System/23 DataMaster, an office computer system introduced in 1980. In fact, many of the engineers who developed the IBM PC had originally worked on the DataMaster.

In 1976, a new company called Apple Computer introduced the Apple I, which originally sold for \$666. The selling price was an arbitrary number selected by one of the co-founders, Steve Jobs. This system consisted of a main circuit board screwed to a piece of plywood. A case and power supply were not included. Only a few of these computers were made, and they reportedly have sold to collectors for more than \$20,000. The Apple II, introduced in 1977, helped set the standard for nearly all the important microcomputers to follow, including the IBM PC.

The microcomputer world was dominated in 1980 by two types of computer systems. One type, the Apple II, claimed a large following of loyal users and a gigantic software base that was growing at a fantastic rate. The other type, CP/M systems, consisted not of a single system but of all the many systems that evolved from the original MITS Altair. These systems were compatible with one another and were distinguished by their use of the CP/M operating system and expansion slots, which followed the S-100 standard. All these systems were built by a variety of companies and sold under various names. For the most part, however, these systems used the same software and plug-in hardware. It is interesting to note that none of these systems were PC-compatible or Macintosh-compatible, the two primary standards in place today.

A new competitor looming on the horizon was able to see that in order to be successful, a personal computer needed to have an open architecture, slots for expansion, a modular design, and healthy support from both hardware and software companies other than the original manufacturer of the system. This competitor turned out to be IBM, which was quite surprising at the time because IBM was not known for systems with these open architecture attributes! IBM in essence became more like the early Apple, and Apple themselves became like everybody expected IBM to be. The open architecture of the forthcoming IBM PC and the closed architecture of the forthcoming Macintosh caused a complete turnaround in the industry.

The IBM Personal Computer

At the end of 1980, IBM decided to truly compete in the rapidly growing low-cost personal computer market. The company established what was called the Entry Systems Division, located in

Boca Raton, Florida, to develop the new system. The division was located intentionally far away from IBM's main headquarters in New York, or any other IBM facilities, in order that this new division be able to operate independently as a separate unit. This small group consisted of 12 engineers and designers under the direction of Don Estridge. The team's chief designer was Lewis Eggebrecht. The Entry Systems Division was charged with developing IBM's first real PC. (IBM considered the previous 5100 system, developed in 1975, to be an intelligent programmable terminal rather than a genuine computer, even though it truly was a computer.) Nearly all these engineers had been moved into the new division from the System/23 DataMaster project, which was a small office computer system introduced in 1980, and was the direct predecessor at IBM to the IBM PC.

Much of the PC's design was influenced by the DataMaster design. In the DataMaster's single-piece design, the display and keyboard were integrated into the unit. Because these features were limiting, they became external units on the PC, although the PC keyboard layout and electrical designs were copied from the DataMaster.

Several other parts of the IBM PC system also were copied from the DataMaster, including the expansion bus (or input/output slots), which included not only the same physical 62-pin connector, but also almost identical pin specifications. This copying of the bus design was possible because the PC used the same interrupt controller as the DataMaster and a similar direct memory access (DMA) controller. Also, expansion cards already designed for the DataMaster could easily be redesigned to function in the PC.

The DataMaster used an Intel 8085 CPU, which had a 64KB address limit, and an 8-bit internal and external data bus. This arrangement prompted the PC design team to use the Intel 8088 CPU, which offered a much larger (1MB) memory address limit and an internal 16-bit data bus, but only an 8-bit external data bus. The 8-bit external data bus and similar instruction set allowed the 8088 to be easily interfaced into the earlier DataMaster designs.

Estridge and the design team rapidly developed the design and specifications for the new system. In addition to borrowing from the System/23 DataMaster, the team studied the marketplace, which also had enormous influence on the IBM PC's design. The designers looked at the prevailing standards and successful systems available at the time, learned from the success of those systems, and incorporated into the new PC all the features of the popular systems, and more. With the parameters for design made obvious by the market, IBM produced a system that quite capably filled its niche in the market.

IBM brought its system from idea to delivery of functioning systems in one year by using existing designs and purchasing as many components as possible from outside vendors. The Entry Systems Division was granted autonomy from IBM's other divisions and could tap resources outside the company, rather than go through the bureaucratic procedures that required exclusive use of IBM resources. IBM contracted out the PC's languages and operating system to a small company named Microsoft. That decision was the major factor in establishing Microsoft as the dominant force in PC software today.

Note

It is interesting to note that IBM had originally contacted Digital Research (the company that created CP/M, then the most popular personal computer operating system) to have them develop an operating system for the new IBM PC, but they were leery of working with IBM, and especially balked at the nondisclosure agreement IBM wanted them to sign. Microsoft jumped on the opportunity left open by Digital Research, and as a result has become one of the largest software companies in the world. IBM's use of outside vendors in developing the PC was an open invitation for the aftermarket to jump in and support the system—and it did.

On Wednesday, August 12, 1981, a new standard was established in the microcomputer industry with the debut of the IBM PC. Since then, hundreds of millions of PC-compatible systems have been sold, as the original PC has grown into an enormous family of computers and peripherals. More software has been written for this computer family than for any other system on the market.

The PC Industry 18 Years Later

In the more than 18 years since the original IBM PC was introduced, many changes have occurred. The IBM-compatible computer, for example, advanced from a 4.77MHz 8088-based system to 500MHz or faster Pentium II-based systems—nearly 4,000 times faster than the original IBM PC (in actual processing speed, not just clock speed). The original PC had only one or two single-sided floppy drives that stored 160KB each using DOS 1.0, whereas modern systems easily can have 20GB (20 billion bytes) or more of hard disk storage.

A rule of thumb in the computer industry (called Moore's Law, originally set forth by Intel co-founder Gordon Moore) is that available processor performance and disk-storage capacity doubles every two years, give or take.

Since the beginning of the PC industry, this pattern has shown no sign of changing.

In addition to performance and storage capacity, another major change since the original IBM PC was introduced is that IBM is not the only manufacturer of "PC-compatible" systems. IBM originated the PC-compatible standard, of course, but today they no longer set the standards for the system they originated. More often than not, new standards in the PC industry are developed by companies and organizations other than IBM. Today, it is Intel and Microsoft who are primarily responsible for developing and extending the PC hardware and software standards, respectively. Some have even taken to calling PCs "Wintel" systems, owing to the dominance of those two companies.

In more recent years Intel and Microsoft have carried the evolution of the PC forward. The introduction of hardware standards such as the PCI (Peripheral Component Interconnect) bus, AGP (Accelerated Graphics Port) bus, ATX and NLX motherboard form factors, Socket 1 through 8 as well as Slot 1 and 2 processor interfaces, and numerous others show that Intel is really pushing PC hardware design these days. In a similar fashion, Microsoft is pushing the software side of things with the continual evolution of the Windows operating system as well as applications such as the Office suite.

Today there are literally hundreds of system manufacturers following the collective PC standard and producing computers that are fully PC-compatible. There are also thousands of peripheral manufacturers whose components expand and enhance PC-compatible systems.

PC-compatible systems have thrived, not only because compatible hardware can be assembled easily, but also because the primary operating system was available not from IBM but from a third party (Microsoft). The core of the system software is the BIOS (basic input/output system), and this was also available from third-party companies such as AMI, Award, Phoenix, and others. This situation allowed other manufacturers to license the operating system and BIOS software and to sell their own compatible systems. The fact that DOS borrowed the functionality and user interface from both CP/M and UNIX probably had a lot to do with the amount of software that became available. Later, with the success of Windows, there would be even more reasons for software developers to write programs for PC-compatible systems.

One of the reasons why Apple Macintosh systems will likely never enjoy the success of PC systems is that Apple controls all the primary systems software (BIOS and OS), and has never licensed it to other companies for use in compatible systems.

At some point in their development, Apple seemed to recognize this flawed stance, and in the mid-1990s, licensed its software to third-party manufacturers such as Power Computing. After a short time, Apple cancelled its licensing agreements with other manufacturers. Since Apple remains essentially a closed system, other companies cannot develop compatible machines, meaning Macintosh systems are only available from one source—Apple. As such, it seems too late for them to effectively compete with the PC-compatible juggernaut. It is fortunate for the computing public as a whole that IBM created a more open and extendible standard, which today finds systems being offered by hundreds of companies in thousands of configurations. This kind of competition among manufacturers and vendors of PC-compatible systems is the reason why such systems offer so much performance and so many capabilities for the money.

The IBM-compatible market continues to thrive and prosper. New technology continues to be integrated into these systems, enabling them to grow with the times. These systems offer a high value for the money and have plenty of software available to run on them. It's a safe bet that PC-compatible systems will dominate the personal computer marketplace for the next 15–20 years.

Moore's Law

In 1965, Gordon Moore was preparing a speech about the growth trends in computer memory, and he made an interesting observation. When he began to graph the data, he realized there was a striking trend. Each new chip contained roughly twice as much capacity as its predecessor, and each chip was released within 18–24 months of the previous chip. If this trend continued, he reasoned, computing power would rise exponentially over relatively brief periods of time (see Figure 1.1).

Moore's observation, now known as Moore's Law, described a trend that has continued to this day and is still remarkably accurate. It was found to not only describe memory chips, but also accurately describe the growth of processor power and disk-drive storage capacity. It has become the basis for many industry performance forecasts. In 26 years, the number of transistors on a chip has increased more than 3,200 times, from 2,300 on the 4004 in 1971 to more than 7.5 million on the Pentium II processor.

Figure 1.1 Moore's Law as applied to processors, showing that transistor count doubles about every two years.

What does the future hold? For PCs, one thing is sure: They will continue to become faster, smaller, and cheaper. According to Gordon Moore, computing power continues to increase at a rate of about double the power every two years. This has held true not only for speed but storage capacity as well. This means that computers you will be purchasing two years from now will be about twice as fast and store twice as much as what you can purchase today. The really amazing part is that this rapid pace of evolution shows no signs of letting up.

PC Components, Features, and System Design

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

What Is a PC?

System Types

System Components

This chapter defines what a *PC* really is, and then continues by defining the types of PCs on the market. In addition, the chapter gives an overview of the components found in a modern PC.

What Is a PC?

I normally ask the question, “What exactly is a PC?” when I begin one of my PC hardware seminars. Of course, most people immediately answer that PC stands for *personal computer*, which in fact it does. They might then continue by defining a personal computer as any small computer system purchased and used by an individual. Unfortunately, that definition is not nearly precise or accurate enough for our purposes. I agree that a PC is a personal computer, but not all personal computers are PCs. For example, an Apple Macintosh system is clearly a personal computer, but nobody I know would call a Mac a PC, least of all Mac users! For the true definition of what a PC is, you must look deeper.

Calling something a PC implies that it is something much more specific than just any personal computer. One thing it implies is a family relation to the first IBM PC from 1981. In fact, I’ll go so far as to say that IBM literally *invented* the PC; that is, they designed and created the very first one, and it was IBM who originally defined and set all the standards that made the PC distinctive from other personal computers. Note that it is very clear in my mind—as well as in the historical record—that IBM did *not* invent the personal computer. (Most recognize the historical origins of the personal computer in the MITS Altair, introduced in 1975.) IBM did not invent the personal computer, but they did invent the PC. Some people might take this definition a step further and define a PC as any personal computer that is “IBM compatible.” In fact, many years back PCs were called either IBM compatibles or IBM clones, in essence paying homage to the origins of the PC at IBM.

The reality today is that although IBM clearly designed and created the first PC in 1981 and controlled the development and evolution of the PC standard for several years thereafter, IBM is no longer in control of the PC standard; that is, they do not dictate what makes up a PC today. IBM lost control of the PC standard in 1987 when they introduced their PS/2 line of systems. Up until then, other companies that were producing PCs literally copied IBM’s systems right down to the chips, connectors, and even the shapes (form factors) of the boards, cases, and power supplies; after 1987, IBM abandoned many of the standards they created in the first place. That’s why for many years now I have refrained from using the designation “IBM compatible” when referring to PCs.

If a PC is no longer an IBM compatible, what is it? The real question seems to be, “Who is in control of the PC standard today?” That question is best broken down into two parts. First, who is in control of PC software? Second, who is in control of PC hardware?

Who Controls PC Software?

Most of the people in my seminars don’t even hesitate for a split second when I ask this question; they immediately respond “Microsoft!” I don’t think there is any argument with that answer. Microsoft clearly controls the operating systems that are used on PCs, which have migrated from the original MS-DOS to Windows 95/98, Windows NT, and Windows 2000.

Microsoft has effectively used their control of the PC operating system as leverage to also control other types of PC software, such as utilities and applications. For example, many utility programs that were originally offered by independent companies such as disk caching, disk compression, defragmentation, file structure repair, and even calculators and notepads are now bundled (included with) in Windows. They have even bundled applications such as Web browsers, insuring an automatic installed base for these applications—much to the dismay of companies that produce competing versions. Microsoft has also leveraged their control of the operating system to integrate their own networking software and applications suites more seamlessly into the operating system than others. That's why they now dominate most of the PC software universe, from operating systems to utilities, from word processors to spreadsheets.

In the early days of the PC, when IBM was clearly in control of the PC hardware standard, they hired Microsoft to provide most of the core software for the PC. IBM developed the hardware, wrote the BIOS (basic input/output system), and then hired Microsoft to develop the Disk Operating System (DOS) as well as several other programs and utilities for IBM. In what was later viewed as perhaps the most costly business mistake in history, IBM failed to secure exclusive rights to the DOS they had contracted from Microsoft, either by purchasing it outright or by an exclusive license agreement. Instead, IBM licensed it non-exclusively, which subsequently allowed Microsoft to sell the same MS-DOS code they developed for IBM to any other company that was interested. Early PC cloners such as Compaq eagerly licensed this same operating system code, and suddenly you could purchase the same basic MS-DOS operating system with several different company names on the box. In retrospect, that single contractual error made Microsoft into the dominant software company it is today, and subsequently caused IBM to lose control of the very PC standard they had created.

As a writer myself (words, not software) I can appreciate what an incredible oversight this was. Imagine that a book publisher comes up with a great idea for a very popular book, and then contracts with and subsequently pays an author to write it. Then, by virtue of a poorly written contract, the author discovers that he can legally sell the very same book (perhaps with a different title) to all the competitors of the original publisher. Of course no publisher I know would allow this to happen, yet that is exactly what IBM allowed Microsoft to do back in 1981. By virtue of their deal with Microsoft, IBM had essentially lost control of the software they commissioned for their new PC from day one.

►► See "BIOS," p. 345.

It is interesting to note that in the PC business software enjoys copyright protection, whereas hardware can only be protected by patents, which are difficult and time consuming to get and which expire after 17 years. To patent something requires that it be a unique and substantially new design. This made it impossible to patent most aspects of the IBM PC because it was designed using previously existing parts that anybody could purchase off the shelf! In fact, most of the important parts for the original PC came from Intel, such as the 8088 processor, 8284 clock generator, 8253/54 timer, 8259 interrupt controller, 8237 DMA (Direct Memory Access) controller, 8255 peripheral interface, and the 8288 bus controller. These are the chips that made up the heart and soul of the original PC.

Because the design of the original PC was not wholly patentable, anybody could duplicate the hardware of the IBM PC. All they had to do was purchase the same chips from the same manufacturers and suppliers that IBM used and design a new motherboard with a similar circuit. Seemingly as if to aid in this, IBM even published complete schematic diagrams of their motherboards and all their adapter cards in very detailed and easily available Technical Reference manuals. I have several of these early IBM manuals and still refer to them from time to time for specific component-level PC design information. In fact, I still recommend these original manuals to anybody who wants to delve deeply into PC design.

The difficult part of copying the IBM PC was the software, which is protected by copyright law. Phoenix Software was among the first to develop a legal way around this problem, which enabled them to functionally duplicate (but not exactly copy) software such as the BIOS (basic input/output system). The *BIOS* is defined as the core set of control software, which drives the hardware devices in the system directly. These types of programs are normally called *device drivers*, so in essence the BIOS is a collection of all the core device drivers used to operate and control the system hardware. What is called the operating system (such as DOS or Windows) uses the drivers in the BIOS to control and communicate with the various hardware and peripherals in the system.

Phoenix's method for duplicating the BIOS legally was an ingenious form of reverse-engineering. They hired two teams of software engineers, the second of which had to be specially screened to consist only of people who had never seen or studied the IBM BIOS code. The first team did study the IBM BIOS, and wrote as complete a description of what it did as possible. The second team read the description written by the first team, and set out to write from scratch a new BIOS that did everything the first team described. The end result was a new BIOS written from scratch with code that, although not identical to IBM's, had exactly the same functionality.

Phoenix called this a "clean room" approach to reverse engineering software, and it can escape any legal attack. Because IBM's original PC BIOS consisted of only 8KB of code and had limited functionality, duplicating it through the clean room approach was not very difficult or time consuming. As the IBM BIOS evolved, Phoenix—as well as the other BIOS companies—found it relatively easy to keep in step with any changes IBM might make. Discounting the POST (power on self test) or BIOS Setup program (used for configuring the system) portion of the BIOS, most BIOSes, even today, have only about 32K of active code. Today not only Phoenix, but also others such as AMI and Microid Research, are producing BIOS software for PC system manufacturers.

After the hardware and the BIOS of the IBM PC were duplicated, all that was needed to produce a fully IBM-compatible system was DOS. Reverse engineering DOS—even with the clean room approach—would have been a daunting task because DOS is much larger than the BIOS and consists of many more programs and functions. Also, the operating system has evolved and changed more often than the BIOS, which by comparison has remained relatively constant. This means that the only way to get DOS on an IBM compatible is to license it. This is where Microsoft comes in. Because IBM (who hired Microsoft to write DOS in the first place) did not ensure that Microsoft signed an exclusive license agreement, Microsoft was free to sell the same DOS to anybody. With a licensed copy of MS-DOS, the last piece was in place and the floodgates were open for IBM-compatible systems to be produced whether IBM liked it or not.

In retrospect, this is exactly why there are no clones or compatibles of the Apple Macintosh system. It is not that Mac systems cannot be duplicated; in fact, the Mac hardware is fairly simple and easy to produce using off-the-shelf parts. The real problem is that Apple owns the MAC OS as well as the BIOS, and because they have seen fit not to license them, no other company can sell an Apple-compatible system. Also, note that the Mac BIOS and OS are very tightly integrated; the Mac BIOS is very large and complex, and it is essentially a part of the OS, unlike the much more simple and easily duplicated BIOS found on PCs. The greater complexity and integration has allowed both the Mac BIOS and OS to escape any clean room duplication efforts. This means that without Apple's blessing (in the form of licensing), no Mac clones are likely to ever exist.

It might be interesting to note that during '96-'97 there was an effort by the more liberated thinkers at Apple to license their BIOS/OS combination, and several Mac compatible machines were not only developed, but also were produced and sold. Companies such as Sony, Power Computing, Radius, and even Motorola had invested millions of dollars in developing these systems, but shortly after these first Mac clones were sold, Apple rudely canceled all licensing! This was apparently the result of an edict from Steve Jobs, who had been hired back to run the company and who was one of the original architects of the closed-box proprietary design Macintosh system in the first place. By canceling these licenses, Apple has virtually guaranteed that their systems will never be a mainstream success. Along with their smaller market share come much higher system costs, fewer available software applications, and fewer hardware upgrades as compared to PCs. The proprietary design also means that major repair or upgrade components such as motherboards, power supplies, and cases are available only from Apple at very high prices, and upgrades of these components are normally not cost effective.

I often think that if Apple had a different view and had licensed their OS and BIOS early-on, this book might be called "Upgrading and Repairing Macs" instead!

In summary, because IBM did not own DOS (or Windows) but licensed it non-exclusively from Microsoft, anybody else who wanted to put MS-DOS or Windows on their system could license the code from Microsoft. This enabled any company who wanted to develop an IBM-compatible system to circumvent IBM completely, and yet produce a functionally identical machine. Because people desire backward compatibility, when one company controls the operating system, they naturally control all the software that goes around it, including everything from drivers to application programs. As long as PCs are used with Microsoft operating systems, they will have the upper hand in controlling PC software.

Who Controls PC Hardware?

Although it is clear that Microsoft has always controlled PC software by virtue of their control over the PC operating system, what about the hardware? It is easy to see that IBM controlled the PC hardware standard up through 1987. After all, IBM invented the core PC motherboard design, expansion bus slot architecture (8/16-bit ISA bus), serial and parallel port design, video card design through VGA and XGA standards, floppy and hard disk interface and controller designs, power supply design, keyboard interface and design, mouse interface, and even the physical shapes (form factors) of everything from the motherboard to the expansion cards, power supplies, and system chassis. All these pre-1987 IBM PC, XT and AT system design features are still influencing modern systems today.

But to me the real question is what company has been responsible for creating and inventing new and more recent PC hardware designs, interfaces, and standards? When I ask people that question, I normally see some hesitation in their response—some people say Microsoft (but they control the software, not the hardware), some say Compaq or name a few other big name system manufacturers. Only a few surmise the correct answer—Intel.

I can see why many people don't immediately realize this; I mean, how many people actually own an Intel brand PC? No, not just one that says "intel inside" on it (which refers only to the system having an Intel processor), but a system that was designed and built by Intel or even purchased through them. Believe it or not, I think that many, if not most, people today do have Intel PCs!

Certainly this does not mean that they have purchased their systems from Intel because it is well known that Intel does not sell complete PCs direct to end users. You cannot currently order a system from Intel, nor can you purchase an Intel brand system from somebody else. What I am talking about is the motherboard. In my opinion, the single most important part in a PC system is the motherboard, and I'd say that whoever made your motherboard should be considered the legitimate manufacturer of your system. Even back when IBM was the major supplier of PCs, they only made the motherboard, and contracted the other components of the system (power supply, disk drives, and so on) out to others.

►► See "Motherboards and Buses," p. 203.

The top tier system manufacturers do make their own motherboards. According to *Computer Reseller News* magazine, the top three desktop systems manufacturers for the last several years have consistently been Compaq, Packard Bell, and IBM. These companies, for the most part, do design and manufacture their own motherboards, as well as many other system components. In some cases they even design their own chips and chipset components for their own boards. Although sales are high for these individual companies, there is a larger overall segment of the market that can be called the second tier.

In the second tier are companies who do not really manufacture systems, but assemble them instead. That is, they purchase motherboards, cases, power supplies, disk drives, peripherals, and so on, and assemble and market the components together as complete systems. Dell, Gateway, and Micron are some of the larger system assemblers today, but there are hundreds more who can be listed. In overall total volume, this ends up being the largest segment of the PC marketplace today. What is interesting about the second tier systems is that, with very few exceptions, you and I can purchase the same motherboards and other components any of the second tier manufacturers can (although we pay more than they do). We can also assemble a virtually identical system from scratch ourselves, but that is a story for another chapter, and is covered in Chapter 24, "Building or Upgrading Systems."

If Gateway, Dell, Micron, and others do not manufacture their own motherboards, who does? You guessed it—Intel. Not only do those specific companies use pretty much exclusively Intel

motherboards, if you check around you'll find today that many, if not most, of the systems on the market in the second tier come with Intel motherboards. The only place Intel doesn't dominate is the low-end market Socket 7 type systems, which is mainly because Intel had originally abandoned the Socket 7 design and the low end market in general. Now they are coming back strong in the low end PC market with the newer Socket 370 design, with which they intend to dominate the low end market as well.

I checked a review of 10 different Pentium II systems in the current *Computer Shopper* magazine, and I'm not kidding, eight out of the 10 systems they evaluated had Intel motherboards. In fact, those eight used the exact same Intel motherboard. That means that these systems differ only in the cosmetics of the exterior case assembly and by what video card, disk drives, keyboards, and so on the assembler used that week.

The other two systems in the sample review had boards from manufacturers other than Intel, but even those boards used Intel Pentium II processors and Intel motherboard chipsets, which together comprise more than 90 percent of the motherboard cost. This review was not an anomaly; it is consistent with what I have been seeing under the hood of mail-order and mainstream "white box" PC systems for years.

- ▶▶ See "Pentium II Processors," p. 162.
- ▶▶ See "Chipsets," p. 235.

How and when did this happen? Intel has been the dominant PC processor supplier since IBM chose the Intel 8088 CPU in the original IBM PC in 1981. By controlling the processor, Intel naturally had control of the chips needed to integrate their processors into system designs. This naturally led Intel into the chipset business. They started their chipset business in 1989 with the 82350 EISA (Extended Industry Standard Architecture) chipset, and by 1993 they had become—along with the debut of the Pentium processor—the largest volume major motherboard chipset supplier. Now I imagine them sitting there, thinking that they make the processor and all the other chips needed to produce a motherboard, so why not just eliminate the middle man and make the entire motherboard too? The answer to this, and a real turning point in the industry, came about in 1994 when Intel became the largest-volume motherboard manufacturer in the world. And they have remained solidly on top ever since. They don't just lead in this category by any small margin; in fact, during 1997 Intel made more motherboards than the next eight largest motherboard manufacturers combined, with sales of more than 30 million boards, worth more than \$3.6 billion! Note that this figure does not include processors or chipsets—only the boards themselves. These boards end up in the various system assembler brand PCs you and I buy, meaning that most of us are now essentially purchasing Intel-manufactured systems, no matter who actually wielded the screwdriver.

Table 2.1 shows the top 10 motherboard manufacturers, ranked by 1997 sales (1998 sales reports were not available at the time this book was printed).

Note

These figures reflect sales in millions.

Table 2.1 Top Motherboard Manufacturers (Computer Reseller News)

Motherboard Manufacturer	1997 Sales	1996 Sales
Intel	\$3,600	\$3,200
Acer	\$825	\$700
AsusTek	\$640	\$426
Elitegroup	\$600	\$600
First International Computer (FIC)	\$550	\$450
QDI Group	\$320	\$246
Soyo	\$254	\$123
Giga-Byte	\$237	\$165
Micro-Star	\$205	\$180
Diamond Flower (DFI)	\$160	\$100

Without a doubt, Intel controls the PC hardware standard because they control the PC motherboard. They not only make the vast majority of motherboards being used in systems today, but they also supply the vast majority of processors and motherboard chipsets to other motherboard manufacturers. This means that even if you don't have an actual Intel motherboard, the motherboard you do have probably has an Intel processor or chipset.

Intel also has a hand in setting several of the more recent PC hardware standards. It was Intel who originally created the PCI (Peripheral Component Interconnect) local bus interface and the new AGP (Accelerated Graphics Port) interface for high performance video cards. Intel designed the ATX motherboard form factor that replaces the (somewhat long in the tooth) IBM-designed Baby-AT form factor that has been used since the early '80s. Intel also created the NLX motherboard form factor to replace the proprietary and limited LPX design used by many lower-cost systems, which finally brought motherboard upgradability to those systems. Intel also created the DMI (Desktop Management Interface) for monitoring system hardware functions and the DPMA (Dynamic Power Management Architecture) and APM (Advanced Power Management) standards for managing power usage in the PC.

Intel has pushed for advancements in motherboard chipsets; supporting new types of memory such as EDO (Extended Data Out), SDRAM (Synchronous Dynamic RAM), and RDRAM (Rambus Dynamic RAM); new and faster bus interfaces; and faster memory access. They are also having a major effect in the portable market, bringing out special low-power processors, chipsets, and mobile modules (combining processor and chipset together on a daughterboard) to ease portable system design and improve functionality and performance. It doesn't take much to see that Intel is clearly in as much control of the PC hardware standard as Microsoft is in control of the PC software standard.

These days, the Intel processor and chipsets are so ubiquitous that these components are being reverse-engineered, and so called “Intel-compatible” versions are being produced. Companies such as AMD, Cyrix, and others have a variety of processors, which are direct pin-compatible replacements for Intel processors; furthermore, some chipset manufacturers have even produced pin for pin copies of Intel chipsets.

Whoever controls the operating system controls the software for the PC, and whoever controls the processor—and therefore the motherboard—controls the hardware. Because it seems to be a Microsoft and Intel combination for the software and hardware control in the PC today, it is no wonder the modern PC is often called a “Wintel” system.

PC 9x Specifications

Even though Intel has full control of PC hardware, Microsoft recognizes their power over the PC from the operating system perspective and has been releasing a series of documents called the “PC 9x Design Guides” (where 9x designates the year) as a set of standard specifications to guide both hardware and software developers who are creating products that work with Windows. The requirements in these guides are part of Microsoft’s “Designed for Windows” logo requirement. In other words, if you produce either a hardware or software product and you want the official “Designed for Windows” logo to be on your box, your product has to meet the PC 9x minimum requirements.

Following are the documents that have been produced so far:

- Hardware Design Guide for Microsoft Windows 95
- Hardware Design Guide Supplement for PC 95
- PC 97 Hardware Design Guide
- PC 98 System Design Guide
- PC 99 System Design Guide
- PC 2000 System Design Guide

All these documents are available for download from Microsoft’s Web site, and they have also been available as published books from Microsoft Press.

These system design guides present information for engineers who build personal computers, expansion cards, and peripheral devices that are to be used with Windows 95, 98, and NT operating systems. The requirements and recommendations for PC design in these guides form the basis for the requirements of the “Designed for Microsoft Windows” logo program for hardware that Microsoft sponsors.

These guides include requirements for basic (desktop and mobile) systems, workstations, and even entertainment PCs. They also address Plug-and-Play device configuration and power management in PC systems, requirements for universal serial bus (USB) and IEEE 1394, and new devices supported under Windows, including new graphics and video device capabilities, DVD, scanners and digital cameras, and other devices.

Note

Note that these guides do not mean anything directly for the end user; instead, they are meant to be guides for PC manufacturers to build their systems. As such, they are only recommendations, and they do not have to be followed to the letter. In some ways they are a market control tool for Intel and Microsoft to further wield their influence on PC hardware and software. In reality, the market often dictates that some of these recommendations are disregarded, which is one reason why they continue to evolve with new versions year after year.

System Types

PCs can be broken down into many different categories. I like to break them down in two different ways—one by the type of software they can run, the other by the motherboard host bus, or processor bus design and width. Because this book concentrates mainly on hardware, let's look at that first.

When a processor reads data, the data moves into the processor via the processor's external data bus connection. The processor's data bus is directly connected to the processor host bus on the motherboard. The processor data bus or host bus is also sometimes referred to as the *local bus* because it is local to the processor that is connected directly to it. Any other devices that are connected to the host bus essentially appear as if they are directly connected to the processor as well. If the processor has a 32-bit data bus, the motherboard must be wired to have a 32-bit processor host bus. This means that the system can move 32-bits worth of data into or out of the processor in a single cycle.

▶▶ See "Data Bus," p. 50.

Different processors have different data bus widths, and the motherboards that are designed to accept them require a processor host bus with a matching width. Table 2.2 lists all the Intel processors and their data bus widths.

Table 2.2 Intel Processors and Their Data Bus Widths

Processor	Data Bus Width
8088	8-bit
8086	16-bit
286	16-bit
386SX	16-bit
386DX	32-bit
486 (all)	32-bit
Pentium	64-bit
Pentium MMX	64-bit
Pentium Pro	64-bit
Pentium Celeron/II/III	64-bit
Pentium II/III Xeon	64-bit

A common misconception arises in discussions of processor widths. Although the Pentium processors all have 64-bit data bus widths, their internal registers are only 32 bits wide, and they process 32-bit commands and instructions. Thus, from a software point of view, all chips from the 386 to the Pentium III have 32-bit registers and execute 32-bit instructions. From the electronic or physical perspective, these 32-bit software capable processors have been available in physical forms with 16-bit (386SX), 32-bit (386DX, 486), and 64-bit (Pentium) data bus widths. The data bus width is the major factor in motherboard and memory system design because it dictates how many bits move in and out of the chip in one cycle.

▶▶ See "Internal Registers," p. 51.

The future P7 processor, code-named Merced, will have a new Intel Architecture 64-bit (IA-64) instruction set, but it will also process the same 32-bit instructions as 386 through Pentium processors do. It is not known whether Merced will have a 64-bit data bus like the Pentium or whether it will include a 128-bit data bus.

▶▶ See "Processor Specifications," p. 39.

From Table 2.2 you can see that 486 systems have a 32-bit processor bus, which means that any 486 motherboard would have a 32-bit processor host bus. Pentium processors, whether they are the original Pentium, Pentium MMX, Pentium Pro, or even the Pentium II and III, all have 64-bit data busses. This means that Pentium motherboards have a 64-bit processor host bus. You cannot put a 64-bit processor on a 32-bit motherboard, which is one reason that 486 motherboards cannot accept true Pentium processors.

As you can see from this table, we can break systems down into the following hardware categories:

- 8-bit
- 16-bit
- 32-bit
- 64-bit

What is interesting is that besides the bus width, the 16- through 64-bit systems are remarkably similar in basic design and architecture. The older 8-bit systems are very different, however. This gives us two basic system types, or classes, of hardware:

- 8-bit (PC/XT-class) systems
- 16/32/64-bit (AT-class) systems

PC stands for personal computer, XT stands for an eXTended PC, and AT stands for an advanced technology PC. The terms PC, XT, and AT, as they are used here, are taken from the original IBM systems of those names. The XT was basically a PC system that included a hard disk for storage in addition to the floppy drives found in the basic PC system. These systems had an 8-bit 8088 processor and an 8-bit Industry Standard Architecture (ISA) Bus for system expansion. The bus is the name given to expansion slots in which additional plug-in circuit boards can be installed.

The 8-bit designation comes from the fact that the ISA Bus found in the PC/XT class systems can send or receive only eight bits of data in a single cycle. The data in an 8-bit bus is sent along eight wires simultaneously, in parallel.

▶▶ See “The ISA Bus,” p. 283.

16-bit and greater systems are said to be AT-class, which indicates that they follow certain standards, and that they follow the basic design first set forth in the original IBM AT system. AT is the designation IBM applied to systems that first included more advanced 16-bit (and later, 32- and 64-bit) processors and expansion slots. AT-class systems must have a processor that is compatible with Intel 286 or higher processors (including the 386, 486, Pentium, Pentium Pro, and Pentium II processors), and they must have a 16-bit or greater system bus. The system bus architecture is central to the AT system design, along with the basic memory architecture, Interrupt ReQuest (IRQ), DMA (Direct Memory Access), and I/O port address design. All AT-class systems are similar in the way these resources are allocated and how they function.

The first AT-class systems had a 16-bit version of the ISA Bus, which is an extension of the original 8-bit ISA Bus found in the PC/XT-class systems. Eventually, several expansion slot or bus designs were developed for AT-class systems, including those in the following list:

- 16-bit ISA bus
- 16/32-bit Extended ISA (EISA) bus
- 16/32-bit PS/2 Micro Channel Architecture (MCA) bus
- 16-bit PC-Card (PCMCIA) bus
- 32-bit Cardbus (PCMCIA) bus
- 32-bit VESA Local (VL) bus
- 32/64-bit Peripheral Component Interconnect (PCI) bus
- 32-bit Accelerated Graphics Port (AGP)

A system with any of these types of expansion slots is by definition an AT-class system, regardless of the actual Intel or Intel-compatible processor that is used. AT-type systems with 386 or higher processors have special capabilities that are not found in the first generation of 286-based ATs. The 386 and higher systems have distinct capabilities regarding memory addressing, memory management, and possible 32- or 64-bit wide access to data. Most systems with 386DX or higher chips also have 32-bit bus architectures to take full advantage of the 32-bit data transfer capabilities of the processor.

Most PC systems today incorporate 16-bit ISA slots for backward compatibility and lower function adapters, and PCI slots for truly high performance adapters. Most portable systems use PC-Card and Cardbus slots in the portable unit, and ISA and PCI slots in optional docking stations.

Chapter 4, “Motherboards and Buses,” contains a great deal of in-depth information on these and other PC system buses, including technical information such as pinouts, performance specifications, and bus operation and theory.

Table 2.3 summarizes the primary differences between the older 8-bit (PC/XT) systems and a modern AT system. This information distinguishes between these systems and includes all IBM and compatible models.

Table 2.3 Differences Between PC/XT and AT Systems

System Attributes	(8-bit) PC/XT Type	(16/32/64-bit) AT Type
Supported processors	All x86 or x88	286 or higher
Processor modes	Real	Real/ Protected/Virtual Real
Software supported	16-bit only	16- or 32-bit
Bus slot width	8-bit	16/32/64-bit
Slot type	ISA only	ISA, EISA, MCA, PC-Card, Cardbus, VL-Bus, PCI
Hardware interrupts	8 (6 usable)	16 (11 usable)
DMA channels	4 (3 usable)	8 (7 usable)
Maximum RAM	1MB	16MB/4GB or more
Floppy controller speed	250 Kbit/sec	250/300/500/1,000 Kbit/sec
Standard boot drive	360KB or 720KB	1.2MB/1.44MB/2.88MB
Keyboard interface	Unidirectional	Bidirectional
CMOS memory/clock	None standard	MC146818-compatible
Serial-port UART	8250B	16450/16550A

The easiest way to identify a PC/XT (8-bit) system is by the 8-bit ISA expansion slots. No matter what processor or other features the system has, if all the slots are 8-bit ISA, the system is a PC/XT. AT (16-bit plus) systems can be similarly identified—they have 16-bit or greater slots of any type. These can be ISA, EISA, MCA, PC-card (formerly PCMCIA), Cardbus, VL-Bus, or PCI. Using this information, you can properly categorize virtually any system as a PC/XT type or an AT type. There really have been no PC/XT type (8-bit) systems manufactured for many years. Unless you are in a computer museum, virtually every system you encounter today is based on the AT type design.

System Components

A modern PC is both simple and complicated. It is simple in the sense that over the years many of the components used to construct a system have become integrated with other components into fewer and fewer actual parts. It is complicated in the sense that each part in a modern system performs many more functions than did the same types of parts in older systems.

This section briefly examines all the components in a modern PC system. Each of these components is discussed further in later chapters.

Here are the components needed to assemble a basic modern PC system:

- Motherboard
- Processor
- Memory (RAM)

- Case (chassis)
- Power supply
- Floppy drive
- Hard disk
- CD-ROM, CD-R, or DVD-ROM drive
- Keyboard
- Mouse
- Video card
- Monitor (display)
- Sound card
- Speakers

Motherboard

The motherboard is the core of the system. It really is the PC—everything else is connected to it, and it controls everything in the system. Motherboards are available in several different shapes or form factors. The motherboard usually contains the following individual components:

- Processor socket (or slot)
- Processor voltage regulators
- Motherboard chipset
- Level 2 cache (normally found in the CPU today)
- Memory SIMM or DIMM sockets
- Bus slots
- ROM BIOS
- Clock/CMOS battery
- Super I/O chip

The chipset contains all the primary circuitry that makes up the motherboard; in essence, the chipset *is* the motherboard. The chipset controls the CPU or processor bus, the L2 cache and main memory, the PCI (Peripheral Component Interconnect) bus, the ISA (Industry Standard Architecture) bus, system resources, and more. If the processor represents the engine of your system, the chipset represents the chassis in which the engine is installed. As such, the chipset dictates the primary features and specifications of your motherboard, including what types of processors, memory, expansion cards, disk drives, and so on the system supports.

Note that most newer (Pentium Celeron/II/III class) systems include the L2 cache inside the processor rather than on the motherboard. In the newest and best designs, the L2 cache is actually a part of the processor die just like the L1 cache, whereas in others it is simply a separate chip (or chips) in the processor module.

The chipset plays a big role in determining what sorts of features a system can support. For example, which processors you can use, which types and how much memory you can install, what

speeds you can run the machine, and what types of system buses your system can support are all tied in to the motherboard chipset. The ROM BIOS contains the initial POST (Power-On Self Test) program, bootstrap loader (which loads the operating system), drivers for items that are built into the board (the actual BIOS code), and usually a system setup program (often called CMOS setup) for configuring the system. Motherboards are covered in detail in Chapter 4.

Processor

The processor is often thought of as the “engine” of the computer. Also called the CPU (Central Processing Unit), it is the single most important chip in the system because it is the primary circuit that carries out the program instructions of whatever software is being run. Modern processors contain literally millions of transistors, etched onto a tiny square of silicon called a die, which is about the size of your thumbnail. The processor has the distinction of being one of the most expensive parts of most computers, even though it is also one of the smallest parts. In most modern systems, the processor costs from two to ten times more than the motherboard it is plugged into.

Microprocessors are covered in detail in Chapter 3, “Microprocessor Types and Specifications.”

Memory (RAM)

The system memory is often called RAM (for Random Access Memory). This is the primary memory, which holds all the programs and data the processor is using at a given time. RAM requires power to maintain storage, so when you turn off the computer everything in RAM is cleared; when you turn it back on the memory must be reloaded with programs for the processor to run. The initial programs for the processor come from a special type of memory called ROM (Read Only Memory), which is not erased when the power to the system is turned off.

The ROM contains instructions to get the system to load or *boot* an operating system and other programs from one of the disk drives into the main RAM memory so that the system can run normally and perform useful work. Newer operating systems allow several programs to run at one time, with each program or data file that is loaded using some of the main memory. Generally, the more memory your system has, the more programs you can run simultaneously.

Memory is normally purchased and installed in a modern system in SIMM (Single Inline Memory Module) or DIMM (Dual Inline Memory Module) form. Formerly very expensive, memory prices have dropped recently, significantly reducing the cost of memory as compared to other parts of the system. Even so, the cost of the recommended amount of memory for a given system is usually equal or greater than that of the motherboard.

Memory is covered in detail in Chapter 6, “Memory.”

Case (Chassis)

The case is the frame or chassis that houses the motherboard, power supply, disk drives, adapter cards, and any other physical components in the system. There are several different styles of cases available, from small or slim versions that sit horizontally on a desktop to huge tower types that stand vertically on the floor, and even some that are designed to be rackmounted for industrial

use. In addition to the physical styles, different cases are designed to accept different form factor motherboards and power supplies. Some cases have features that make installing or removing components easy, such as a screwless design that requires no tools to disassemble, side open panels or trays that allow easy motherboard access, removable cages or brackets that give easy access to disk drives, and so on. Some cases include additional cooling fans for heavy duty systems, and some are even available with air filters that ensure that the interior will remain clean and dust free. Most cases include a power supply, but you can also purchase bare cases and power supplies separately.

The case is covered in detail in Chapter 21, “Power Supply and Chassis/Case.”

Power Supply

The power supply is what feeds electrical power to every single part in the PC. As such, it has a very important job, but it is one of the least glamorous parts of the system so it receives little attention. Unfortunately, this often means that it is one of the components that is most skimmed on when a system is constructed. The main function of the supply is to convert the 110v AC wall current into the 3.3v, 5v, or 12fv power that the system requires for operation.

The power supply is covered in detail in Chapter 21.

Floppy Disk Drive

The floppy drive is a simple, inexpensive, low capacity removable media magnetic storage device. For many years floppy disks were the primary medium for software distribution and system backup. However, with the advent of CD-ROM and DVD-ROM discs as the primary method of installing or loading new software in a system, and with inexpensive high capacity tape drives for backup, the floppy drive is not used very often in most modern systems, except perhaps by a system builder, installer, or technician. Because the floppy drive is the first device from which a PC attempts to boot, it is still the primary method that is used for loading initial operating systems’ startup software and core hardware diagnostics. Recent advancements in technology have created new types of floppy drives with up to 120MB or more of storage, making the drive much more usable for temporary backups or for moving files from system to system.

Floppy disk drives are covered in detail in Chapter 11, “Floppy Disk Storage.”

Hard Disk Drive

The hard disk is the primary archival storage memory for the system. It contains copies of all programs and data that are not currently active in main memory. A hard drive is so named because it consists of spinning platters of aluminum or ceramic that are coated with a magnetic medium. Hard drives can be created with many different storage capacities, depending on the density, size, and number of platters. Most desktop systems today use drives with 3 1/2-inch platters, whereas most laptop or notebook computers use 2 1/2-inch platter drives.

Hard disk drives are also covered in detail in Chapter 10, “Hard Disk Storage.”

CD-ROM Drive

CD- (Compact Disc) and DVD- (Digital Versatile Disc) ROM (Read Only Memory) drives are relatively high capacity removable media optical drives. They are primarily a read-only medium, which means the drives can only read information, and the data on the discs cannot be altered or rewritten. There are writable or rewritable versions of the discs and drives available, but they are much more expensive than their read-only counterparts, and therefore are not included standard in most PCs. CD-ROM and DVD-ROM are the most popular media for distributing software or large amounts of data because they are very inexpensive when produced in quantity and they can hold a great deal of information.

CD-ROM drives are covered in detail in Chapter 13, "Optical Storage."

Keyboard

The keyboard is the primary device on a PC that is used by a human being to communicate with and control a system. Keyboards are available in a large number of different languages, layouts, sizes, shapes, and with numerous special features or characteristics. One of the best features of the PC as designed by IBM is that it was one of the first personal computers to use a detached keyboard. Most systems prior to the PC had the keyboard as an integral part of the system chassis, which severely limited flexibility. Because the PC uses a detached keyboard with a standardized connector and signal design, in most cases it is possible to connect any PC compatible keyboard you want to your system, which gives you the freedom to choose the one that suits you best.

Keyboards are covered in detail in Chapter 17, "Input Devices."

Mouse

With the advent of computer operating systems that used a Graphical User Interface (GUI), it became necessary to have a device that enabled a user to point at or select items that were shown on the screen. Although there are many different types of pointing devices on the market today, the first and most popular device for this purpose is the mouse. By moving the mouse across a desk or tabletop, a corresponding pointer can be moved across the computer screen, allowing items to be more easily selected or manipulated than they can with a keyboard alone. Standard mice, as used on PCs, have two buttons: one for selecting items under the pointer, and the other for activating menus. Mice are also available with a third button, a wheel, or a stick, which can be used to scroll the display or for other special functions.

The mouse is covered in detail in Chapter 17.

Video Card

The video card controls the information you see on the monitor. All video cards have four basic parts: a video chip or chipset, Video RAM, a DAC (Digital to Analog Converter), and a BIOS. The video chip actually controls the information on the screen by writing data to the video RAM. The DAC reads the video RAM and converts the digital data there into analog signals to drive the

monitor. The BIOS holds the primary video driver that allows the display to function during boot time and at a DOS prompt in basic text mode. More enhanced drivers are then usually loaded from disk to enable advanced video modes for Windows or applications software.

Video cards are covered in detail in Chapter 15, "Video Hardware."

Monitor (Display)

In most systems, the monitor is housed in its own protective case, separate from the system case and chassis. In portable systems and some low-cost PCs, however, the monitor is built into the system case. Monitors are generally classified by three major criteria: diagonal size in inches, resolution in pixels, and refresh rate in hertz (Hz). Desktop monitors usually range from 14" to 21" diagonal measure (although as you will see in Chapter 8, "The SCSI Interface," the actual viewable area is smaller than the advertised measure). LCD monitors in portable systems range from 11" to 14". Resolution ranges from 640×480 pixels (horizontal measurement first, and then vertical) to 1600×1200 pixels. Each pixel in the monitor is made up of a trio of dots, one each for the colors red, blue, and green. An average monitor is capable of refreshing 60 times per second (60Hz), whereas higher quality monitors might refresh at 100Hz. The refresh rate measures how often the display of the screen is redrawn from the contents of the video adapter memory. Both the resolution and refresh rate of the monitor are tied to the capability of the system video adapter. Most monitors are capable of supporting several different resolutions and refresh rates (with the common exception of LCD screens in portables).

Monitors are covered in detail in Chapter 15.

Microprocessor Types and Specifications

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Processor Specifications
SSE (Streaming SIMD Extensions)
Dual Independent Bus (DIB) Architecture
Processor Manufacturing
PGA Chip Packaging
Single Edge Contact (SEC) and Single Edge Processor (SEP) Packaging
Processor Sockets
Processor Slots
CPU Operating Voltages
Heat and Cooling Problems
Intel-Compatible Processors (AMD and Cyrix)
P1 (086) First-Generation Processors
P2 (286) Second-Generation Processors
P3 (386) Third-Generation Processors
P4 (486) Fourth-Generation Processors
P5 (586) Fifth-Generation Processors
Intel P6 (686) Sixth-Generation Processors
P7 (786) Seventh-Generation Processors
Processor Troubleshooting Techniques

Microprocessors

The brain or engine of the PC is the processor (sometimes called microprocessor), or Central Processing Unit (CPU). The CPU performs the system's calculating and processing. The processor is easily the most expensive single component in the system, costing up to four or more times greater than the motherboard it plugs into. Intel is generally credited with creating the first microprocessor in 1971 with the introduction of a chip called the 4004. Today they have almost total control over the processor market, at least for PC systems. This means that all PC-compatible systems use either Intel processors or Intel-compatible processors from a handful of competitors (such as AMD or Cyrix).

Intel's dominance in the processor market had not always been assured. Although they are generally credited with inventing the processor and introducing the first one on the market, by the late 70s the two most popular processors for PCs were *not* from Intel (although one was a clone of an Intel processor). Personal computers of that time primarily used the Z-80 by Zilog and the 6502 by MOS Technologies. The Z-80 was noted for being an improved and less expensive clone of the Intel 8080 processor, similar to the way companies today such as AMD, Cyrix, IDT, and Rise Technologies have cloned Intel's Pentium processors.

Back then I had a system containing both of those processors, consisting of a 1MHz (yes, that's one as in 1MHz!) 6502-based Apple main system with a Microsoft Softcard (Z-80 card) plugged into one of the slots. The Softcard contained a 2MHz Z-80 processor. This allowed me to run software for both types of processors on the one system. The Z-80 was used in systems of the late 70s and early 80s that ran the CP/M operating system, while the 6502 was best known for its use in the early Apple computers (before the Mac).

The fate of both Intel and Microsoft were dramatically changed in 1981 when IBM introduced the IBM PC, which was based on a 4.77MHz Intel 8088 processor running the Microsoft Disk Operating System (DOS) 1.0. Since that fateful decision was made, PC-compatible systems have used a string of Intel or Intel compatible processors, each new one capable of running the software of the processor before it, from the 8088 to the current Pentium III. The following sections cover the different types of processor chips that have been used in personal computers since the first PC was introduced almost two decades ago. These sections provide a great deal of technical detail about these chips and explain why one type of CPU chip can do more work than another in a given period of time.

Pre-PC Microprocessor History

It is interesting to note that the microprocessor had only existed for 10 years prior to the creation of the PC! The microprocessor was invented by Intel in 1971. The PC was created by IBM in 1981. Now nearly 20 years later, we are still using systems based on the design of that first PC (and mostly backward compatible with it). The processors powering our PCs today are still backward compatible with the one selected by IBM in 1981.

The story of the development of the first microprocessor, the Intel 4004, can be read in Chapter 1, “Personal Computer Background.” The 4004 processor was introduced on November 15, 1971, and originally ran at a clock speed of 108KHz (108,000 cycles per second, or 0.108MHz). The 4004 contained 2,300 transistors and was built on a 10 micron process. This means that each line, trace, or transistor could be spaced about 10 microns (millionths of a meter) apart. Data was transferred four bits at a time, and the maximum addressable memory was only 640 bytes. The 4004 was designed for use in a calculator, but proved to be useful for many other functions because of its inherent programmability.

In April 1972, Intel released the 8008 processor, which originally ran at a clock speed of 200KHz (0.2MHz). The 8008 processor contained 3,500 transistors and was built on the same 10 micron process as the previous processor. The big change in the 8008 was that it had an 8-bit data bus, which meant it could move data 8 bits at a time—twice as much as the previous chip. It could also address more memory, up to 16KB. This chip was primarily used in dumb terminals and general-purpose calculators.

The next chip in the lineup was the 8080, introduced in April 1974, running at a clock rate of 2MHz. Due mostly to the faster clock rate, the 8080 processor had 10 times the performance of the 8008. The 8080 chip contained 6,000 transistors and was built on a 6 micron process. Like the previous chip, the 8080 had an 8-bit data bus, so it could transfer 8 bits of data at a time. The 8080 could address up to 64KB of memory, significantly more than the previous chip.

It was the 8080 that helped start the PC revolution, as this was the processor chip used in what is generally regarded as the first personal computer, the Altair 8800. The CP/M operating system was written for the 8080 chip, and Microsoft was founded and delivered their first product: Microsoft BASIC for the Altair. These initial tools provided the foundation for a revolution in software because thousands of programs were written to run on this platform.

In fact, the 8080 became so popular that it was cloned. A company called Zilog formed in late 1975, joined by several ex-Intel 8080 engineers. In July of 1976, they released the Z-80 processor, which was a vastly improved version of the 8080. It was not pin compatible, but instead combined functions such as the memory interface and RAM refresh circuitry, which allowed cheaper and simpler systems to be designed. The Z-80 also incorporated a superset of 8080 instructions, meaning it could run all 8080 programs. It also included new instructions and new internal registers, so software that was designed for the Z-80 would not necessarily run on the older 8080. The Z-80 ran initially at 2.5MHz (later versions ran up to 10MHz), and contained 8,500 transistors. The Z-80 could access 64KB of memory.

Radio Shack selected the Z-80 for the TRS-80 Model 1, their first PC. The chip was also the first to be used by many pioneering systems including the Osborne and Kaypro machines. Other companies followed suit, and soon the Z-80 was the standard processor for systems running the CP/M operating system and the popular software of the day.

Intel released the 8085, their follow up to the 8080, in March of 1976. Even though it pre-dated the Z-80 by several months, it never achieved the popularity of the Z-80 in personal computer systems. It was popular as an embedded controller, finding use in scales and other computerized equipment. The 8085 ran at 5MHz and contained 6,500 transistors. It was built on a 3 micron process and incorporated an 8-bit data bus.

Along different architectural lines, MOS Technologies introduced the 6502 in 1976. This chip was designed by several ex-Motorola engineers who had worked on Motorola's first processor, the 6800. The 6502 was an 8-bit processor like the 8080, but it sold for around \$25, whereas the 8080 cost about \$300 when it was introduced. The price appealed to Steve Wozniak who placed the chip in his Apple I and Apple II designs. The chip was also used in systems by Commodore and other system manufacturers. The 6502 and its successors were also used in computer games, including the original Nintendo Entertainment System (NES) among others. Motorola went on to create the 68000 series, which became the basis for the Apple Macintosh line of computers. Today those systems use the PowerPC chip, also by Motorola, and a successor to the original 68000 series.

All these previous chips set the stage for the first PC chips. Intel introduced the 8086 in June 1978. The 8086 chip brought with it the original x86 instruction set that is still present on x86-compatible chips such as the Pentium III. A dramatic improvement over the previous chips, the 8086 was a full 16-bit design with 16-bit internal registers and a 16-bit data bus. This meant that it could work on 16-bit numbers and data internally and also transfer 16-bits at a time in and out of the chip. The 8086 contained 29,000 transistors and initially ran at up to 5MHz. The chip also used 20-bit addressing, meaning it could directly address up to 1MB of memory. Although not directly backward compatible with the 8080, the 8086 instructions and language was very similar and allowed older programs to be ported over quickly to run. This later proved important to help jumpstart the PC software revolution with recycled CP/M (8080) software.

Although the 8086 was a great chip, it was expensive at the time and more importantly required an expensive 16-bit support chips and board design. To help bring costs down, in 1979, Intel released a crippled version of the 8086 called the 8088. The 8088 processor used the same internal core as the 8086, had the same 16-bit registers, and could address the same 1MB of memory, but the external data bus was reduced to 8 bits. This allowed support chips from the older 8-bit 8085 to be used, and far less expensive boards and systems could be made. It is for these reasons that IBM chose the crippled chip, the 8088, for the first PC.

This decision would affect history in several ways. The 8088 was fully software compatible with the 8086, so it could run 16-bit software. Also, because the instruction set was very similar to the previous 8085 and 8080, programs written for those older chips could be quickly and easily modified to run. This allowed a large library of programs to be quickly released for the IBM PC, thus helping it become a success. The overwhelming blockbuster success of the IBM PC left in its wake

the legacy of requiring backward compatibility with it. In order to maintain the momentum, Intel has pretty much been forced to maintain backward compatibility with the 8088/8086 in most of the processors they have released since then.

In some ways the success of the PC, and the Intel architecture it contains, has limited the growth of the personal computer. In other ways, however, its success has caused a huge number of programs, peripherals, and accessories to be developed, and the PC to become a de facto standard in the industry. The original 8088 processor used in the first PC contained close to 30,000 transistors and ran at less than 5MHz. The most recent processors from Intel contain close to 30 million transistors and run at over 500MHz. Intel has already demonstrated processors running at 1GHz. According to Moore's Law, these will be commonplace in only a few years, along with transistor counts in the hundreds of millions.

Processor Specifications

Many confusing specifications often are quoted in discussions of processors. The following sections discuss some of these specifications, including the data bus, address bus, and speed. The next section includes a table that lists the specifications of virtually all PC processors.

Processors can be identified by two main parameters: how wide they are and how fast they are. The speed of a processor is a fairly simple concept. Speed is counted in megahertz (MHz), which means millions of cycles per second—and faster is better! The width of a processor is a little more complicated to discuss because there are three main specifications in a processor that are expressed in width. They are

- Data input and output bus
- Internal registers
- Memory address bus

Table 3.1 lists the primary specifications for the Intel family of processors used in IBM and compatible PCs. Table 3.2 lists the Intel compatible processors from AMD, Cyrix, Nexgen, IDT, and Rise. The following sections explain these specifications in detail.

Note that most Pentium II and III processors include 512KB of 1/2-core speed L2 cache on the processor card, while the Xeon includes 512KB, 1MB, or 2MB of full-core speed L2 cache. The Celeron and Pentium II PE processors, as well as the K6-3 from AMD, all include on-die L2 cache, which runs at the full core speed of the processor. Most all future processors will contain the L2 cache directly in the CPU die and run it at full core speed.

The transistor count figures do not include the standard 256KB or 512KB L2 cache built in to the Pentium Pro and Pentium II CPU packages. The L2 cache contains an additional 15.5 (256KB), 31 (512KB), or optionally 62 million (1MB) transistors!

Table 3.1 Intel Processor Specifications

Processor	CPU Clock	Voltage	Internal Register Size	Data Bus Width	Max. Memory	L1 Cache
8088	1x	5v	16-bit	8-bit	1MB	-
8086	1x	5v	16-bit	16-bit	1MB	-

3DNow = MMX plus 21 additional instructions for graphics and sound processing

SSE = Streaming SIMD (Single Instruction Multiple Data) Extensions, MMX plus 70 additional instructions for graphics and sound processing

¹ The 386SL contains an integral-cache controller, but the cache memory must be provided outside the chip.

² Intel later marketed SL Enhanced versions of the SX, DX, and DX2 processors. These processors were available in both 5v and 3.3v versions and included power-management capabilities.

³ The Enhanced mobile PII has on-die L2 cache similar to the Celeron.

Note

Note in Table 3.1, that the Pentium Pro processor includes 256KB, 512KB, or 1MB of full core speed L2 cache in a separate die within the chip. The Pentium II/III processors include 512KB of 1/2 core speed L2 cache on the processor card. The Celeron and Pentium II PE processors include full core speed L2 cache integrated directly within the processor die.

The transistor count figures do not include the external (off-die) 256KB, 512KB, 1MB, or 2MB L2 cache built in to the Pentium Pro and Pentium II/III or Xeon CPU packages. The external L2 cache contains an additional 15.5 (256KB), 31 (512KB), 62 million (1MB), or 124 million (2MB) transistors!

Processor Speed Ratings

A common misunderstanding about processors is their different speed ratings. This section covers processor speed in general, and then provides more specific information about Intel processors.

A computer system's clock speed is measured as a frequency, usually expressed as a number of cycles per second. A crystal oscillator controls clock speeds using a sliver of quartz sometimes contained in what looks like a small tin container. Newer systems include the oscillator circuitry in the motherboard chipset, so it might not be a visible separate component on newer boards. As voltage is applied to the quartz, it begins to vibrate (oscillate) at a harmonic rate dictated by the shape and size of the crystal (sliver). The oscillations emanate from the crystal in the form of a current that alternates at the harmonic rate of the crystal. This alternating current is the clock signal that forms the time base on which the computer operates. A typical computer system runs millions of these cycles per second, so speed is measured in megahertz. (One hertz is equal to one cycle per second.) An alternating current signal is like a sine wave, with the time between the peaks of each wave defining the frequency (see Figure 3.1).

Figure 3.1 Alternating current signal showing clock cycle timing.

Note

The hertz was named for the German physicist Heinrich Rudolf Hertz. In 1885, Hertz confirmed the electromagnetic theory, which states that light is a form of electromagnetic radiation and is propagated as waves.

A single cycle is the smallest element of time for the processor. Every action requires at least one cycle and usually multiple cycles. To transfer data to and from memory, for example, a modern processor such as the Pentium II needs a minimum of three cycles to set up the first memory transfer, and then only a single cycle per transfer for the next three to six consecutive transfers. The extra cycles on the first transfer are normally called *wait states*. A wait state is a clock tick in which nothing happens. This ensures that the processor isn't getting ahead of the rest of the computer.

►► See "SIMMs and DIMMs," p. 437.

The time required to execute instructions also varies:

- *8086 and 8088*. The original 8086 and 8088 processors take an average of 12 cycles to execute a single instruction.
- *286 and 386*. The 286 and 386 processors improve this rate to about 4.5 cycles per instruction.
- *486*. The 486 and most other fourth generation Intel compatible processors such as the AMD 5x86 drop the rate further, to about two cycles per instruction.
- *Pentium*. The Pentium architecture and other fifth generation Intel compatible processors such as those from AMD and Cyrix include twin instruction pipelines and other improvements that provide for operation at one or two instructions per cycle.
- *Pentium Pro, Pentium II/III, Celeron and Xeon*. These Intel P6 class processors, as well as other sixth generation processors such as those from AMD and Cyrix, can execute as many as three or more instructions per cycle.

Different instruction execution times (in cycles) make it difficult to compare systems based purely on clock speed, or number of cycles per second. How can two processors that run at the same clock rate perform differently with one running "faster" than the other? The answer is simple: efficiency.

The main reason why the 486 was considered fast relative to a 386 is that it executes twice as many instructions in the same number of cycles. The same thing is true for a Pentium; it executes about twice as many instructions in a given number of cycles as a 486. This means that given the same clock speed, a Pentium will be twice as fast as a 486, and consequently a 133MHz 486 class processor (such as the AMD 5x86-133) is not even as fast as a 75MHz Pentium! That is because Pentium megahertz are "worth" about double what 486 megahertz are worth in terms of instructions completed per cycle. The Pentium II and III are about 50 percent faster than an equivalent Pentium at a given clock speed because they can execute about that many more instructions in the same number of cycles.

Comparing relative processor performance, you can see that a 600MHz Pentium III is about equal to a (theoretical) 900MHz Pentium, which is about equal to an 1,800MHz 486, which is about equal to a 3,600MHz 386 or 286, which is about equal to a 7,200MHz 8088. The original PCs' 8088 ran at only 4.77MHz; today, we have systems that are comparatively about 1,500 times faster. As you can see, you have to be careful in comparing systems based on pure MHz alone, because many other factors affect system performance.

Evaluating CPU performance can be tricky. CPUs with different internal architectures do things differently and may be relatively faster at certain things and slower at others. To fairly compare different CPUs at different clock speeds, Intel has devised a specific series of benchmarks called the iCOMP (Intel Comparative Microprocessor Performance) index that can be run against processors to produce a relative gauge of performance. The iCOMP index benchmark has been updated twice and released in original iCOMP, iCOMP 2.0, and now iCOMP 3.0 versions.

Table 3.3 shows the relative power, or iCOMP 2.0 index, for several processors.

Table 3.3 Intel iCOMP 2.0 Index Ratings

Processor	iCOMP 2.0 Index	Processor	iCOMP 2.0 Index
Pentium 75	67	Pentium Pro 200	220
Pentium 100	90	Celeron 300	226
Pentium 120	100	Pentium II 233	267
Pentium 133	111	Celeron 300A	296
Pentium 150	114	Pentium II 266	303
Pentium 166	127	Celeron 333	318
Pentium 200	142	Pentium II 300	332
Pentium-MMX 166	160	Pentium II Overdrive 300	351
Pentium Pro 150	168	Pentium II 333	366
Pentium-MMX 200	182	Pentium II 350	386
Pentium Pro 180	197	Pentium II Overdrive 333	387
Pentium-MMX 233	203	Pentium II 400	440
Celeron 266	213	Pentium II 450	483

The iCOMP 2.0 index is derived from several independent benchmarks and is a stable indication of relative processor performance. The benchmarks balance integer with floating point and multimedia performance.

Recently Intel discontinued the iCOMP 2.0 index and released the iCOMP 3.0 index. iCOMP 3.0 is an updated benchmark that incorporates an increasing use of 3D, multimedia, and Internet technology and software, as well as the increasing use of rich data streams and compute-intensive applications, including 3D, multimedia, and Internet technology. iCOMP 3.0 combines six benchmarks: WinTune 98 Advanced CPU Integer test, CPUmark 99, 3D WinBench 99-3D Lighting and Transformation Test, MultimediaMark 99, Jmark 2.0 Processor Test, and WinBench 99-FPU WinMark. These newer benchmarks take advantage of the SSE (Streaming SIMD Extensions), additional graphics and sound instructions built in to the PIII. Without taking advantage of these new instructions, the PIII would benchmark at about the same speed as a PII at the same clock rate.

The following table shows the iCOMP Index 3.0 ratings for newer Intel processors.

Processor	iCOMP 3.0 Index
Pentium II 450MHz	1240
Pentium III 450MHz	1500
Pentium III 500MHz	1650
Pentium III 550MHz	1780

Considerations When Interpreting iCOMP Scores

Each processor's rating is calculated at the time the processor is introduced, using a particular, well-configured, commercially available system. Relative iCOMP Index 3.0 scores and actual system performance might be affected by future changes in software design and configuration. Relative scores and actual system performance also may be affected by differences in components or characteristics of microprocessors such as L2 cache, bus speed, extended multimedia or graphics instructions, or improvements in the microprocessor manufacturing process.

Differences in hardware components other than microprocessors used in the test systems also can affect how iCOMP scores relate to actual system performance. iCOMP 3.0 ratings cannot be compared with earlier versions of the iCOMP index because different benchmarks and weightings are used in calculating the result.

Processor Speeds and Markings Versus Motherboard Speed

Another confusing factor when comparing processor performance is that virtually all modern processors since the 486DX2 run at some multiple of the motherboard speed. For example, a Celeron 466 runs at a multiple of seven times the motherboard speed of 66MHz, while a Pentium III 550 runs at five and a half times the motherboard speed of 100MHz. Up until early 1998, most motherboards ran at 66MHz or less because that is all Intel supported with their processors until then. Starting in April 1998, Intel released both processors and motherboard chipsets designed to run at 100MHz. Cyrix has a few processors designed to run on 75MHz motherboards, and many Pentium motherboards are capable of running that speed as well, although technically Intel never supported it. AMD also has versions of the K6-2 designed to run at motherboard speeds of 100MHz.

By late 1999, motherboards running at 133MHz should be available, which is the next step in board speed.

Normally, you can set the motherboard speed and multiplier setting via jumpers or other configuration mechanism (such as CMOS setup) on the motherboard.

Modern systems use a variable-frequency synthesizer circuit usually found in the main motherboard chipset to control the motherboard and CPU speed. Most Pentium motherboards will have three or four speed settings. The processors used today are available in a variety of versions that run at different frequencies based on a given motherboard speed. For example, most of the Pentium chips run at a speed that is some multiple of the true motherboard speed. For example, Pentium processors and motherboards run at the speeds shown in Table 3.4.

For information on specific AMD or Cyrix processors, see their respective sections later in this chapter.

Table 3.4 Intel Processor and Motherboard Speeds

CPU Type	CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)
Pentium	60	1x	60
Pentium	66	1x	66
Pentium	75	1.5x	50
Pentium	90	1.5x	60
Pentium	100	1.5x	66
Pentium	120	2x	60
Pentium	133	2x	66
Pentium	150	2.5x	60
Pentium/Pentium Pro	166	2.5x	66
Pentium/Pentium Pro	180	3x	60
Pentium/Pentium Pro	200	3x	66
Pentium/Pentium II	233	3.5x	66
Pentium(Mobile)/Pentium-II/Celeron	266	4x	66
Pentium II/Celeron	300	4.5x	66
Pentium II/Celeron	333	5x	66
Pentium II/Celeron	366	5.5x	66
Pentium Celeron	400	6x	66
Pentium Celeron	433	6.5x	66
Pentium Celeron	466	7x	66
Pentium Celeron	500	7.5x	66
Pentium II	350	3.5x	100
Pentium II/Xeon	400	4x	100
Pentium II/III/Xeon	450	4.5x	100
Pentium III/Xeon	500	5x	100
Pentium III/Xeon	533	4x	133
Pentium III/Xeon	550	5.5x	100
Pentium III/Xeon	600	4.5x	133

If all other variables are equal—including the type of processor, the number of wait states (empty cycles) added to different types of memory accesses, and the width of the data bus—you can compare two systems by their respective clock rates. However, the construction and design of the memory controller (contained in the motherboard chipset) as well as the type and amount of memory installed can have an enormous effect on a system's final execution speed.

In building a processor, a manufacturer tests it at different speeds, temperatures, and pressures. After the processor is tested, it receives a stamp indicating the maximum safe speed at which the

unit will operate under the wide variation of temperatures and pressures encountered in normal operation. The rating system usually is simple. For example, the top of the processor in one of my systems is marked like this:

A80486DX2-66

The A is Intel's indicator that this chip has a Ceramic Pin Grid Array form factor, or an indication of the physical packaging of the chip.

The 80486DX2 is the part number, which identifies this processor as a clock-doubled 486DX processor.

The -66 at the end indicates that this chip is rated to run at a maximum speed of 66MHz. Because of the clock doubling, the maximum motherboard speed is 33MHz. This chip would be acceptable for any application in which the chip runs at 66MHz or slower. For example, you could use this processor in a system with a 25MHz motherboard, in which case the processor would happily run at 50MHz.

Most 486 motherboards also had a 40MHz setting, in which case the DX2 would run at 80MHz internally. Because this is 14MHz beyond its rated speed, many would not work; or if it worked at all, it would be only for a short time. On the other hand, I have found that most of the newer chips marked with -66 ratings seem to run fine (albeit somewhat hotter) at the 40/80MHz settings. This is called overlocking and can end up being a simple, cost-effective way to speed up your system. However, I would not recommend this for mission-critical applications where the system reliability is of the utmost importance; a system pushed beyond specification like this can often exhibit erratic behavior under stress.

Note

One good source of online overlocking information is located at <http://www.sysopt.com>. It includes, among other things, fairly thorough overlocking FAQs and an ongoing survey of users who have successfully (and sometimes unsuccessfully) overlocked their CPUs. Note that many of the newer Intel processors incorporate fixed bus multipliers, which effectively prevent or certainly reduce the ability to overlock. Unfortunately this can be overridden with a simple hardware fix, and many counterfeit processor vendors are selling remarked (overlocked) chips.

Sometimes, however, the markings don't seem to indicate the speed directly. In the older 8086, for example, -3 translates to 6MHz operation. This marking scheme is more common in some of the older chips, which were manufactured before some of the marking standards used today were standardized.

The Processor Heat Sink Might Hide the Rating

Most processors have heat sinks on top of them, which can prevent you from reading the rating printed on the chip.

A *heat sink* is a metal device that draws heat away from an electronic device. Most processors running at 50MHz and faster should have a heat sink installed to prevent the processor from overheating.

Fortunately, most CPU manufacturers are placing marks on the top and bottom of the processor. If the heat sink is difficult to remove from the chip, you can take the heat sink and chip out of the socket together and read the markings on the bottom of the processor to determine what you have.

Cyrix P-Ratings

Cyrix/IBM 6x86 processors use a PR (Performance Rating) scale that is not equal to the true clock speed in megahertz. For example, the Cyrix 6x86MX/MII-PR366 actually runs at only 250MHz ($2.5 \times 100\text{MHz}$). This is a little misleading—you must set up the motherboard as if a 250MHz processor were being installed, not the 366MHz you might suspect. Unfortunately this leads people to believe these systems are faster than they really are. Table 3.5 shows the relationship between the Cyrix 6x86, 6x86MX, and M-II P-Ratings versus the actual chip speeds in MHz.

Table 3.5 Cyrix P-Ratings Versus Actual Chip Speeds in MHz

Cyrix CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)
6x86	PR90	80	2x	40
6x86	PR120	100	2x	50
6x86	PR133	110	2x	55
6x86	PR150	120	2x	60
6x86	PR166	133	2x	66
6x86	PR200	150	2x	75
6x86MX	PR133	100	2x	50
6x86MX	PR133	110	2x	55
6x86MX	PR150	120	2x	60
6x86MX	PR150	125	2.5x	50
6x86MX	PR166	133	2x	66
6x86MX	PR166	137.5	2.5x	55
6x86MX	PR166	150	3x	50
6x86MX	PR166	150	2.5x	60
6x86MX	PR200	150	2x	75
6x86MX	PR200	165	3x	55
6x86MX	PR200	166	2.5x	66
6x86MX	PR200	180	3x	60
6x86MX	PR233	166	2x	83
6x86MX	PR233	187.5	2.5x	75
6x86MX	PR233	200	3x	66
6x86MX	PR266	207.5	2.5x	83
6x86MX	PR266	225	3x	75
6x86MX	PR266	233	3.5x	66
M-II	PR300	225	3x	75
M-II	PR300	233	3.5x	66
M-II	PR333	250	3x	83
M-II	PR366	250	2.5x	100

Note that a given P-Rating can mean several different actual CPU speeds, for example a Cyrix 6x86MX-PR200 might actually be running at 150MHz, 165MHz, 166MHz, or 180MHz, but *not* at 200MHz.

This P-Rating was supposed to indicate speed in relation to an Intel Pentium processor, but the processor they are comparing to is the original non-MMX, small L1 cache version running on an older motherboard platform with an older chipset and slower technology memory. The P-Rating does not compare well against the Celeron, Pentium II, or Pentium III processors. In that case these chips are more comparative at their true speed. In other words, the MII-PR366 really runs at only 250MHz, and compares well against Intel processors running at closer to that speed. I consider calling a chip an MII-366 when it really runs at only 250MHz very misleading, to say the least.

AMD P-Ratings

Although both AMD and Cyrix concocted this misleading P-Rating system, AMD thankfully only used it for a short time and only on the older K5 processor. They still have the PR designation stamped on their newer chips, but all K6 processors have PR numbers that match their actual CPU speed in MHz. Table 3.6 shows the P-Rating and actual speeds of the AMD K5 and K6 processors.

Table 3.6 AMD P-Ratings Versus Actual Chip Speeds in MHz

Cyrix CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)
K5	PR75	75	1.5x	50
K5	PR90	90	1.5x	60
K5	PR100	100	1.5x	66
K5	PR120	90	1.5x	60
K5	PR133	100	1.5x	66
K5	PR166	116.7	1.75x	66
K6	PR166	166	2.5x	66
K6	PR200	200	3x	66
K6	PR233	233	3.5x	66
K6	PR266	266	4x	66
K6	PR300	300	4.5x	66
K6-2	PR233	233	3.5x	66
K6-2	PR266	266	4x	66
K6-2	PR300	300	4.5x	66
K6-2	PR300	300	3x	100
K6-2	PR333	333	5x	66
K6-2	PR333	333	3.5x	95
K6-2	PR350	350	3.5x	100
K6-2	PR366	366	5.5x	66
K6-2	PR380	380	4x	95
K6-2	PR400	400	4x	100
K6-2	PR450	450	4.5x	100
K6-2	PR475	475	5x	95
K6-3	PR400	400	4x	100
K6-3	PR450	450	4.5x	100

Data Bus

Perhaps the most common ways to describe a processor is by the speed at which it runs and the width of the processor's external data bus. This defines the number of data bits that can be moved into or out of the processor in one cycle. A *bus* is a series of connections that carry common signals. Imagine running a pair of wires from one end of a building to another. If you connect a 110v AC power generator to the two wires at any point and place outlets at convenient locations along the wires, you have constructed a power bus. No matter which outlet you plug the wires into, you have access to the same signal, which in this example is 110v AC power. Any transmission medium that has more than one outlet at each end can be called a bus. A typical computer system has several internal and external buses.

The processor bus discussed most often is the external data bus—the bundle of wires (or pins) used to send and receive data. The more signals that can be sent at the same time, the more data can be transmitted in a specified interval and, therefore, the faster (and wider) the bus. A wider data bus is like having a highway with more lanes, which allows for greater throughput.

Data in a computer is sent as digital information consisting of a time interval in which a single wire carries 5v to signal a 1 data bit, or 0v to signal a 0 data bit. The more wires you have, the more individual bits you can send in the same time interval. A chip such as the 286 or 386SX, which has 16 wires for transmitting and receiving such data, has a 16-bit data bus. A 32-bit chip, such as the 386DX and 486, has twice as many wires dedicated to simultaneous data transmission as a 16-bit chip; a 32-bit chip can send twice as much information in the same time interval as a 16-bit chip. Modern processors such as the Pentium series have 64-bit external data buses. This means that Pentium processors including the original Pentium, Pentium Pro, and Pentium II can all transfer 64 bits of data at a time to and from the system memory.

A good way to understand this flow of information is to consider a highway and the traffic it carries. If a highway has only one lane for each direction of travel, only one car at a time can move in a certain direction. If you want to increase traffic flow, you can add another lane so that twice as many cars pass in a specified time. You can think of an 8-bit chip as being a single-lane highway because one byte flows through at a time. (One byte equals eight individual bits.) The 16-bit chip, with two bytes flowing at a time, resembles a two-lane highway. You may have four lanes in each direction to move a large number of automobiles; this structure corresponds to a 32-bit data bus, which has the capability to move four bytes of information at a time. Taking this further, a 64-bit data bus is like having an 8-lane highway moving data in and out of the chip!

Just as you can describe a highway by its lane width, you can describe a chip by the width of its data bus. When you read an advertisement that describes a 32-bit or 64-bit computer system, the ad usually refers to the CPU's data bus. This number provides a rough idea of the chip's performance potential (and, therefore, the system).

Perhaps the most important ramification of the data bus in a chip is that the width of the data bus also defines the size of a bank of memory. This means that a 32-bit processor, such as the 486 class chips, reads and writes memory 32 bits at a time. Pentium class processors, including the Pentium II, read and write memory 64 bits at a time. Because standard 72-pin SIMMs (Single

Inline Memory Modules) are only 32 bits wide, they must be installed one at a time in most 486 class systems; they're installed two at a time in most Pentium class systems. Newer DIMMs (Dual Inline Memory Modules) are 64 bits wide, so they are installed one at a time in Pentium class systems. Each DIMM is equal to a complete bank of memory in Pentium systems, which makes system configuration easy, because they can then be installed or removed one at a time.

▶▶ See "Memory Banks," p. 451.

Internal Registers (Internal Data Bus)

The size of the internal registers indicate how much information the processor can operate on at one time and how it moves data around internally within the chip. This is sometimes also referred to as the internal data bus. The register size is essentially the same as the internal data bus size. A register is a holding cell within the processor; for example, the processor can add numbers in two different registers, storing the result in a third register. The register size determines the size of data the processor can operate on. The register size also describes the type of software or commands and instructions a chip can run. That is, processors with 32-bit internal registers can run 32-bit instructions that are processing 32-bit chunks of data, but processors with 16-bit registers cannot. Most advanced processors today—chips from the 386 to the Pentium II—use 32-bit internal registers and can therefore run the same 32-bit operating systems and software.

Some processors have an internal data bus (made up of data paths and storage units called registers) that is larger than the external data bus. The 8088 and 386SX are examples of this structure. Each chip has an internal data bus twice the width of the external bus. These designs, which sometimes are called hybrid designs, usually are low-cost versions of a "pure" chip. The 386SX, for example, can pass data around internally with a full 32-bit register size; for communications with the outside world, however, the chip is restricted to a 16-bit-wide data path. This design enables a systems designer to build a lower-cost motherboard with a 16-bit bus design and still maintain software and instruction set compatibility with the full 32-bit 386.

Internal registers often are larger than the data bus, which means that the chip requires two cycles to fill a register before the register can be operated on. For example, both the 386SX and 386DX have internal 32-bit registers, but the 386SX has to "inhale" twice (figuratively) to fill them, whereas the 386DX can do the job in one "breath." The same thing would happen when the data is passed from the registers back out to the system bus.

The Pentium is an example of this type of design. All Pentiums have a 64-bit data bus and 32-bit registers—a structure that might seem to be a problem until you understand that the Pentium has two internal 32-bit pipelines for processing information. In many ways, the Pentium is like two 32-bit chips in one. The 64-bit data bus provides for very efficient filling of these multiple registers. Multiple pipelines are called *superscalar* architecture, which was introduced with the Pentium processor.

▶▶ See "Pentium Processors," p. 129.

More advanced sixth-generation processors such as the Pentium Pro and Pentium II/III have as many as six internal pipelines for executing instructions. Although some of these internal pipes are dedicated to special functions, these processors can still execute as many as three instructions in one clock cycle.

Address Bus

The address bus is the set of wires that carry the addressing information used to describe the memory location to which the data is being sent or from which the data is being retrieved. As with the data bus, each wire in an address bus carries a single bit of information. This single bit is a single digit in the address. The more wires (digits) used in calculating these addresses, the greater the total number of address locations. The size (or width) of the address bus indicates the maximum amount of RAM that a chip can address.

The highway analogy can be used to show how the address bus fits in. If the data bus is the highway and the size of the data bus is equivalent to the number of lanes, the address bus relates to the house number or street address. The size of the address bus is equivalent to the number of digits in the house address number. For example, if you live on a street in which the address is limited to a two-digit (base 10) number, no more than 100 distinct addresses (00–99) can exist for that street (10 to the power of 2). Add another digit, and the number of available addresses increases to 1,000 (000–999), or 10 to the power of 3.

Computers use the binary (base 2) numbering system, so a two-digit number provides only four unique addresses (00, 01, 10, and 11) calculated as 2 to the power of 2. A three-digit number provides only eight addresses (000–111), which is 2 to the third power. For example, the 8086 and 8088 processors use a 20-bit address bus that calculates as a maximum of 2 to the 20th power or 1,048,576 bytes (1MB) of address locations. Table 3.7 describes the memory-addressing capabilities of Intel processors.

Table 3.7 Intel and Intel Compatible Processor Memory-Addressing Capabilities

Processor Family	Address Bus	Bytes	KB	MB	GB
8088/8086	20-bit	1,048,576	1,024	1	—
286/386SX	24-bit	16,777,216	16,384	16	—
386DX/486/P5 Class	32-bit	4,294,967,296	4,194,304	4,096	4
P6 Class	36-bit	68,719,476,736	67,108,864	65,536	64

The data bus and address bus are independent, and chip designers can use whatever size they want for each. Usually, however, chips with larger data buses have larger address buses. The sizes of the buses can provide important information about a chip's relative power, measured in two important ways. The size of the data bus is an indication of the chip's information-moving capability, and the size of the address bus tells you how much memory the chip can handle.

Internal Level 1 (L1) Cache

All modern processors starting with the 486 family include an integrated (L1) cache and controller. The integrated L1 cache size varies from processor to processor, starting at 8KB for the original 486DX and now up to 32KB, 64KB, or more in the latest processors.

Since L1 cache is always built in to the processor die, it runs at the *full core speed* of the processor internally. By full core speed, I mean this cache runs at the higher clock multiplied internal processor speed rather than the external motherboard speed. This cache basically is an area of very fast memory built in to the processor and is used to hold some of the current working set of code and data. Cache memory can be accessed with no wait states because it is running at the same speed as the processor core.

Using cache memory reduces a traditional system bottleneck because system RAM often is much slower than the CPU. This prevents the processor from having to wait for code and data from much slower main memory therefore improving performance. Without the L1 cache, a processor frequently would be forced to wait until system memory caught up.

L1 cache is even more important in modern processors because it is often the only memory in the entire system that can truly keep up with the chip. Most modern processors are clock multiplied, which means they are running at a speed that is really a multiple of the motherboard they are plugged into. The Pentium II 333MHz, for example, runs at a very high multiple of five times the true motherboard speed of 66MHz. Because the main memory is plugged in to the motherboard, it can also run at only 66MHz maximum. The only 333MHz memory in such a system is the L1 cache built into the processor core. In this example, the Pentium II 333MHz processor has 32KB of integrated L1 cache in two separate 16KB blocks.

►► See "Memory Speeds," p. 424.

If the data that the processor wants is already in the internal cache, the CPU does not have to wait. If the data is not in the cache, the CPU must fetch it from the Level 2 cache or (in less sophisticated system designs) from the system bus, meaning main memory directly.

In order to understand the importance of cache, you need to know the relative speeds of processors and memory. The problem with this is that processor speed is normally expressed in MHz (millions of cycles per second), while memory speeds are often expressed in nanoseconds (billionths of a second per cycle).

Both are really time or frequency based measurements, and a chart comparing them can be found in Chapter 6, "Memory," Table 6.3. In this table you will note that a 200MHz processor equates to five nanosecond cycling, which means you would need 5ns memory to keep pace with a 200MHz CPU. Also note that the motherboard of a 200MHz system will normally run at 66MHz, which corresponds to a speed of 15ns per cycle, and require 15ns memory to keep pace. Finally note that 60ns main memory (common on many Pentium class systems) equates to a clock speed of approximately 16MHz. So in a typical Pentium 200 system, you have a processor running at 200MHz (5ns per cycle), a motherboard running at 66MHz (15ns per cycle), and main memory running at 16MHz (60ns per cycle).

To learn how the L1 and L2 cache work, consider the following analogy.

This story involves a person (in this case you) eating food to act as the processor requesting and operating on data from memory. The kitchen where the food is prepared is the main memory (SIMM/DIMM) RAM. The cache controller is the waiter, and the L1 cache is the table you are seated at. L2 cache will be introduced as a food cart, which is positioned between your table and the kitchen.

Okay, here's the story. Say you start to eat at a particular restaurant every day at the same time. You come in, sit down, and order a hot dog. To keep this story proportionately accurate, let's say you normally eat at the rate of one bite (byte? <g>) every five seconds (200MHz = 5ns cycling). It also takes 60 seconds for the kitchen to produce any given item that you order (60ns main memory).

So, when you first arrive, you sit down, order a hot dog, and you have to wait for 60 seconds for the food to be produced before you can begin eating. Once the waiter brings the food, you start eating at your normal rate. Pretty quickly you finish the hot dog, so you call the waiter and order a hamburger. Again you wait 60 seconds while the hamburger is being produced. When it arrives again you begin eating at full speed. After you finish the hamburger, you order a plate of fries. Again you wait, and after it is delivered 60 seconds later you eat it at full speed. Finally, you decide to finish the meal and order cheesecake for dessert. After another 60-second wait, you can again eat dessert at full speed. Your overall eating experience consists of mostly a lot of waiting, followed by short bursts of actual eating at full speed.

After coming into the restaurant for two consecutive nights at exactly 6 p.m. and ordering the same items in the same order each time, on the third night the waiter begins to think; "I know this guy is going to be here at 6 p.m., order a hot dog, a hamburger, fries, and then cheesecake. Why don't I have these items prepared in advance and surprise him, maybe I'll get a big tip." So you enter the restaurant, order a hot dog, and the waiter immediately puts it on your plate, with no waiting! You then proceed to finish the hot dog and right as you were about to request the hamburger, the waiter deposits one on your plate. The rest of the meal continues in the same fashion, and you eat the entire meal, taking a bite every five seconds, and never have to wait for the kitchen to prepare the food. Your overall eating experience this time consists of all eating, with no waiting for the food to be prepared, due primarily to the intelligence and thoughtfulness of your waiter.

This analogy exactly describes the function of the L1 cache in the processor. The L1 cache itself is the table that can contain one or more plates of food. Without a waiter, the space on the table is a simple food buffer. When stocked, you can eat until the buffer is empty, but nobody seems to be intelligently refilling it. The waiter is the cache controller who takes action and adds the intelligence to decide what dishes are to be placed on the table in advance of your needing them. Like the real cache controller, he uses his skills to literally guess what food you will require next, and if and when he guesses right, you never have to wait.

Let's now say on the fourth night you arrive exactly on time and start off with the usual hot dog. The waiter, by now really feeling confident, has the hot dog already prepared when you arrive, so there is no waiting.

Just as you finish the hot dog, and right as he is placing a hamburger on your plate, you say “Gee, I’d really like a bratwurst now; I didn’t actually order this hamburger.” The waiter guessed wrong, and the consequence is that this time you have to wait the full 60 seconds as the kitchen prepares your brat. This is known as a cache miss, where the cache controller did not correctly fill the cache with the data the processor actually needed next. The result is waiting, or in the case of a sample 200MHz Pentium system, the system essentially throttles back to 16MHz (RAM speed) whenever there is a cache miss. According to Intel, the L1 cache in most of their processors has approximately a 90 percent hit ratio. This means that the cache has the correct data 90 percent of the time and consequently the processor runs at full speed, 200MHz in this example, 90 percent of the time. However, 10 percent of the time the cache controller guesses wrong and the data has to be retrieved out of the significantly slower main memory, meaning the processor has to wait. This essentially throttles the system back to RAM speed, which in this example was 60ns or 16MHz.

Level 2 (L2) Cache

To mitigate the dramatic slowdown every time there is a cache miss, a secondary or L2 cache can be employed.

Using the restaurant analogy I used to explain L1 cache in the previous section, I’ll equate the L2 cache to a cart of additional food items placed strategically such that the waiter can retrieve food from it in 15 seconds. In an actual Pentium class system, the L2 cache is mounted on the motherboard, which means it runs at motherboard speed—66MHz or 15ns in this example. Now if you ask for an item the waiter did not bring in advance to your table, instead of making the long trek back to the kitchen to retrieve the food and bring it back to you 60 seconds later, he can first check the cart where he has placed additional items. If the requested item is there, he will return with it in only 15 seconds. The net effect in the real system is that instead of slowing down from 200MHz to 16MHz waiting for the data to come from the 60ns main memory, the data can instead be retrieved from the 15ns (66MHz) L2 cache instead. The effect is that the system slows down from 200MHz to 66MHz.

Most L2 caches have a hit ratio also in the 90 percent range, which means that if you look at the system as a whole, 90 percent of the time it will be running at full speed (200MHz in this example) by retrieving data out of the L1 cache. Ten percent of the time it will slow down to retrieve the data from the L2 cache. Ninety percent of that time the data will be in the L2, and 10 percent of that time you will have to go to the slow main memory to get the data due to an L2 cache miss. This means that our sample system runs at full processor speed 90 percent of the time (200MHz in this case), motherboard speed 9 percent of the time (66MHz in this case), and RAM speed about 1 percent of the time (16MHz in this case). You can clearly see the importance of both the L1 and L2 caches; without them the system will be using main memory more often, which is significantly slower than the processor.

In Pentium (P5) class systems, the L2 cache is normally found on the motherboard and must therefore run at motherboard speed. Intel made a dramatic improvement to this in the P6 class systems by migrating the L2 cache from the motherboard directly into the processor. In the Xeon and Celeron processors, the L2 cache runs at full processor core speed, which means there is no

waiting or slowing down after an L1 cache miss. In the mainstream Pentium II processors, for economy reasons, the L2 cache runs at half the core processor speed, which is still significantly faster than the motherboard.

Cache Organization

The organization of the cache memory in the 486 and Pentium family is called a four-way set associative cache, which means that the cache memory is split into four blocks. Each block also is organized as 128 or 256 lines of 16 bytes each.

To understand how a four-way set associative cache works, consider a simple example. In the simplest cache design, the cache is set up as a single block into which you can load the contents of a corresponding block of main memory. This procedure is similar to using a bookmark to locate the current page of a book that you are reading. If main memory equates to all the pages in the book, the bookmark indicates which pages are held in cache memory. This procedure works if the required data is located within the pages marked with the bookmark, but it does not work if you need to refer to a previously read page. In that case, the bookmark is of no use.

An alternative approach is to maintain multiple bookmarks to mark several parts of the book simultaneously. Additional hardware overhead is associated with having multiple bookmarks, and you also have to take time to check all the bookmarks to see which one marks the pages of data you need. Each additional bookmark adds to the overhead, but also increases your chance of finding the desired pages.

If you settle on marking four areas in the book, you have essentially constructed a four-way set associative cache. This technique splits the available cache memory into four blocks, each of which stores different lines of main memory. Multitasking environments, such as Windows, are good examples of environments in which the processor needs to operate on different areas of memory simultaneously and in which a four-way cache would improve performance greatly.

The contents of the cache must always be in sync with the contents of main memory to ensure that the processor is working with current data. For this reason, the internal cache in the 486 family is a *write-through* cache. Write-through means that when the processor writes information out to the cache, that information is automatically written through to main memory as well.

By comparison, the Pentium and later chips have an internal write-back cache, which means that both reads and writes are cached, further improving performance. Even though the internal 486 cache is write-through, the system can employ an external write-back cache for increased performance. In addition, the 486 can buffer up to four bytes before actually storing the data in RAM, improving efficiency in case the memory bus is busy.

Another feature of improved cache designs is that they are non-blocking. This is a technique for reducing or hiding memory delays by exploiting the overlap of processor operations with data accesses. A non-blocking cache allows program execution to proceed concurrently with cache misses as long as certain dependency constraints are observed. In other words, the cache can handle a cache miss much better and allow the processor to continue doing something non-dependent on the missing data.

The cache controller built into the processor also is responsible for watching the memory bus when alternative processors, known as busmasters, are in control of the system. This process of watching the bus is referred to as *bus snooping*. If a busmaster device writes to an area of memory that also is stored in the processor cache currently, the cache contents and memory no longer agree. The cache controller then marks this data as invalid and reloads the cache during the next memory access, preserving the integrity of the system.

A secondary external L2 cache of extremely fast static RAM (SRAM) chips also is used in most 486 and Pentium-based systems. It further reduces the amount of time that the CPU must spend waiting for data from system memory. The function of the secondary processor cache is similar to that of the onboard cache. The secondary processor cache holds information that is moving to the CPU, thereby reducing the time that the CPU spends waiting and increasing the time that the CPU spends performing calculations. Fetching information from the secondary processor cache rather than from system memory is much faster because of the SRAM chips' extremely fast speed—15 nanoseconds (ns) or less.

Pentium systems incorporate the secondary cache on the motherboard, while Pentium Pro and Pentium II systems have the secondary cache inside the processor package. By moving the L2 cache into the processor, systems are capable of running at speeds higher than the motherboard—up to as fast as the processor core.

As clock speeds increase, cycle time decreases. Most SIMM memory used in Pentium and earlier systems was 60ns, which works out to be only about 16MHz! Standard motherboard speeds are now 66MHz, 100MHz, or 133MHz, and processors are available at 600MHz or more. Newer systems don't use cache on the motherboard any longer, as the faster SDRAM or RDRAM used in modern Pentium Celeron/II/III systems can keep up with the motherboard speed. The trend today is toward integrating the L2 cache into the processor die just like the L1 cache. This allows the L2 to run at full core speed because it is now a part of the core. Cache speed is always more important than size. The rule is that a smaller but faster cache is always better than a slower but bigger cache. Table 3.8 illustrates the need for and function of L1 (internal) and L2 (external) caches in modern systems.

Table 3.8 CPU Speeds Relative to Cache, SIMM/DIMM, and Motherboard

CPU Type:	Pentium	Pentium Pro	Pentium II 333
CPU speed:	233MHz	200MHz	333MHz
L1 cache speed:	4ns (233MHz)	5ns (200MHz)	3ns (333MHz)
L2 cache speed:	15ns (66MHz)	5ns (200MHz)	6ns (167MHz)
Motherboard speed:	66MHz	66MHz	66MHz
SIMM/DIMM speed:	60ns (16MHz)	60ns (16MHz)	15ns (66MHz)
SIMM/DIMM type:	FPM/EDO	FPM/EDO	SDRAM

(continues)

Table 3.8 Continued

CPU Type:	Celeron 500	Pentium III 500	Pentium III 600
CPU speed:	500 Hz	500MHz	600MHz
L1 cache speed:	2ns (500MHz)	2ns (500 Hz)	1.7ns (600MHz)
L2 cache speed:	2ns (500MHz)	4ns (250MHz)	1.7ns (600MHz)
Motherboard speed:	66MHz	100MHz	133MHz
SIMM/DIMM speed:	15ns (66MHz)	10ns (100MHz)	7.5ns (133MHz)
SIMM/DIMM type:	SDRAM	SDRAM	SDRAM/RDRAM

As you can see, having two levels of cache between the very fast CPU and the much slower main memory helps minimize any wait states the processor might have to endure. This allows the processor to keep working closer to its true speed.

Processor Modes

All Intel 32-bit and later processors, from the 386 on up, can run in several modes. Processor modes refer to the various operating environments and affect the instructions and capabilities of the chip. The processor mode controls how the processor sees and manages the system memory and the tasks that use it.

Three different modes of operation possible are

- Real mode (16-bit software)
- Protected mode (32-bit software)
- Virtual Real mode (16-bit programs within a 32-bit environment)

Real Mode

The original IBM PC included an 8088 processor that could execute 16-bit instructions using 16-bit internal registers, and could address only 1MB of memory using 20 address lines. All original PC software was created to work with this chip and was designed around the 16-bit instruction set and 1MB memory model. For example, DOS and all DOS software, Windows 1.x through 3.x, and all Windows 1.x through 3.x applications are written using 16-bit instructions. These 16-bit operating systems and applications are designed to run on an original 8088 processor.

◀◀ See "Internal Registers," p. 51.

◀◀ See "Address Bus," p. 52.

Later processors such as the 286 could also run the same 16-bit instructions as the original 8088, but much faster. In other words, the 286 was fully compatible with the original 8088 and could run all 16-bit software just the same as an 8088, but, of course, that software would run faster. The 16-bit instruction mode of the 8088 and 286 processors has become known as real mode. All software running in real mode must use only 16-bit instructions and live within the 20-bit (1MB) memory architecture it supports. Software of this type is normally single-tasking, which means that only one program can run at a time. There is no built-in protection to keep one program

from overwriting another program or even the operating system in memory, which means that if more than one program is running, it is possible for one of them to bring the entire system to a crashing halt.

Protected (32-bit) Mode

Then came the 386, which was the PC industry's first 32-bit processor. This chip could run an entirely new 32-bit instruction set. To take full advantage of the 32-bit instruction set you needed a 32-bit operating system and a 32-bit application. This new 32-bit mode was referred to as protected mode, which alludes to the fact that software programs running in that mode are protected from overwriting one another in memory. Such protection helps make the system much more crash-proof, as an errant program cannot very easily damage other programs or the operating system. In addition, a crashed program can be terminated, while the rest of the system continues to run unaffected.

Knowing that new operating systems and applications—which take advantage of the 32-bit protected mode—would take some time to develop, Intel wisely built in a backward compatible real mode into the 386. That allowed it to run unmodified 16-bit operating systems and applications. It ran them quite well—much faster than any previous chip. For most people, that was enough; they did not necessarily want any new 32-bit software—they just wanted their existing 16-bit software to run faster. Unfortunately, that meant the chip was never running in the 32-bit protected mode, and all the features of that capability were being ignored.

When a high-powered processor such as a Pentium III is running DOS (real mode), it acts like a “Turbo 8088.” Turbo 8088 means that the processor has the advantage of speed in running any 16-bit programs; it otherwise can use only the 16-bit instructions and access memory within the same 1MB memory map of the original 8088. This means if you have a 128MB Pentium III system running Windows 3.x or DOS, you are effectively using only the first megabyte of memory, leaving the other 127MB largely unused!

New operating systems and applications that ran in the 32-bit protected mode of the modern processors were needed. Being stubborn, we resisted all the initial attempts at getting switched over to a 32-bit environment. It seems that as a user community, we are very resistant to change and would be content with our older software running faster rather than adopting new software with new features. I'll be the first one to admit that I was one of those stubborn users myself!

Because of this resistance, 32-bit operating systems such as UNIX or variants such as Linux, OS/2, and even Windows NT and Windows 2000 have had a very hard time getting any mainstream share in the PC marketplace. Out of those, Windows 2000 is the only one that will likely become a true mainstream product, and that is mainly because Microsoft has coerced us in that direction with Windows 95 and 98. Windows 3.x was the last full 16-bit operating system. In fact, it was not a complete operating system because it ran on top of DOS.

Microsoft realized how stubborn the installed base of PC users was so it developed Windows 95 as a bridge to a full 32-bit world. Windows 95 is a mostly 32-bit operating system, but it retains enough 16-bit capability to fully run our old 16-bit applications. Windows 95 came out in August

1995, a full 10 years later than the introduction of the first 32-bit PC processor! It has taken us only 10 years to migrate to software that can fully use the processors we have in front of us.

Virtual Real Mode

The key to the backward compatibility of the Windows 95 32-bit environment is the third mode in the processor: virtual real mode. Virtual real is essentially a virtual real mode 16-bit environment that runs inside 32-bit protected mode. When you run a DOS prompt window inside Windows 95/98, you have created a virtual real mode session. Because protected mode allows true multitasking, you can actually have several real mode sessions running, each with its own software running on a virtual PC. This can all run simultaneously, even while other 32-bit applications are running.

Note that any program running in a virtual real mode window can access up to only 1MB of memory, which that program will believe is the first and only megabyte of memory in the system. In other words, if you run a DOS application in a virtual real window, it will have a 640KB limitation on memory usage. That is because there is only 1MB of total RAM in a 16-bit environment, and the upper 384KB is reserved for system use. The virtual real window fully emulates an 8088 environment, so that aside from speed, the software runs as if it were on an original real mode-only PC. Each virtual machine gets its own 1MB address space, an image of the real hardware BIOS routines, and emulation of all other registers and features found in real mode.

Virtual real mode is used when you use a DOS window or run a DOS or Windows 3.x 16-bit program in Windows 95/98. When you start a DOS application, Windows 95 creates a virtual DOS machine under which it can run.

One interesting thing to note is that all Intel (and Intel compatible—such as AMD and Cyrix) processors power up in real mode. If you load a 32-bit operating system, it will automatically switch the processor into 32-bit mode and take control from there.

Some DOS and Windows 3.x applications misbehave, which means they do things that even virtual real mode will not support. Diagnostics software is a perfect example of this. Such software will not run properly in a real mode (virtual real) window under Windows 95/98 or NT, and Windows 2000. In that case, you can still run your Pentium II in the original no-frills real mode by interrupting the boot process and commanding the system to boot plain DOS. This is accomplished on most Windows 95/98/NT systems by pressing the F8 key when you see the prompt *Starting Windows...* on the screen. You will then see the Startup menu; you can select one of the command prompt choices, which tell the system to boot plain 16-bit real mode DOS. The choice of Safe Mode Command Prompt is best if you are going to run true hardware diagnostics, which do not normally run in protected mode and should be run with a minimum of drivers and other software loaded.

Although real mode is used by DOS and “standard” DOS applications, there are special programs available that “extend” DOS and allow access to extended memory (over 1MB). These are sometimes called DOS extenders and are usually included as a part of any DOS or Windows 3.x software that uses them. The protocol that describes how to make DOS work in protected mode is

called DPMI (DOS protected mode interface). DPMI was used by Windows 3.x to access extended memory for use with Windows 3.x applications. It allowed them to use more memory even though they were still 16-bit programs. DOS extenders are especially popular in DOS games, because they allow them to access much more of the system memory than the standard 1MB most real mode programs can address. These DOS extenders work by switching the processor in and out of real mode, or in the case of those that run under Windows, they use the DPMI interface built in to Windows, allowing them to share a portion of the system's extended memory.

Another exception in real mode is that the first 64KB of extended memory is actually accessible to the PC in real mode, despite the fact that it's not supposed to be possible. This is the result of a bug in the original IBM AT with respect to the 21st memory address line, known as A20 (A0 is the first address line). By manipulating the A20 line, real mode software can gain access to the first 64KB of extended memory—the first 64KB of memory past the first megabyte. This area of memory is called the high memory area (HMA).

SMM (Power Management)

Spurred on primarily by the goal of putting faster and more powerful processors in laptop computers, Intel has created power management circuitry. This circuitry enables processors to conserve energy use and lengthen battery life. This was introduced initially in the Intel 486SL processor, which is an enhanced version of the 486DX processor. Subsequently, the power-management features were universalized and incorporated into all Pentium and later processors. This feature set is called SMM, which stands for System Management Mode.

SMM circuitry is integrated into the physical chip but operates independently to control the processor's power use based on its activity level. It allows the user to specify time intervals after which the CPU will be partially or fully powered down. It also supports the suspend/resume feature that allows for instant power on and power off, used mostly with laptop PCs. These settings are normally controlled via system BIOS settings.

Superscalar Execution

The fifth-generation Pentium and newer processors feature multiple internal instruction execution pipelines, which enable them to execute multiple instructions at the same time. The 486 and all preceding chips can perform only a single instruction at a time. Intel calls the capability to execute more than one instruction at a time superscalar technology. This technology provides additional performance compared with the 486.

▶▶ See "Pentium Processor," p. 129.

Superscalar architecture usually is associated with high-output RISC (Reduced Instruction Set Computer) chips. An RISC chip has a less complicated instruction set with fewer and simpler instructions. Although each instruction accomplishes less, overall the clock speed can be higher, which can usually increase performance. The Pentium is one of the first CISC (Complex

Instruction Set Computer) chips to be considered superscalar. A CISC chip uses a more rich, full-featured instruction set, which has more complicated instructions. As an example, say you wanted to instruct a robot to screw in a light bulb. Using CISC instructions you would say

1. Pick up the bulb.
2. Insert it into the socket.
3. Rotate clockwise until tight.

Using RISC instructions you would say something more along the lines of

1. Lower hand.
2. Grasp bulb.
3. Raise hand.
4. Insert bulb into socket.
5. Rotate clockwise one turn.
6. Is bulb tight? If not repeat step 5.
7. End.

Overall many more RISC instructions are required to do the job because each instruction is simpler and does less. The advantage is that there are fewer overall commands the robot (or processor) has to deal with, and it can execute the individual commands more quickly, and thus in many cases execute the complete task (or program) more quickly as well. The debate goes on whether RISC or CISC is really better, but in reality there is no such thing as a pure RISC or CISC chip.

Intel and compatible processors have generally been regarded as CISC chips, although the fifth and sixth generation versions have many RISC attributes, and internally break CISC instructions down into RISC versions.

MMX Technology

MMX technology is named for multi-media extensions, or matrix math extensions, depending on whom you ask. Intel states that it is actually not an acronym and stands for nothing special; however, the internal origins are probably one of the preceding. MMX technology was introduced in the later fifth-generation Pentium processors (see Figure 3.2) as a kind of add-on that improves video compression/decompression, image manipulation, encryption, and I/O processing—all of which are used in a variety of today's software.

MMX consists of two main processor architectural improvements. The first is very basic; all MMX chips have a larger internal L1 cache than their non-MMX counterparts. This improves the performance of any and all software running on the chip, regardless of whether it actually uses the MMX-specific instructions.

The other part of MMX is that it extends the processor instructions set with 57 new commands or instructions, as well as a new instruction capability called Single Instruction, Multiple Data (SIMD).

Figure 3.2 An Intel Pentium MMX chip shown from the top and bottom (exposing the die). Photograph used by permission of Intel Corporation.

Modern multimedia and communication applications often use repetitive loops that, while occupying 10 percent or less of the overall application code, can account for up to 90 percent of the execution time. SIMD enables one instruction to perform the same function on multiple pieces of data, similar to a teacher telling an entire class to “sit down,” rather than addressing each student one at a time. SIMD allows the chip to reduce processor-intensive loops common with video, audio, graphics, and animation.

Intel also added 57 new instructions specifically designed to manipulate and process video, audio, and graphical data more efficiently. These instructions are oriented to the *highly parallel* and often repetitive sequences often found in multimedia operations. Highly parallel refers to the fact that the same processing is done on many different data points, such as when modifying a graphic image.

Intel licensed the MMX capabilities to competitors such as AMD and Cyrix, who were then able to upgrade their own Intel-compatible processors with MMX technology.

SSE (Streaming SIMD Extensions)

The Pentium III processor introduced in February 1999 included an update to MMX called Streaming SIMD Extensions (SSE). SSE includes 70 new instructions for graphics and sound processing over what MMX provided. SSE is similar to MMX, in fact, it was originally called MMX-2 before it was released. Besides adding more MMX style instructions, the SSE instructions allow for floating-point calculations, and now use a separate unit within the processor instead of sharing the standard floating-point unit as MMX did.

The Streaming SIMD Extensions consist of 70 new instructions, including Single Instruction Multiple Data (SIMD) floating-point, additional SIMD integer, and cacheability control instructions. Some of the technologies that benefit from the Streaming SIMD Extensions include advanced imaging, 3D, streaming audio and video (DVD playback), and speech recognition applications. The benefits of SSE include the following:

- Higher resolution and higher quality image viewing and manipulation
- High quality audio, MPEG2 video, and simultaneous MPEG2 encoding and decoding
- Reduced CPU utilization for speech recognition, as well as higher accuracy and faster response times

The SSE instructions are particularly useful with MPEG2 decoding, which is the standard scheme used on DVD video discs. This means that SSE equipped processors should be capable of doing MPEG2 decoding in software at full speed without requiring an additional hardware MPEG2 decoder card. SSE-equipped processors are much better and faster than previous processors when it comes to speech recognition.

Note that for any of the SSE instructions to be beneficial, they must be encoded in the software, which means that SSE-aware applications must be used to see the benefits. Most software companies writing graphics and sound-related software have updated those applications to be SSE-aware and utilize the features of SSE. The processors, which include SSE, will also include MMX, so standard MMX-enabled applications will still run as they did on processors without SSE.

Dynamic Execution

First used in the P6 or sixth-generation processors, dynamic execution is an innovative combination of three processing techniques designed to help the processor manipulate data more efficiently. Those techniques are multiple branch prediction, data flow analysis, and speculative execution. Dynamic execution enables the processor to be more efficient by manipulating data in a more logically ordered fashion rather than simply processing a list of instructions, and it is one of the hallmarks of all sixth-generation processors.

The way software is written can dramatically influence a processor's performance. For example, performance will be adversely affected if the processor is frequently required to stop what it is doing and jump or branch to a point elsewhere in the program. Delays also occur when the processor cannot process a new instruction until the current instruction is completed. Dynamic execution allows the processor to not only dynamically predict the order of instructions, but execute them out of order internally, if necessary, for an improvement in speed.

Multiple Branch Prediction

Multiple branch prediction predicts the flow of the program through several branches. Using a special algorithm, the processor can anticipate jumps or branches in the instruction flow. It uses this to predict where the next instructions can be found in memory with an accuracy of 90 percent or greater. This is possible because while the processor is fetching instructions, it is also looking at instructions further ahead in the program.

Data Flow Analysis

Data flow analysis analyzes and schedules instructions to be executed in an optimal sequence, independent of the original program order. The processor looks at decoded software instructions and determines whether they are available for processing or are instead dependent on other instructions to be executed first. The processor then determines the optimal sequence for processing and executes the instructions in the most efficient manner.

Speculative Execution

Speculative execution increases performance by looking ahead of the program counter and executing instructions that are likely to be needed later. Because the software instructions being processed are based on predicted branches, the results are stored in a pool for later referral. If they are to be executed by the resultant program flow, the already completed instructions are retired and the results are committed to the processor's main registers in the original program execution order. This technique essentially allows the processor to complete instructions in advance, and then grab the already completed results when necessary.

Dual Independent Bus (DIB) Architecture

The Dual Independent Bus (DIB) architecture was first implemented in the first sixth-generation processor. DIB was created to improve processor bus bandwidth and performance. Having two (dual) independent data I/O buses enables the processor to access data from either of its buses simultaneously and in parallel, rather than in a singular sequential manner (as in a single-bus system). The second or backside bus in a processor with DIB is used for the L2 cache, allowing it to run at much greater speeds than if it were to share the main processor bus.

Note

The DIB architecture is explained more fully in Chapter 4, "Motherboards and Buses." To see the typical Pentium system architecture, see Figure 4.34.

Two buses make up the DIB architecture: the L2 cache bus and the processor-to-main-memory, or system, bus. The P6 class processors from the Pentium Pro to the Celeron and Pentium II/III processors can use both buses simultaneously, eliminating a bottleneck there. The Dual Independent Bus architecture enables the L2 cache of the 500MHz Celeron processor, for example, to run seven and a half times faster than the L2 cache of older Pentium processors. Because the backside or L2 cache bus is coupled to the speed of the processor core, as the frequency of future P6 class processors (Celeron, Pentium II/III) increases, so will the speed of the L2 cache.

The key to implementing DIB was to move the L2 cache memory off of the motherboard and into the processor package. L1 cache has always been directly a part of the processor die, but L2 was larger and had to be external. By moving the L2 cache into the processor, the L2 cache could run at speeds more like the L1 cache, much faster than the motherboard or processor bus. To move the L2 cache into the processor initially, modifications had to be made to the CPU socket or slot. There are two socket-based processors that fully support DIB. The Pentium Pro, which plugs into Socket 8, and the Celeron, which is available in Socket 370 or Slot 1 versions. In the Pentium Pro, the L2 cache is contained within the chip package but on separate die(s). This, unfortunately, made the chip expensive and difficult to produce, although it did mean that the L2 cache ran at full processor speed. The Celeron updates this design and includes both the L1 and L2 caches directly on the processor die. This allows the L1 and L2 to both run at full processor speed, and makes the chip much less expensive to produce.

The Pentium II/III adopted an initially less expensive and easier-to-manufacture approach called the Single Edge Contact (SEC) or Single Edge Processor (SEP) package, which are covered in more detail later in this chapter.

Most Pentium II/III processors run the L2 cache at exactly 1/2-core speed, but that can easily be scaled up or down in the future. For example the 300MHz and faster Pentium IIPE (Performance Enhanced) processors used in laptop or mobile applications and the 600MHz Pentium III have on-die L2 cache like the Celeron, which runs at full core speed. Also, most have 512KB of L2 cache internally, but the PII/III processors with on-die L2 cache only use 256KB. Even so, they are faster than the 512KB versions, because it is better to have a cache that is twice as fast than one that is twice as large.

Cache design can be easily changed in the future because Intel makes Xeon versions of the PII and PIII that include 512KB, 1MB, or even 2MB of full core speed L2 cache. These aren't on-die, but consist of special high-speed Intel manufactured cache chips located within the cartridge. The flexibility of the P6 processor design will allow Intel to make Pentium IIIs with any amount of cache they like.

The Pentium II/III SEC processor connects to a motherboard via a single-edge connector instead of the multiple pins used in existing Pin Grid Array (PGA) socket packages.

DIB also allows the system bus to perform multiple simultaneous transactions (instead of singular sequential transactions), accelerating the flow of information within the system and boosting performance. Overall DIB architecture offers up to three times the bandwidth performance over a single-bus architecture processor.

Processor Manufacturing

Processors are manufactured primarily from silicon, the second most common element on Earth—only oxygen is more abundant. Silicon is the primary ingredient in beach sand; however, in that form it isn't pure enough to be used in chips.

To be made into chips, raw silicon is purified, melted down, and then processed in special ovens where a seed crystal is used to grow large cylindrical crystals called boules (see Figure 3.3). Each boule is larger than eight inches in diameter and over 50 inches long, weighing hundreds of pounds.

Figure 3.3 Growing a pure silicon boule in a high pressure, high temperature oven.

The boule is then ground into a perfect 200mm-diameter cylindrical ingot (the current standard), with a flat cut on one side for positioning accuracy and handling. Each ingot is then cut with a high-precision diamond saw into over a thousand circular wafers, each less than a millimeter thick (see Figure 3.4). Each wafer is polished to a mirror-smooth surface.

Figure 3.4 Slicing a silicon ingot into wafers with a diamond saw.

Chips are manufactured from the wafers using a process called *photolithography*. Through this photographic process, transistors and circuit and signal pathways are created in semiconductors by depositing different layers of various materials on the chip, one after the other. Where two specific circuits intersect, a transistor or switch can be formed.

The photolithographic process starts when an insulating layer of silicon dioxide is grown on the wafer through a vapor deposition process. Then a coating of photoresist material is applied and an image of that layer of the chip is projected through a mask onto the now light-sensitive surface.

Doping is the term used to describe chemical impurities added to silicon (which is naturally a non-conductor), creating a material with semiconductor properties. The projector uses a specially created mask, which is essentially a negative of that layer of the chip etched in chrome on a quartz plate. The Pentium III currently uses five masks and has as many layers, although other processors may have six or more layers. Each processor design requires as many masks as layers to produce the chips.

As the light passes through the first mask, the light is focused on the wafer surface, imprinting it with the image of that layer of the chip. Each individual chip image is called a die. A device called a stepper then moves the wafer over a little bit and the same mask is used to imprint another chip die immediately next to the previous one. After the entire wafer is imprinted with chips, a caustic solution washes away the areas where the light struck the photoresist, leaving the mask imprints of the individual chip vias (interconnections between layers) and circuit pathways.

Then, another layer of semiconductor material is deposited on the wafer with more photoresist on top, and the next mask is used to produce the next layer of circuitry. Using this method, the layers of each chip are built one on top of the other, until the chips are completed.

The final masks add the *metallization* layers, which are the metal interconnects used to tie all the individual transistors and other components together. Most chips use aluminum interconnects today, although many will be moving to copper in the future. Copper is a better conductor than aluminum and will allow smaller interconnects with less resistance, meaning smaller and faster chips can be made. The reason copper hasn't been used up until recently is that there were difficult corrosion problems to overcome during the manufacturing process that were not as much a problem with aluminum.

A completed circular wafer will have as many chips imprinted on it as can possibly fit. Because each chip is normally square or rectangular, there are some unused portions at the edges of the wafer, but every attempt is made to use every square millimeter of surface.

The standard wafer size used in the industry today is 200mm in diameter, or just under 8 inches. This results in a wafer of about 31,416 square millimeters. The current Pentium II 300MHz processor is made up of 7.5 million transistors using a 0.35 micron (millionth of a meter) process. This process results in a die of exactly 14.2mm on each side, which is 202 square millimeters of area. This means that about 150 total Pentium II 300MHz chips on the .35 micron process can be made from a single 200mm-diameter wafer.

The trend in the industry is to go to both larger wafers and a smaller chip die process. Process refers to the size of the individual circuits and transistors on the chip. For example, the Pentium II 333MHz and faster processors are made on a newer and smaller .25 micron process, which reduces the total chip die size to only 10.2mm on each side, or a total chip area of 104 square millimeters. On the same 200mm (8-inch) wafer as before, Intel can make about 300 Pentium II chips using this process, or double the amount over the larger .35 micron process 300MHz version.

The Pentium III is currently built on a .25 micron process and has a die size of 128 square millimeters, which is about 11.3mm on each side. This is slightly larger than the Pentium II because the III has about two million more transistors.

In the future, processes will move from .25 micron to .18, and then .13 micron. This will allow for more than double the number of chips to be made on existing wafers, or more importantly, will allow more transistors to be incorporated into the die, yet it will not be larger overall than die today. This means the trend for incorporating L2 cache within the die will continue, and transistor counts will rise up to 100 million per chip or more in the future.

The trend in wafers is to move from the current 200mm (8-inch) diameter to a bigger, 300mm (12-inch) diameter wafer. This will increase surface area dramatically over the smaller 200mm design and boost chip production to about 675 chips per wafer. Intel and other manufacturers expect to have 300mm wafer production in place just after the year 2000. After that happens, chip prices should continue to drop dramatically as supply increases.

Note that not all the chips on each wafer will be good, especially as a new production line starts. As the manufacturing process for a given chip or production line is perfected, more and more of the chips will be good. The ratio of good to bad chips on a wafer is called the yield. Yields well under 50 percent are common when a new chip starts production; however, by the end of a given chip's life, the yields are normally in the 90 percent range. Most chip manufacturers guard their yield figures and are very secretive about them because knowledge of yield problems can give their competitors an edge. A low yield causes problems both in the cost per chip and in delivery delays to their customers. If a company has specific knowledge of competitors' improving yields, they can set prices or schedule production to get higher market share at a critical point. For example, AMD was plagued by low-yield problems during 1997 and 1998, which cost them significant market share. They have been solving the problems, but it shows that yields are an important concern.

After a wafer is complete, a special fixture tests each of the chips on the wafer and marks the bad ones to be separated out later. The chips are then cut from the wafer using either a high-powered laser or diamond saw.

After being cut from the wafers, the individual die are then retested, packaged, and retested again. The packaging process is also referred to as bonding, because the die is placed into a chip housing where a special machine bonds fine gold wires between the die and the pins on the chip. The package is the container for the chip die, and it essentially seals it from the environment.

After the chips are bonded and packaged, final testing is done to determine both proper function and rated speed. Different chips in the same batch will often run at different speeds. Special test fixtures run each chip at different pressures, temperatures, and speeds, looking for the point at which the chip stops working. At this point, the maximum successful speed is noted and the final chips are sorted into bins with those that tested at a similar speed. For example, the Pentium III 450, 500, and 550 are all exactly the same chip made using the same die. They were sorted at the end of the manufacturing cycle by speed.

One interesting thing about this is that as a manufacturer gains more experience and perfects a particular chip assembly line, the yield of the higher speed versions goes way up. This means that out of a wafer of 150 total chips, perhaps more than 100 of them check out at 550MHz, while only a few won't run at that speed. The paradox is that Intel often sells a lot more of the lower priced 450 and 500MHz chips, so they will just dip into the bin of 550MHz processors and label them as 450 or 500 chips and sell them that way. People began discovering that many of the lower-rated chips would actually run at speeds much higher than they were rated, and the business of overclocking was born. Overclocking describes the operation of a chip at a speed higher than it was rated for. In many cases, people have successfully accomplished this because, in essence, they had a higher-speed processor already—it was marked with a lower rating only because it was sold as the slower version.

Intel has seen fit to put a stop to this by building overclock protection into most of their newer chips. This is usually done in the bonding or cartridge manufacturing process, where the chips are intentionally altered so they won't run at any speeds higher than they are rated. Normally

this involves changing the bus frequency (BF) pins on the chip, which control the internal multipliers the chip uses. Even so, enterprising individuals have found ways to run their motherboards at bus speeds higher than normal, so even though the chip won't allow a higher multiplier, you can still run it at a speed higher than it was designed.

Be Wary of PII and PIII Overclocking Fraud

Also note that unscrupulous individuals have devised a small logic circuit that bypasses the overclock protection, allowing the chip to run at higher multipliers. This small circuit can be hidden in the PII or PIII cartridge, and then the chip can be remarked or relabeled to falsely indicate it is a higher speed version. This type of chip remarketing fraud is far more common in the industry than people want to believe. In fact, if you purchase your system or processor from a local computer flea market type show, you have an excellent chance of getting a remarked chip. I recommend purchasing processors only from more reputable direct distributors or dealers. Contact Intel, AMD, or Cyrix, for a list of their reputable distributors and dealers.

I recently installed a 200MHz Pentium processor in a system that is supposed to run at a 3x multiplier based off a 66MHz motherboard speed. I tried changing the multiplier to 3.5x but the chip refused to go any faster; in fact, it ran at the same or lower speed than before. This is a sure sign of overclock protection inside, which is to say that the chip won't support any higher level of multiplier. My motherboard included a jumper setting for an unauthorized speed of 75MHz, which when multiplied by 3x resulted in an actual processor speed of 225MHz. This worked like a charm, and the system is now running fast and clean. Note that I am not necessarily recommending overclocking for everybody; in fact, I normally don't recommend it at all for any important systems. If you have a system you want to fool around with, it is interesting to try. Like my cars, I always seem to want to hotrod my computers.

PGA Chip Packaging

PGA packaging has been the most common chip package used until recently. It was used starting with the 286 processor in the 1980s and is still used today for Pentium and Pentium Pro processors. PGA takes its name from the fact that the chip has a grid-like array of pins on the bottom of the package. PGA chips are inserted into sockets, which are often of a ZIF (Zero Insertion Force) design. A ZIF socket has a lever to allow for easy installation and removal of the chip.

Most Pentium processors use a variation on the regular PGA called SPGA (Staggered Pin Grid Array), where the pins are staggered on the underside of the chip rather than in standard rows and columns. This was done to move the pins closer together and decrease the overall size of the chip when a large number of pins is required. Figure 3.5 shows a Pentium Pro that uses the dual-pattern SPGA (on the right) next to an older Pentium 66 that uses the regular PGA. Note that the right half of the Pentium Pro shown here has additional pins staggered among the other rows and columns.

Figure 3.5 PGA on Pentium 66 (left) and dual-pattern SPGA on Pentium Pro (right).

Single Edge Contact (SEC) and Single Edge Processor (SEP) Packaging

Abandoning the chip-in-a-socket approach used by virtually all processors until this point, the Pentium II/III chips are characterized by their Single Edge Contact (SEC) cartridge design. The processor, along with several L2 cache chips, is mounted on a small circuit board (much like an oversized memory SIMM), which is then sealed in a metal and plastic cartridge. The cartridge is then plugged into the motherboard through an edge connector called Slot 1, which looks very much like an adapter card slot.

By placing the processor and L2 cache as separate chips inside a cartridge, they now have a CPU module that is easier and less expensive to make than the Pentium Pro that preceded it. The Single Edge Contact (SEC) cartridge is an innovative—if a bit unwieldy—package design that incorporates the backside bus and L2 cache internally. Using the SEC design, the core and L2 cache are fully enclosed in a plastic and metal cartridge. These subcomponents are surface mounted directly to a substrate (or base) inside the cartridge to enable high-frequency operation. The SEC cartridge technology allows the use of widely available, high-performance industry standard Burst Static RAMs (BSRAMs) for the dedicated L2 cache. This greatly reduces the cost compared to the proprietary cache chips used inside the CPU package in the Pentium Pro.

A less expensive version of the SEC is called the Single Edge Processor (SEP) package. The SEP package is basically the same circuit board containing processor and (optional) cache as the Pentium II, but without the fancy plastic cover. The SEP package plugs directly into the same Slot 1 connector used by the standard Pentium II. Four holes on the board allow for the heat sink to be installed.

Slot 1 is the connection to the motherboard and has 242 pins. The Slot 1 dimensions are shown in Figure 3.6. The SEC cartridge or SEP processor is plugged into Slot 1 and secured with a processor-retention mechanism, which is a bracket that holds it in place. There may also be a retention mechanism or support for the processor heat sink. Figure 3.7 shows the parts of the cover that make up the SEC package. Note the large thermal plate used to aid in dissipating the heat from this processor. The SEP package is shown in Figure 3.8.

Figure 3.6 Pentium II Processor Slot 1 dimensions (metric/English).

Figure 3.7 Pentium II Processor SEC package parts.

Figure 3.8 Celeron Processor SEP package front side view.

With the Pentium III, Intel introduced a variation on the SEC packaging called SECC2 (Single Edge Contact Cartridge version 2). This new package covers only one side of the processor board and allows the heat sink to directly attach to the chip on the other side. This direct thermal interface allows for better cooling, and the overall lighter package is cheaper to manufacture. Note that a new Universal Retention System, consisting of a new design plastic upright stand, is required to hold the SECC2 package chip in place on the board. The Universal Retention System will also work with the older SEC package as used on most Pentium II processors, as well as the SEP package used on the slot based Celeron processors, making it the ideal retention mechanism for all Slot 1-based processors. Figure 3.9 shows the SECC2 package.

Figure 3.9 SECC2 packaging used in newer Pentium II and III processors.

The main reason for going to the SEC and SEP packages in the first place was to be able to move the L2 cache memory off the motherboard and onto the processor in an economical and scalable way. Using the SEC/SEP design, Intel can easily offer Pentium II/III processors with more or less cache and faster or slower cache.

Processor Sockets

Intel has created a set of socket designs—Socket 1 through Socket 8, and the new Socket 370—used for their chips from the 486 through the Pentium Pro and Celeron. Each socket is designed to support a different range of original and upgrade processors. Table 3.9 shows the specifications of these sockets.

Table 3.9 Intel 486/Pentium CPU Socket Types and Specifications

Socket Number	Pins	Pin Layout	Voltage	Supported Processors
Socket 1	169	17x17 PGA	5v	486 SX/SX2, DX/DX2*, DX4 Overdrive
Socket 2	238	19x19 PGA	5v	486 SX/SX2, DX/DX2*, DX4 Overdrive, 486 Pentium Overdrive
Socket 3	237	19x19 PGA	5v/3.3v	486 SX/SX2, DX/DX2, DX4, 486 Pentium Overdrive, AMD 5x86
Socket 4	273	21x21 PGA	5v	Pentium 60/66, Overdrive
Socket 5	320	37x37 SPGA	3.3/3.5v	Pentium 75-133, Overdrive
Socket 6**	235	19x19 PGA	3.3v	486 DX4, 486 Pentium Overdrive
Socket 7	321	37x37 SPGA	VRM	Pentium 75-233+, MMX, Overdrive, AMD K5/K6, Cyrix M1/II
Socket 8	387	dual pattern SPGA	Auto VRM	Pentium Pro
PGA370	370	37x37 SPGA	Auto VRM	Celeron
Slot 1	242	Slot	Auto VRM	Pentium II/III, Celeron
Slot 2	330	Slot	Auto VRM	Pentium II/III Xeon

**Non-overdrive DX4 or AMD 5x86 also can be supported with the addition of an aftermarket 3.3v voltage-regulator adapter.*

***Socket 6 was a paper standard only and was never actually implemented in any systems.*

PGA = Pin Grid Array.

SPGA = Staggered Pin Grid Array.

VRM = Voltage Regulator Module.

Sockets 1, 2, 3, and 6 are 486 processor sockets and are shown together in Figure 3.10 so you can see the overall size comparisons and pin arrangements between these sockets. Sockets 4, 5, 7, and 8 are Pentium and Pentium Pro processor sockets and are shown together in Figure 3.11 so you can see the overall size comparisons and pin arrangements between these sockets. More detailed drawings of each socket are included throughout the remainder of this section with the thorough descriptions of the sockets.

Figure 3.10 486 processor sockets.

Figure 3.11 Pentium and Pentium Pro processor sockets.

Socket 1

The original OverDrive socket, now officially called Socket 1, is a 169-pin PGA socket. Motherboards that have this socket can support any of the 486SX, DX, and DX2 processors, and the DX2/OverDrive versions. This type of socket is found on most 486 systems that originally were designed for OverDrive upgrades. Figure 3.12 shows the pinout of Socket 1.

The original DX processor draws a maximum 0.9 amps of 5v power in 33MHz form (4.5 watts) and a maximum 1 amp in 50MHz form (5 watts). The DX2 processor, or OverDrive processor, draws a maximum 1.2 amps at 66MHz (6 watts). This minor increase in power requires only a passive heat sink consisting of aluminum fins that are glued to the processor with thermal transfer epoxy. Passive heat sinks don't have any mechanical components like fans. Heat sinks with fans or other devices that use power are called active heat sinks. OverDrive processors rated at 40MHz or less do not have heat sinks.

Figure 3.12 Intel Socket 1 pinout.

Socket 2

When the DX2 processor was released, Intel was already working on the new Pentium processor. The company wanted to offer a 32-bit, scaled-down version of the Pentium as an upgrade for systems that originally came with a DX2 processor. Rather than just increasing the clock rate, Intel created an all new chip with enhanced capabilities derived from the Pentium.

The chip, called the Pentium OverDrive processor, plugs into a processor socket with the Socket 2 or Socket 3 design. These sockets will hold any 486 SX, DX, or DX2 processor, as well as the Pentium OverDrive. Because this chip is essentially a 32-bit version of the (normally 64-bit) Pentium chip, many have taken to calling it a Pentium-SX. It is available in 25/63MHz and 33/83MHz versions. The first number indicates the base motherboard speed; the second number indicates the actual operating speed of the Pentium OverDrive chip. As you can see, it is a clock-multiplied chip that runs at 2.5 times the motherboard speed. Figure 3.13 shows the pinout configuration of the official Socket 2 design.

Notice that although the new chip for Socket 2 is called Pentium OverDrive, it is not a full-scale (64-bit) Pentium. Intel released the design of Socket 2 a little prematurely and found that the chip ran too hot for many systems. The company solved this problem by adding a special active heat sink to the Pentium OverDrive processor. This active heat sink is a combination of a standard heat sink and a built-in electric fan. Unlike the aftermarket glue-on or clip-on fans for processors that you might have seen, this one actually draws 5v power directly from the socket to

drive the fan. No external connection to disk drive cables or the power supply is required. The fan/heat sink assembly clips and plugs directly into the processor and provides for easy replacement if the fan fails.

Figure 3.13 238-pin Intel Socket 2 configuration.

Another requirement of the active heat sink is additional clearance—no obstructions for an area about 1.4 inches off the base of the existing socket to allow for heat-sink clearance. The Pentium OverDrive upgrade will be difficult or impossible in systems that were not designed with this feature.

Another problem with this particular upgrade is power consumption. The 5v Pentium OverDrive processor will draw up to 2.5 amps at 5v (including the fan) or 12.5 watts, which is more than double the 1.2 amps (6 watts) drawn by the DX2 66 processor. Intel did not provide this information when it established the socket design, so the company set up a testing facility to certify systems for thermal and mechanical compatibility with the Pentium OverDrive upgrade. For the greatest peace of mind, ensure that your system is certified compatible before you attempt this upgrade.

Note

See Intel's Web site (<http://www.intel.com>) for a comprehensive list of certified OverDrive-compatible systems.

Figure 3.14 shows the dimensions of the Pentium OverDrive processor and the active heat sink/fan assembly.

Figure 3.14 The physical dimensions of the Intel Pentium OverDrive processor and active heat sink.

Socket 3

Because of problems with the original Socket 2 specification and the enormous heat the 5v version of the Pentium OverDrive processor generates, Intel came up with an improved design. The new processor is the same as the previous Pentium OverDrive processor, except that it runs on 3.3v and draws a maximum 3.0 amps of 3.3v (9.9 watts) and 0.2 amp of 5v (1 watt) to run the fan—a total 10.9 watts. This configuration provides a slight margin over the 5v version of this processor. The fan will be easy to remove from the OverDrive processor for replacement, should it ever fail.

Intel had to create a new socket to support both the DX4 processor, which runs on 3.3v, and the 3.3v Pentium OverDrive processor. In addition to the new 3.3v chips, this new socket supports the older 5v SX, DX, DX2, and even the 5v Pentium OverDrive chip. The design, called Socket 3, is the most flexible upgradable 486 design. Figure 3.15 shows the pinout specification of Socket 3.

Notice that Socket 3 has one additional pin and several others plugged compared with Socket 2. Socket 3 provides for better keying, which prevents an end user from accidentally installing the processor in an improper orientation. However, one serious problem exists: This socket cannot automatically determine the type of voltage that will be provided to it. A jumper is likely to be added on the motherboard near the socket to enable the user to select 5v or 3.3v operation.

Caution

Because this jumper must be manually set, however, a user could install a 3.3v processor in this socket when it is configured for 5v operation. This installation will instantly destroy a very expensive chip when the system is powered on. So, it is up to the end user to make sure that this socket is properly configured for voltage, depending on which type of processor is installed. If the jumper is set in 3.3v configuration and a 5v processor is installed, no harm will occur, but the system will not operate properly unless the jumper is reset for 5v.

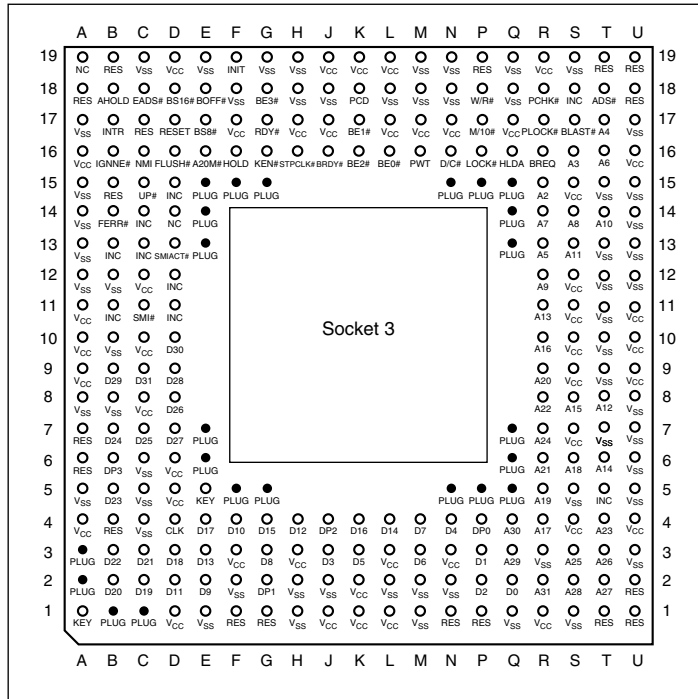

Figure 3.15 237-pin Intel Socket 3 configuration.

Socket 4

Socket 4 is a 273-pin socket that was designed for the original Pentium processors. The original Pentium 60MHz and 66MHz version processors had 273 pins and would plug into Socket 4—a 5v-only socket, because all the original Pentium processors run on 5v. This socket will accept the original Pentium 60MHz or 66MHz processor, and the OverDrive processor. Figure 3.16 shows the pinout specification of Socket 4.

Somewhat amazingly, the original Pentium 66MHz processor consumes up to 3.2 amps of 5v power (16 watts), not including power for a standard active heat sink (fan). The 66MHz OverDrive processor that replaced it consumes a maximum 2.7 amps (13.5 watts), including about 1 watt to drive the fan. Even the original 60MHz Pentium processor consumes up to 2.91 amps at 5v (14.55 watts). It might seem strange that the replacement processor, which is twice as fast, consumes less power than the original, but this has to do with the manufacturing processes used for the original and OverDrive processors.

Although both processors will run on 5v, the original Pentium processor was created with a circuit size of 0.8 micron, making that processor much more power-hungry than the newer 0.6 micron circuits used in the OverDrive and the other Pentium processors. Shrinking the circuit size is one of the best ways to decrease power consumption. Although the OverDrive processor for Pentium-based systems will draw less power than the original processor, additional clearance

may have to be allowed for the active heat sink assembly that is mounted on top. As in other OverDrive processors with built-in fans, the power to run the fan will be drawn directly from the chip socket, so no separate power-supply connection is required. Also, the fan will be easy to replace should it ever fail.

Figure 3.16 273-pin Intel Socket 4 configuration.

Socket 5

When Intel redesigned the Pentium processor to run at 75, 90, and 100MHz, the company went to a 0.6 micron manufacturing process and 3.3v operation. This change resulted in lower power consumption: only 3.25 amps at 3.3v (10.725 watts). Therefore, the 100MHz Pentium processor can use far less power than even the original 60MHz version. The newest 120 and higher Pentium, Pentium Pro, and Pentium II chips use an even smaller die 0.35 micron process. This results in lower power consumption and allows the extremely high clock rates without over-heating.

The Pentium 75 and higher processors actually have 296 pins, although they plug into the official Intel Socket 5 design, which calls for a total 320 pins. The additional pins are used by the Pentium OverDrive for Pentium processors. This socket has the 320 pins configured in a staggered Pin Grid Array, in which the individual pins are staggered for tighter clearance.

Several OverDrive processors for existing Pentiums are currently available. If you have a first-generation Pentium 60 or 66 with a Socket 4, you can purchase a standard Pentium OverDrive chip that effectively doubles the speed of your old processor. An OverDrive chip with MMX technology is available for second-generation 75MHz, 90MHz, and 100MHz Pentiums using Socket 5 or Socket 7. Processor speeds after upgrade are 125MHz for the Pentium 75, 150MHz for the Pentium 90, and 166MHz for the Pentium 100. MMX greatly enhances processor performance, particularly under multimedia applications, and is discussed in the section "Pentium-MMX Processors," later in this chapter. Figure 3.17 shows the standard pinout for Socket 5.

The Pentium OverDrive for Pentium processors has an active heat sink (fan) assembly that draws power directly from the chip socket. The chip requires a maximum 4.33 amps of 3.3v to run the chip (14.289 watts) and 0.2 amp of 5v power to run the fan (1 watt), which means total power consumption of 15.289 watts. This is less power than the original 66MHz Pentium processor requires, yet it runs a chip that is as much as four times faster!

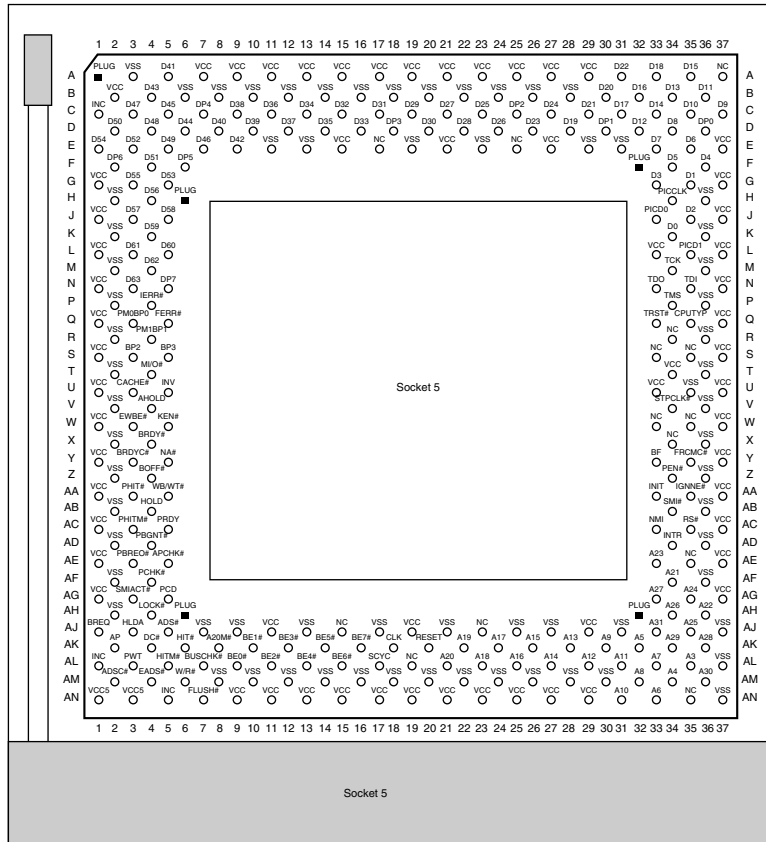

Figure 3.17 320-pin Intel Socket 5 configuration.

Soldering these circuits on the motherboard, as has been done with the Pentium Socket 5 design, makes it very likely that a failure of the regulator will require a complete motherboard replacement. Although technically the regulator could be replaced, many are surface-mount soldered, which would make the whole procedure very time-consuming and expensive. Besides, in this day and age, when the top-of-the-line motherboards are worth only \$150, it is just not cost-effective to service them. Having a replaceable VRM plugged into a socket will make it easy to replace the regulators should they ever fail.

Although replaceability is nice, the main reason behind the VRM design is that Intel and other manufacturers have built Pentium processors to run on a variety of voltages. Intel has several different versions of the Pentium and Pentium-MMX processors that run on 3.3v (called VR), 3.465v (called VRE), or 2.8v, while AMD, Cyrix and others use different variations. Because of this, most newer motherboard manufacturers are either including VRM sockets or building adaptable VRMs into the motherboard.

Figure 3.19 shows the Socket 7 pinout.

Figure 3.19 Socket 7 (Pentium) Pinout (top view).

AMD, along with Cyrix and several chipset manufacturers, pioneered an improvement or extension to the Intel Socket 7 design called Super Socket 7 (or Super7), taking it from 66MHz to

95MHz and 100MHz. This allows for faster Socket 7 type systems to be made, which are nearly as fast as the newer Slot 1 and Socket 370 type systems using Intel processors. Super7 systems also have support for the AGP video bus, as well as Ultra-DMA hard disk controllers, and advanced power management.

New chipsets are required for Super7 boards. Major third-party chipset suppliers, including Acer Laboratories Inc. (Ali), VIA Technologies, and SiS, are supporting the Super7 platform. ALi has the Aladdin V, VIA the Apollo MVP3, and SiS the SiS530 chipset for Super7 boards. Most of the major motherboard manufacturers are making Super7 boards in both Baby-AT and ATX form factors.

If you want to purchase a Pentium class board that can be upgraded to the next generation of even higher speed Socket 7 processors, look for a system with a Super7 socket and an integrated VRM that supports different voltage selections.

Socket 8

Socket 8 is a special SPGA socket featuring a whopping 387 pins! This was specifically designed for the Pentium Pro processor with the integrated L2 cache. The additional pins are to allow the chipset to control the L2 cache that is integrated in the same package as the processor. Figure 3.20 shows the Socket 8 pinout.

Figure 3.20 Socket 8 (Pentium Pro) Pinout showing power pin locations.

Socket PGA-370

In January 1999, Intel introduced a new socket for P6 class processors. The new socket is called PGA-370, because it has 370 pins and was designed for lower cost PGA (Pin Grid Array) versions of the Celeron and Pentium III processors. PGA-370 is designed to directly compete in the lower end system market along with the Super7 platform supported by AMD and Cyrix. PGA-370 brings the low cost of a socketed design, with less expensive processors, mounting systems, heat sinks, etc. to the high performance P6 line of processors.

Initially all the Celeron and Pentium III processors were made in SECC (Single Edge Contact Cartridge) or SEPP (Single Edge Processor Package) formats. These are essentially circuit boards containing the processor and separate L2 cache chips on a small board that plugs into the motherboard via Slot 1. This type of design was necessary when the L2 cache chips were made a part of the processor, but were not directly integrated into the processor die. Intel did make a multi-die chip package for the Pentium Pro, but this proved to be a very expensive way to package the chip. And, a board with separate chips was cheaper, which is why the Pentium II looks different from the Pentium Pro.

Starting with the Celeron 300A processor introduced in August 1998, Intel began combining the L2 cache directly on the processor die; it was no longer in separate chips. With the cache fully integrated into the die, there was no longer a need for a board-mounted processor. Because it costs more to make a Slot 1 board or cartridge-type processor instead of a socketed type, Intel moved back to the socket design to reduce the manufacturing cost—especially with the Celeron, which competes on the low end with Socket 7 chips from AMD and Cyrix.

The Socket PGA-370 pinout is shown in Figure 3.21.

The Celeron is gradually being shifted over to PGA-370, although for a time both were available. All Celeron processors at 333MHz and lower were only available in the Slot 1 version. Celeron processors from 366MHz–433MHz were available in both Slot 1 and Socket PGA-370 versions; all Celeron processors from 466MHz and up are only available in the PGA-370 version.

A motherboard with a Slot 1 can be designed to accept almost any Celeron, Pentium II, or Pentium III processor. To use the newer 466MHz and faster Celerons, which are only available in PGA-370 form, a low-cost adapter called a “slot-ket” has been made available by several manufacturers. This is essentially a Slot 1 board containing only a PGA-370 socket, which allows you to use a PGA-370 processor in any Slot 1 board. A typical slot-ket adapter is shown in the “Celeron” section, later in this chapter.

▶▶ See “Celeron,” p. 174.

Figure 3.21 Socket PGA-370 (PGA Celeron) pinout (top view).

Zero Insertion Force (ZIF) Sockets

When Intel created the Socket 1 specification, they realized that if users were going to upgrade processors, they had to make the process easier. They found that it typically takes 100 pounds of insertion force to install a chip in a standard 169-pin screw Socket 1 motherboard. With this much force involved, you easily could damage either the chip or socket during removal or reinstallation. Because of this, some motherboard manufacturers began using Low Insertion Force (LIF) sockets, which typically required only 60 pounds of insertion force for a 169-pin chip. With the LIF or standard socket, I usually advise removing the motherboard—that way you can support the board from behind when you insert the chip. Pressing down on the motherboard with 60–100 pounds of force can crack the board if it is not supported properly. A special tool is also

required to remove a chip from one of these sockets. As you can imagine, even the low insertion force was relative, and a better solution was needed if the average person was going to ever replace their CPU.

Manufacturers began inserting special Zero Insertion Force (ZIF) sockets in their later Socket 1 motherboard designs. Since then, virtually all processor sockets have been of the ZIF design. Note, however, that a given Socket X specification has nothing to do with whether it is ZIF, LIF, or standard; the socket specification covers only the pin arrangement. These days, nearly all motherboard manufacturers are using ZIF sockets. These sockets almost eliminate the risk involved in upgrading because no insertion force is necessary to install the chip. Most ZIF sockets are handle-actuated; you lift the handle, drop the chip into the socket, and then close the handle. This design makes replacing the original processor with the upgrade processor an easy task.

Because of the number of pins involved, virtually all CPU sockets from Socket 2 through the present are implemented in ZIF form. This means that since the 486 era, removing the CPU from most motherboards does not require any tools.

Processor Slots

After introducing the Pentium Pro with its integrated L2 cache, Intel discovered that the physical package they chose was very costly to produce. They were looking for a way to easily integrate cache and possibly other components into a processor package, and they came up with a cartridge or board design as the best way to do this. In order to accept their new cartridges, Intel designed two different types of slots that could be used on motherboards.

Slot 1 is a 242-pin slot that is designed to accept Pentium II, Pentium III, and most Celeron processors. Slot 2 is a more sophisticated 330-pin slot that is designed for the Pentium II and III Xeon processors, which are primarily for workstations and servers. Besides the extra pins, the biggest difference between Slot 1 and Slot 2 is the fact that Slot 2 was designed to host up to four-way or more processing in a single board. Slot 1 only allows single or dual processing functionality.

Note that Slot 2 is also called SC330, which stands for Slot Connector with 330 pins.

Slot 1

Slot 1 is used by the SEC (Single Edge Cartridge) design used with the Pentium II processors. Inside the cartridge is a substrate card that includes the processor and L2 cache. Unlike the Pentium Pro, the L2 cache is mounted on the circuit board and not within the same chip package as the processor. This allows Intel to use aftermarket SRAM chips instead of making them internally, and also allows them to make Pentium II processors with different amounts of cache easily. For example, the Celeron versions of the Pentium II have no L2 cache, whereas other future versions will have more than the standard 512KB included in most Pentium II processors. Figure 3.22 shows the Slot 1 connector dimensions and pin layout.

Slot 2 (SC330)

Slot 2 (otherwise called SC330) is used on high-end motherboards that support the Pentium II and III Xeon processors. Figure 3.23 shows the Slot 2 connector.

Figure 3.23 Slot 2 (SC330) connector dimensions and pin layout.

The Pentium II or III is designed in a cartridge similar to, but larger than, that used for the Pentium II. Figure 3.24 shows the Xeon cartridge.

Figure 3.24 Pentium II/III Xeon cartridge.

Motherboards featuring Slot 2 are primarily found in higher end systems such as workstations or servers, which use the Pentium II or III Xeon processors. These are Intel's high-end chips, which differ from the standard Pentium II/III mainly by virtue of having full core-speed L2 cache, and more of it.

CPU Operating Voltages

One trend that is clear to anybody that has been following processor design is that the operating voltages have gotten lower and lower. The benefits of lower voltage are threefold. The most obvious is that with lower voltage comes lower overall power consumption. By consuming less power, the system will be less expensive to run, but more importantly for portable or mobile systems, it will run much longer on existing battery technology. The emphasis on battery operation has driven many of the advances in lowering processor voltage, because this has a great effect on battery life.

The second major benefit is that with less voltage and therefore less power consumption, there will be less heat produced. Processors that run cooler can be packed into systems more tightly and will last longer. The third major benefit is that a processor running cooler on less power can be made to run faster. Lowering the voltage has been one of the key factors in allowing the clock rates of processors to go higher and higher.

Until the release of the mobile Pentium and both desktop and mobile Pentium MMX, most processors used a single voltage level to power both the core as well as run the input/output circuits. Originally, most processors ran both the core and I/O circuits at 5 volts, which was later reduced to 3.5 or 3.3 volts to lower power consumption. When a single voltage is used for

both the internal processor core power as well as the external processor bus and I/O signals, the processor is said to have a single or unified power plane design.

When originally designing a version of the Pentium processor for mobile or portable computers, Intel came up with a scheme to dramatically reduce the power consumption while still remaining compatible with the existing 3.3v chipsets, bus logic, memory, and other components. The result was a dual-plane or split-plane power design where the processor core ran off of a lower voltage while the I/O circuits remained at 3.3v. This was originally called Voltage Reduction Technology (VRT) and first debuted in the Mobile Pentium processors released in 1996. Later, this dual-plane power design also appeared in desktop processors such as the Pentium MMX, which used 2.8v to power the core and 3.3v for the I/O circuits. Now most recent processors, whether for mobile or desktop use, feature a dual-plane power design. Some of the more recent Mobile Pentium II processors run on as little as 1.6v for the core while still maintaining compatibility with 3.3v components for I/O.

Knowing the processor voltage requirements is not a big issue with Pentium Pro (Socket 8) or Pentium II (Slot 1 or Slot 2) processors, because these sockets and slots have special voltage ID (VID) pins that the processor uses to signal to the motherboard the exact voltage requirements. This allows the voltage regulators built in to the motherboard to be automatically set to the correct voltage levels by merely installing the processor.

Unfortunately, this automatic voltage setting feature is not available on Socket 7 and earlier motherboard and processor designs. This means you must normally set jumpers or otherwise configure the motherboard according to the voltage requirements of the processor you are installing. Pentium (Socket 4, 5, or 7) processors have run on a number of voltages, but the latest MMX versions are all 2.8v, except for mobile Pentium processors, which are as low as 1.8v. Table 3.11 lists the voltage settings used by Intel Pentium (non-MMX) processors that use a single power plane. This means that both the CPU core and the I/O pins run at the same voltage.

Table 3.11 shows voltages used by Socket 7 processors.

Table 3.11 Socket 7 Single- and Dual-Plane Processor Voltages

Voltage Setting	Processor	Core Voltage	I/O Voltage	Voltage Planes
VRE (3.5v)	Intel Pentium	3.5v	3.5v	Single
STD (3.3v)	Intel Pentium	3.3v	3.3v	Single
MMX (2.8v)	Intel MMX Pentium	2.8v	3.3v	Dual
VRE (3.5v)	AMD K5	3.5v	3.5v	Single
3.2v	AMD-K6	3.2v	3.3v	Dual
2.9v	AMD-K6	2.9v	3.3v	Dual
2.4v	AMD-K6-2/K6-3	2.4v	3.3v	Dual
2.2v	AMD-K6/K6-2	2.2v	3.3v	Dual
VRE (3.5v)	Cyrix 6x86	3.5v	3.5v	Single
2.9v	Cyrix 6x86MX/M-II	2.9v	3.3v	Dual
MMX (2.8v)	Cyrix 6x86L	2.8v	3.3v	Dual
2.45v	Cyrix 6x86LV	2.45v	3.3v	Dual

Normally, the acceptable range is plus or minus five percent from the nominal intended setting.

Most Socket 7 and later Pentium motherboards supply several voltages (such as 2.5v, 2.7v, 2.8v, and 2.9v) for compatibility with future devices. A voltage regulator built into the motherboard converts the power supply voltage into the different levels required by the processor core. Check the documentation for your motherboard and processor to find the appropriate settings.

The Pentium Pro and Pentium II processors automatically determine their voltage settings by controlling the motherboard-based voltage regulator through built-in voltage ID (VID) pins. Those are explained in more detail later in this chapter.

- ▶▶ See "Pentium Pro Processors," p. 156.
- ▶▶ See "Pentium II Processors," p. 162.

Note that on the STD or VRE settings, the core and I/O voltages are the same; these are single plane voltage settings. Anytime a different voltage other than STD or VRE is set, the motherboard defaults to a dual-plane voltage setting where the core voltage can be specifically set, while the I/O voltage remains constant at 3.3v no matter what.

Socket 5 was only designed to supply STD or VRE settings, so any processor that can work at those settings can work in Socket 5 as well as Socket 7. Older Socket 4 designs can only supply 5v, plus they have a completely different pinout (fewer pins overall), so it is not possible to use a processor designed for Socket 7 or Socket 5 in Socket 4.

Most Socket 7 and later Pentium motherboards supply several voltages (such as 2.2v, 2.4v, 2.5v, 2.7v, 2.8v, and 2.9v as well as the older STD or VRE settings) for compatibility with many processors. A voltage regulator built into the motherboard converts the power supply voltage into the different levels required by the processor core. Check the documentation for your motherboard and processor to find the appropriate settings.

The Pentium Pro, Celeron, and Pentium II/III processors automatically determine their voltage settings by controlling the motherboard-based voltage regulator. That's done through built-in voltage ID (VID) pins.

For hot rodding purposes, many newer motherboards for these processors have override settings that allow for manual voltage adjustment if desired. Many people have found that when attempting to overclock a processor, it often helps to increase the voltage by a tenth of a volt or so. Of course this increases the heat output of the processor and must be accounted for with adequate heat sinking.

Heat and Cooling Problems

Heat can be a problem in any high-performance system. The higher speed processors normally consume more power and therefore generate more heat. The processor is usually the single most power-hungry chip in a system, and in most situations, the fan inside your computer case might not be capable of handling the load without some help.

Heat Sinks

To cool a system in which processor heat is a problem, you can buy (for less than \$5, in most cases) a special attachment for the CPU chip called a heat sink, which draws heat away from the CPU chip. Many applications may need only a larger standard heat sink with additional or longer fins for a larger cooling area. Several heat-sink manufacturers are listed in the Vendor List, on the CD.

A heat sink works like the radiator in your car, pulling heat away from the engine. In a similar fashion, the heat sink conducts heat away from the processor so that it can be vented out of the system. It does this by using a thermal conductor (usually metal) to carry heat away from the processor into fins that expose a high amount of surface area to moving air. This allows the air to be heated, thus cooling the heat sink and the processor as well. Just like the radiator in your car, the heat sink depends on airflow. With no moving air, a heat sink is incapable of radiating the heat away. To keep the engine in your car from overheating when the car is not moving, auto engineers incorporate a fan. Likewise, there is always a fan somewhere inside your PC helping to move air across the heat sink and vent it out of the system. Sometimes the fan included in the power supply is enough, other times an additional fan must be added to the case, or even directly over the processor to provide the necessary levels of cooling.

The heat sink is clipped or glued to the processor. A variety of heat sinks and attachment methods exist. Figure 3.25 shows various passive heat sinks and attachment methods.

Figure 3.25 Passive heat sinks for socketed processors showing various attachment methods.

Tip

According to data from Intel, heat sink clips are the number two destroyer of motherboards (screwdrivers are number one). When installing or removing a heat sink that is clipped on, make sure you don't scrape the surface of the motherboard. In most cases, the clips hook over protrusions in the socket, and when installing or removing the clips, it is very easy to scratch or scrape the surface of the board right below where the clip ends attach. I like to place a thin sheet of plastic underneath the edge of the clip while I work, especially if there are board traces that can be scratched in the vicinity.

Heat sinks are rated for their cooling performance. Typically the ratings are expressed as a resistance to heat transfer, in degrees centigrade per watt ($^{\circ}\text{C}/\text{W}$), where lower is better. Note that the resistance will vary according to the airflow across the heat sink. To ensure a constant flow of air and more consistent performance, many heat sinks incorporate fans so they don't have to rely on the airflow within the system. Heat sinks with fans are referred to as active heat sinks (see Figure 3.26). Active heat sinks have a power connection, often using a spare disk drive power connector, although most newer motherboards now have dedicated heat sink power connections right on the board.

Figure 3.26 Active heat sinks for socketed processors.

Active heat sinks use a fan or other electric cooling device, which require power to run. The fan type is most common but some use a peltier cooling device, which is basically a solid-state refrigerator. Active heat sinks require power and normally plug into a disk drive power connector or special 12v fan power connectors on the motherboard. If you do get a fan type heat sink, be aware that some on the market are very poor quality. The bad ones have motors that use sleeve bearings, which freeze up after a very short life. I only recommend fans with ball-bearing motors, which will last about 10 times longer than the sleeve-bearing types. Of course, they cost more, but only about twice as much, which means you'll save money in the long run.

Figure 3.27 shows an active heat sink arrangement on a Pentium II/III type processor. This is common on what Intel calls their "boxed processors," which are sold individually and through dealers.

The passive heat sinks are 100 percent reliable, as they have no mechanical components to fail. Passive heat sinks (see Figure 3.28) are basically an aluminum-finned radiator that dissipates heat through convection. Passive types don't work well unless there is some airflow across the fins,

normally provided by the power supply fan or an extra fan in the case. If your case or power supply is properly designed, you can use a less expensive passive heat sink instead of an active one.

Figure 3.27 An active (fan powered) heat sink and supports used with Pentium II/III type processors.

Figure 3.28 A passive heat sink and supports used with Pentium II/III type processors.

Tip

To function effectively, a heat sink must be as directly attached to the processor as possible. To eliminate air gaps and ensure a good transfer of heat, in most cases, you should put a thin coating of thermal transfer grease on the surface of the processor where the heat sink attaches. This will dramatically decrease the thermal resistance properties and is required for maximum performance.

In order to have the best possible transfer of heat from the processor to the heat sink, most heat sink manufacturers specify some type of thermal interface material to be placed between the processor and the heat sink. This normally consists of a zinc-based white grease (similar to what skiers put on their noses to block the sun), but can also be a special pad or even a type of double-stick tape. Using a thermal interface aid such as thermal grease can improve heat sink performance dramatically. Figure 3.29 shows the thermal interface pad or grease positioned between the processor and heat sink.

Figure 3.29 Thermal interface material helps transfer heat from the processor die to the heat sink.

Most of the newer systems on the market use an improved motherboard form factor (shape) design called ATX. Systems made from this type of motherboard and case allow for improved cooling of the processor due to the processor being repositioned in the case near the power supply. Also, most of these cases now feature a secondary fan to further assist in cooling. Normally the larger case mounted fans are more reliable than the smaller fans included in active heat sinks. A properly designed case can move sufficient air across the processor, allowing for a more reliable and less expensive passive (no fan) heat sink to be used.

►► See "ATX," p. 214.

Math Coprocessors (Floating-Point Units)

This section covers the floating-point unit (FPU) contained in the processor, which was formerly a separate external math coprocessor in the 386 and older chips. Older central processing units designed by Intel (and cloned by other companies) used an external math coprocessor chip. However, when Intel introduced the 486DX, they included a built-in math coprocessor, and every processor built by Intel (and AMD and Cyrix, for that matter) since then includes a math coprocessor. Coprocessors provide hardware for floating-point math, which otherwise would create an excessive drain on the main CPU. Math chips speed your computer's operation only when you are running software designed to take advantage of the coprocessor. All the subsequent fifth and sixth generation Intel and compatible processors (such as those from AMD and Cyrix) have featured an integrated floating-point unit, although the Intel ones are known for having the best performance.

Math chips (as coprocessors sometimes are called) can perform high-level mathematical operations—long division, trigonometric functions, roots, and logarithms, for example, at 10 to 100 times the speed of the corresponding main processor. The operations performed by the math chip are all operations that make use of noninteger numbers (numbers that contain digits after the decimal point). The need to process numbers in which the decimal is not always the last character leads to the term *floating point* because the decimal (point) can move (float), depending on the operation. The integer units in the primary CPU work with integer numbers, so they perform addition, subtraction, and multiplication operations. The primary CPU is designed to handle such computations; these operations are not offloaded to the math chip.

The instruction set of the math chip is different from that of the primary CPU. A program must detect the existence of the coprocessor, and then execute instructions written explicitly for that coprocessor; otherwise, the math coprocessor draws power and does nothing else. Fortunately, most modern programs that can benefit from the use of the coprocessor correctly detect and use the coprocessor. These programs usually are math-intensive: spreadsheet programs, database applications, statistical programs, and graphics programs, such as computer-aided design (CAD) software. Word processing programs do not benefit from a math chip and therefore are not designed to use one. Table 3.12 summarizes the coprocessors available for the Intel family of processors.

Table 3.12 matches processors and the coprocessor it uses.

Table 3.12 Math Coprocessor Summary

Processor	Coprocessor
8086	8087
8088	8087
286	287
386SX	387SX
386DX	387DX
486SX	487SX, DX2/OverDrive*
487SX*	Built-in FPU
486SX2	DX2/OverDrive**
486DX	Built-in FPU
486DX2	Built-in FPU
486DX4/5x86	Built-in FPU
Intel Pentium/Pentium MMX	Built-in FPU
Cyrix 6x86/MI/MII	Built-in FPU
AMD K5/K6	Built-in FPU
Pentium II/III/Celeron/Xeon	Built-in FPU

FPU = Floating-point unit

*The 487SX chip is a modified pinout 486DX chip with the math coprocessor enabled. When you plug in a 487SX chip, it disables the 486SX main processor and takes over all processing.

**The DX2/OverDrive is equivalent to the SX2 with the addition of a functional FPU.

Although virtually all processors since the 486 series have built-in floating-point units, they vary in performance. Historically the Intel processor FPUs have dramatically outperformed those from AMD and Cyrix, although AMD and Cyrix are achieving performance parity in their newer offerings.

Within each of the original 8087 group, the maximum speed of the math chips varies. A suffix digit after the main number, as shown in Table 3.13, indicates the maximum speed at which a system can run a math chip.

Table 3.13 Maximum Math Chip Speeds

Part	Speed	Part	Speed
8087	5MHz	287	6MHz
8087-3	5MHz	287-6	6MHz
8087-2	8MHz	287-8	8MHz
8087-1	10MHz	287-10	10MHz

The 387 math coprocessors, and the 486 or 487 and Pentium processors, always indicate their maximum speed rating in MHz in the part number suffix. A 486DX2-66, for example, is rated to run at 66MHz. Some processors incorporate clock multiplication, which means that they can run at different speeds compared with the rest of the system.

Tip

The performance increase in programs that use the math chip can be dramatic—usually, a geometric increase in speed occurs. If the primary applications that you use can take advantage of a math coprocessor, you should upgrade your system to include one.

Most systems that use the 386 or earlier processors are socketed for a math coprocessor as an option, but they do not include a coprocessor as standard equipment. A few systems on the market don't even have a socket for the coprocessor because of cost and size considerations. These systems are usually low cost or portable systems, such as older laptops, the IBM PS/1, and the PCjr. For more specific information about math coprocessors, see the discussions of the specific chips—8087, 287, 387, and 487SX—in the later sections. Table 3.14 shows the specifications of the various math coprocessors.

Table 3.14 Older Intel Math Coprocessor Specifications

Name	Power Consumption	Case Minimum Temperature	Case Maximum Temperature	No. of Transistors	Date Introduced
8087	3 watts	0°C, 32°F	85°C, 185°F	45,000	1980
287	3 watts	0°C, 32°F	85°C, 185°F	45,000	1982
287XL	1.5 watts	0°C, 32°F	85°C, 185°F	40,000	1990
387SX	1.5 watts	0°C, 32°F	85°C, 185°F	120,000	1988
387DX	1.5 watts	0°C, 32°F	85°C, 185°F	120,000	1987

Most often, you can learn what CPU and math coprocessor are installed in a particular system by checking the markings on the chip.

Processor Bugs

Processor manufacturers use specialized equipment to test their own processors, but you have to settle for a little less. The best processor-testing device to which you have access is a system that you know is functional; you then can use the diagnostics available from various utility software companies or your system manufacturer to test the motherboard and processor functions.

Companies such as Diagsoft, Symantec, Micro 2000, Trinitech, Data Depot, and others offer specialized diagnostics software that can test the system, including the processor. If you don't want to purchase this kind of software, you can perform a quick-and-dirty processor evaluation by using the diagnostics program supplied with your system.

Perhaps the most infamous of these is the floating-point division math bug in the early Pentium processors. This and a few other bugs are discussed in detail later in this chapter.

Because the processor is the brain of a system, most systems don't function with a defective processor. If a system seems to have a dead motherboard, try replacing the processor with one from a functioning motherboard that uses the same CPU chip. You might find that the processor in the original board is the culprit. If the system continues to play dead, however, the problem is elsewhere, most likely in the motherboard, memory, or power supply. See the chapters that cover those parts of the system for more information on troubleshooting those components. I must say that in all my years of troubleshooting and repairing PCs, I have rarely encountered defective processors.

A few system problems are built in at the factory, although these bugs or design defects are rare. By learning to recognize these problems, you can avoid unnecessary repairs or replacements. Each processor section describes several known defects in that generation of processors, such as the infamous floating-point error in the Pentium. For more information on these bugs and defects, see the following sections, and check with the processor manufacturer for updates.

Processor Update Feature

All processors can contain design defects or errors. Many times, the effects of any given bug can be avoided by implementing hardware or software workarounds. Intel documents these bugs and workarounds well for their processors in their processor Specification Update manuals; this manual is available from their Web site. Most of the other processor manufacturers also have bulletins or tips on their Web sites listing any problems or special fixes or patches for their chips.

Previously, the only way to fix a processor bug was to work around it or replace the chip with one that had the bug fixed. Now, a new feature built into the Intel P6 processors, including the Pentium Pro and Pentium II, can allow many bugs to be fixed by altering the *microcode* in the processor. Microcode is essentially a set of instructions and tables in the processor that control how the processor operates. These processors incorporate a new feature called reprogrammable microcode, which allows certain types of bugs to be worked around via microcode updates. The

microcode updates reside in the system ROM BIOS and are loaded into the processor by the system BIOS during the power on self test (POST). Each time the system is rebooted, the fix code is reloaded, ensuring that it will have the bug fix installed anytime the processor is operating.

The easiest method for checking the microcode update is to use the Pentium Pro and Pentium II processor update utility, which is developed and supplied by Intel. This utility can verify whether the correct update is present for all Pentium Pro processor-based motherboards. The utility displays the processor *stepping* and version of the microcode update. A stepping is the processor hardware equivalent of a new version. In software, we refer to minor version changes as 1.0, 1.1, 1.2, etc., while in processors we call these minor revisions *steppings*.

To install a new microcode update, however, the motherboard BIOS must contain the routines to support the microcode update, which virtually all Pentium Pro and Pentium II BIOSes do have. The Intel processor update utility determines whether the code is present in the BIOS, compares the processor stepping with the microcode update currently loaded, and installs the new update, if needed. Use of this utility with motherboards containing the BIOS microcode update routine allows just the microcode update data to be changed; the rest of the BIOS is unchanged. A version of the update utility is provided with all Intel boxed processors. The term *boxed processors* refers to processors packaged for use by system integrators, that is, people who build systems. If you want the most current version of this utility, you have to contact an Intel processor dealer to download it, because Intel only supplies it to their dealers.

Note that if the BIOS in your motherboard does not include the processor microcode update routine, you should get a complete system BIOS upgrade from the motherboard vendor.

When you are building a system with a Pentium Pro, Celeron, or Pentium II/III processor, you must use the processor update utility to check that the system BIOS contains microcode updates that are specific to particular silicon stepping of the processor you are installing. In other words, you must ensure that the update matches the processor stepping being used.

Table 3.15 contains the current microcode update revision for each processor stepping. These update revisions are contained in the microcode update database file that comes with the Pentium Pro processor and Pentium II processor update utility. Processor steppings are listed in the sections on the Pentium, Pentium Pro, and Pentium II processors later in this chapter.

Table 3.15 Processor Steppings (Revisions) and Microcode Update Revisions Supported by the Update Database File PEP6.PDB

Processor	Stepping	Stepping Signature	Microcode Update Revision Required
Pentium Pro	C0	0x612	0xC6
Pentium Pro	sA0	0x616	0xC6
Pentium Pro	sA1	0x617	0xC6
Pentium Pro	sB1	0x619	0xD1
Pentium II	C0	0x633	0x32
Pentium II	C1	0x634	0x33
Pentium II	dA0	0x650	0x15

Using the processor update utility (CHECKUP3.EXE) available from Intel, a system builder can easily verify that the correct microcode update is present in all systems based on the P6 (Pentium Pro, Celeron, Pentium II/III and Xeon) processors. For example, if a system contains a processor with stepping C1 and stepping signature 0x634, the BIOS should contain the microcode update revision 0x33. The processor update utility identifies the processor stepping, signature, and microcode update revision that is currently in use.

If a new microcode update needs to be installed in the system BIOS, the system BIOS must contain the Intel-defined processor update routines so the processor update utility can permanently install the latest update. Otherwise, a complete system BIOS upgrade is required from the motherboard manufacturer. It is recommended that the processor update utility be run after upgrading a motherboard BIOS and before installing the operating system when building a system based on any P6 processor. The utility is easy to use and executes in just a few seconds. Because the update utility may need to load new code into your BIOS, ensure that any jumper settings on the motherboard are placed in the “enable flash upgrade” position. This enables writing to the flash memory.

After running the utility, turn off power to the system and reboot—do not warm boot—to ensure that the new update is correctly initialized in the processor. Also ensure that all jumpers, such as any flash upgrade jumpers and so on, are returned to their normal position.

Intel Processor Codenames

Intel has always used codenames when talking about future processors. The codenames are normally not supposed to become public, but often they do. They can often be found in magazine articles talking about future generation processors. Sometimes, they even appear in motherboard manuals because the manuals are written before the processors are officially introduced. Table 3.16 lists Intel processor codenames for reference.

Table 3.16 Intel Processors and Codenames

Codename	Processor
P4	486DX
P4S	486SX
P23	486SX
P23S	487SX
P23N	487SX
P23T	486 OverDrive for the 80486 (169-pin PGA)
P4T	486 OverDrive for the 486 (168-pin PGA)
P24	486DX2
P24S	486DX2
P24D	486DX2WB (Write Back)
P24C	486DX4
P24CT	486DX4WB (Write Back)
P5	Pentium 60 or 66MHz, Socket 4, 5v

Codename	Processor
P24T	486 Pentium OverDrive, 63 or 83MHz, Socket 3
P54C	Classic Pentium 75–200MHz, Socket 5/7, 3.3v
P55C	Pentium MMX 166–266MHz, Socket 7, 2.8v
P54CTB	Pentium MMX OverDrive 125+, Socket 5/7, 3.3v
Tillamook	Mobile Pentium MMX 0.25 micron, 166–266MHz, 1.8v
P6	Pentium Pro, Socket 8
Klamath	Original Pentium II, 0.35 micron, Slot 1
Deschutes	Pentium II, 0.25 micron, Slot 1 or 2
Covington	Celeron, PII w/ no L2 cache
Mendocino	Celeron, PII w/ 128KB L2 cache on die
Dixon	Pentium IIPE (mobile), 256KB on-die L2 cache
Katmai	Pentium III, PII w/ SSE instructions
Willamette	Pentium III w/ on-die L2
Tanner	Pentium III Xeon
Cascades	PIII, 0.18 micron, on-die L2
Merced	P7, First IA-64 processor, on-die L2, 0.18 micron
McKinley	1GHz, Improved Merced, IA-64, 0.18 micron w/ copper interconnects
Foster	Improved PIII, IA-32
Madison	Improved McKinley, IA-64, 0.13 micron

Intel-Compatible Processors (AMD and Cyrix)

Several companies—mainly AMD and Cyrix—have developed processors that are compatible with Intel processors. These chips are fully Intel-compatible, so they emulate every processor instruction in the Intel chips. Most of the chips are pin-compatible, which means that they can be used in any system designed to accept an Intel processor; others require a custom motherboard design. Any hardware or software that works on Intel-based PCs will work on PCs made with these third-party CPU chips. A number of companies currently offer Intel-compatible chips, and I will discuss some of the most popular ones here.

AMD Processors

Advanced Micro Devices (AMD) has become a major player in the Pentium-compatible chip market with their own line of Intel-compatible processors. AMD ran into trouble with Intel several years ago because their 486-clone chips used actual Intel microcode. These differences have been settled and AMD now has a five-year cross-license agreement with Intel. In 1996, AMD finalized a deal to absorb NexGen, another maker of Intel-compatible CPUs. NexGen had been working on a chip they called the Nx686, which was renamed the K6 and introduced by AMD. Since then, AMD has refined the design as the K6-2 and K6-3. Their new chip, called the K7, is designed similarly to the Pentium II and III, and uses the same cartridge design. AMD currently offers a wide variety of CPUs, from 486 upgrades to the K6 series and the new K7. Table 3.17 lists the basic processors offered by AMD and their Intel socket.

Table 3.17 AMD CPU Summary

AMD CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)	Socket
Am486DX4-100	n/a	100	3x	33	Socket 1,2,3
Am486DX4-120	n/a	120	3x	40	Socket 1,2,3
Am5x86-133	75	133	4x	33	Socket 1,2,3
K5	PR75	75	1.5x	50	Socket 5,7
K5	PR90	90	1.5x	60	Socket 5,7
K5	PR100	100	1.5x	66	Socket 5,7
K5	PR120	90	1.5x	60	Socket 5,7
K5	PR133	100	1.5x	66	Socket 5,7
K5	PR166	116.7	1.75x	66	Socket 5,7
K6	PR166	166	2.5x	66	Socket 7
K6	PR200	200	3x	66	Socket 7
K6	PR233	233	3.5x	66	Socket 7
K6	PR266	266	4x	66	Socket 7
K6	PR300	300	4.5x	66	Socket 7
K6-2	PR233	233	3.5x	66	Socket 7
K6-2	PR266	266	4x	66	Socket 7
K6-2	PR300	300	4.5x	66	Socket 7
K6-2	PR300	300	3x	100	Super7
K6-2	PR333	333	5x	66	Socket 7
K6-2	PR333	333	3.5x	95	Super7
K6-2	PR350	350	3.5x	100	Super7
K6-2	PR366	366	5.5x	66	Socket 7
K6-2	PR380	380	4x	95	Super7
K6-2	PR400	400	4x	100	Super7
K6-2	PR450	450	4.5x	100	Super7
K6-2	PR475	475	5x	95	Super7
K6-3	PR400	400	4x	100	Super7
K6-3	PR450	450	4.5x	100	Super7

Notice in the table that for the K5 PR120 through PR166 the model designation does not match the CPU clock speed. This is called a PR rating instead and is further described earlier in this chapter.

Starting with the K6, the P-Rating equals the true MHz clock speed.

The model designations are meant to represent performance comparable with an equivalent Pentium-based system. AMD chips, particularly the new K6, have typically fared well in performance comparisons and usually have a much lower cost. There is more information on the respective AMD chips in the sections for each different type of processor.

As you can see from the table, most of AMD's newer processors are designed to use the Super7 interface they pioneered with Cyrix. Super7 is an extension to the standard Socket 7 design, allowing for increased board speeds of up to 100MHz.

Cyrix

Cyrix has become an even larger player in the market since being purchased by National Semiconductor in November 1997. Prior to that they had been a fabless company, meaning they had no chip-manufacturing capability. All the Cyrix chips were manufactured for Cyrix first by Texas Instruments, and then mainly IBM up through the end of 1998. Starting in 1999, National Semiconductor has taken over manufacturing of the Cyrix processors. More recently, National has been looking to sell the Cyrix division, as the PC business has not been what they thought it would be. For now the future of Cyrix is a little unclear.

Like Intel, Cyrix has begun to limit its selection of available CPUs to only the latest technology. Cyrix is currently focusing on the Pentium market with the M1 (6x86) and M2 (6x86MX) processors. The 6x86 has dual internal pipelines and a single, unified 16KB internal cache. It offers speculative and out-of-order instruction execution, much like the Intel Pentium Pro processor. The 6x86MX adds MMX technology to the CPU. The chip is Socket 7 compatible, but some require modified chipsets and new motherboard designs. Table 3.18 lists Cyrix M1 processors and bus speeds.

Table 3.18 Cyrix Processor Ratings Versus Actual Speeds

Cyrix CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)	Socket
6x86	PR90	80	2x	40	Socket 5,7
6x86	PR120	100	2x	50	Socket 5,7
6x86	PR133	110	2x	55	Socket 5,7
6x86	PR150	120	2x	60	Socket 5,7
6x86	PR166	133	2x	66	Socket 5,7
6x86	PR200	150	2x	75	Super7
6x86MX	PR133	100	2x	50	Socket 7
6x86MX	PR133	110	2x	55	Socket 7
6x86MX	PR150	120	2x	60	Socket 7
6x86MX	PR150	125	2.5x	50	Socket 7
6x86MX	PR166	133	2x	66	Socket 7
6x86MX	PR166	137.5	2.5x	55	Socket 7
6x86MX	PR166	150	3x	50	Socket 7
6x86MX	PR166	150	2.5x	60	Socket 7
6x86MX	PR200	150	2x	75	Super7
6x86MX	PR200	165	3x	55	Socket 7
6x86MX	PR200	166	2.5x	66	Socket 7
6x86MX	PR200	180	3x	60	Socket 7
6x86MX	PR233	166	2x	83	Super7
6x86MX	PR233	187.5	2.5x	75	Super7
6x86MX	PR233	200	3x	66	Socket 7

(continues)

Table 3.18 Continued

Cyrix CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)	Socket
6x86MX	PR266	207.5	2.5x	83	Super7
6x86MX	PR266	225	3x	75	Super7
6x86MX	PR266	233	3.5x	66	Socket 7
M-II	PR300	225	3x	75	Super7
M-II	PR300	233	3.5x	66	Socket 7
M-II	PR333	250	3x	83	Super7
M-II	PR366	250	2.5x	100	Super7

Not all motherboards support bus speeds such as 40MHz or 55MHz.

A Super7 motherboard is required to support the 100MHz bus speed

Most Super7 motherboards support bus speeds lower than 100MHz

The 6x86MX features 64KB of unified L1 cache and more than double the performance of the previous 6x86 CPUs. The 6x86MX is offered in clock speeds ranging from 180–266MHz, and like the 6x86, it is Socket 7 compatible. When running at speeds of 300MHz and higher, the 686MX was renamed as the MII. Besides the higher speeds, all other functions are virtually identical. All Cyrix chips were manufactured by other companies such as IBM, who also markets the 6x86 chips under its own name. National began manufacturing Cyrix processors during 1998, but now that Cyrix is selling them off, the future is unclear.

Note that later versions of the 6x86MX chip have been renamed the MII to deliberately invoke comparisons with the Pentium II, instead of the regular Pentium processor. The MII chips are not redesigned; they are, in fact, the same 6x86MX chips as before, only running at higher clock rates. The first renamed 6x86MX chip is the MII 300, which actually runs at only 233MHz on a 66MHz Socket 7 motherboard. There is also an MII 333, which will run at a 250MHz clock speed on newer 100MHz Super7 motherboards.

Cyrix also has made an attempt at capturing even more of the low-end market than they already have by introducing a processor called the MediaGX. This is a low-performance cross between a 486 and a Pentium combined with a custom motherboard chipset in a two-chip package. These two chips contain everything necessary for a motherboard, except the Super I/O chip, and make very low-cost PCs possible. Expect to see the MediaGX processors on the lowest end, virtually disposable-type PCs. Later versions of these chips will include more multimedia and even network support.

IDT Winchip

Another offering in the chip market is from Integrated Device Technology (IDT). A longtime chip manufacturer who was more well-known for making SRAM (cache memory) chips, IDT acquired Centaur Technology, who had designed a chip called the C6 Winchip. Now with IDT's manufacturing capability, the C6 processor became a reality.

Featuring a very simple design, the C6 Winchip is more like a 486 than a Pentium. It does not have the superscalar (multiple instruction pipelines) of a Pentium; it has a single high-speed pipeline instead. Internally, it seems the C6 has little in common with other fifth- and sixth-generation x86 processors. Even so, according to Centaur, it closely matches the performance of a Pentium MMX when running the Winstone 97 business benchmark, although that benchmark does not focus on multimedia performance. It also has a much smaller die (88 mm²) than a typical Pentium, which means it should cost significantly less to manufacture.

The C6 has two large internal caches (32KB each for instructions and data), and will run at 180, 200, 225, and 240MHz. The power consumption is very low—14W maximum at 200MHz for the desktop chip, and 7.1 to 10.6W for the mobile chips. This processor will likely have some success in the low-end market.

P-Ratings

To make it easier to understand processor performance, the P-Rating system was jointly developed by Cyrix, IBM Microelectronics, SGS-Thomson Microelectronics, and Advanced Micro Devices. This new rating, titled the (Performance) P-Rating, equates delivered performance of microprocessor to that of an Intel Pentium. To determine a specific P-Rating, Cyrix and AMD use benchmarks such as Winstone 9x. Winstone 9x is a widely used, industry-standard benchmark that runs a number of Windows-based software applications.

The idea is fine, but in some cases it can be misleading. A single benchmark or even a group of benchmarks cannot tell the whole story on system or processor performance. In most cases, the companies selling PR-rated processors have people believing that they are really running at the speed indicated on the chip. For example, a Cyrix/IBM 6x86MX-PR200 does not really run at 200MHz; instead, it runs at 166MHz. I guess the idea is that it “feels” like 200MHz, or compares to some Intel processor running at 200MHz (which one?). I am not in favor of the P-Rating system and prefer to just report the processor’s true speed in MHz. If it happens to be 166 but runs faster than most other 166 processors, so be it—but I don’t like to number it based on some comparison like that.

Note

See “Cyrix P-Ratings” and “AMD P-Ratings” earlier in this chapter to see how P-Ratings stack up against the actual processor speed in MHz.

The Ziff-Davis Winstone benchmark is used because it is a real-world, application-based benchmark that contains the most popular software applications (based on market share) that run on a Pentium processor. Winstone also is a widely used benchmark and is freely distributed and available.

P1 (086) First-Generation Processors

8088 and 8086 Processors

Intel introduced a revolutionary new processor called the 8086 back in June of 1978. The 8086 was one of the first 16-bit processor chips on the market; at the time virtually all other processors were 8-bit designs. The 8086 had 16-bit internal registers and could run a new class of software using 16-bit instructions. It also had a 16-bit external data path, which meant it could transfer data to memory 16 bits at a time.

The address bus was 20 bits wide, meaning that the 8086 could address a full 1MB (2 to the 20th power) of memory. This was in stark contrast to most other chips of that time that had 8-bit internal registers, an 8-bit external data bus, and a 16-bit address bus allowing a maximum of only 64KB of RAM (2 to the 16th power).

Unfortunately, most of the personal computer world at the time was using 8-bit processors, which ran 8-bit CP/M (Control Program for Microprocessors) operating systems and software. The board and circuit designs at the time were largely 8-bit as well. Building a full 16-bit motherboard and memory system would be costly, pricing such a computer out of the market.

The cost was high because the 8086 needed a 16-bit data bus rather than a less expensive 8-bit bus. Systems available at that time were 8-bit, and slow sales of the 8086 indicated to Intel that people weren't willing to pay for the extra performance of the full 16-bit design. In response, Intel introduced a kind of crippled version of the 8086, called the 8088. The 8088 essentially deleted 8 of the 16 bits on the data bus, making the 8088 an 8-bit chip as far as data input and output were concerned. However, because it retained the full 16-bit internal registers and the 20-bit address bus, the 8088 ran 16-bit software and was capable of addressing a full 1MB of RAM.

For these reasons, IBM selected the 8-bit 8088 chip for the original IBM PC. Years later, they were criticized for using the 8-bit 8088 instead of the 16-bit 8086. In retrospect, it was a very wise decision. IBM even covered up the physical design in their ads, which at the time indicated their new PC had a "high-speed 16-bit microprocessor." They could say that because the 8088 still ran the same powerful 16-bit software the 8086 ran, just a little more slowly. In fact, programmers universally thought of the 8088 as a 16-bit chip because there was virtually no way a program could distinguish an 8088 from an 8086. This allowed IBM to deliver a PC capable of running a new generation of 16-bit software, while retaining a much less expensive 8-bit design for the hardware. Because of this, the IBM PC was actually priced less at its introduction than the most popular PC of the time, the Apple II. For the trivia buffs out there, the IBM PC listed for \$1,265 and included only 16KB of RAM, while a similarly configured Apple II cost \$1,355.

The original IBM PC used the Intel 8088. The 8088 was introduced in June 1979, but the IBM PC did not appear until August 1981. Back then, there was often a significant lag time between the introduction of a new processor and systems that incorporated it. That is unlike today, when new processors and systems using them are often released on the same day.

The 8088 in the IBM PC ran at 4.77MHz, or 4,770,000 cycles (essentially computer heartbeats) per second. Each cycle represents a unit of time to the system, with different instructions or operations requiring one or more cycles to complete. The average instruction on the 8088 took 12 cycles to complete.

Computer users sometimes wonder why a 640KB conventional-memory barrier exists if the 8088 chip can address 1MB of memory. The conventional-memory barrier exists because IBM reserved 384KB of the upper portion of the 1,024KB (1MB) address space of the 8088 for use by adapter cards and system BIOS. The lower 640KB is the conventional memory in which DOS and software applications execute.

80186 and 80188 Processors

After Intel produced the 8086 and 8088 chips, it turned its sights toward producing a more powerful chip with an increased instruction set. The company's first efforts along this line—the 80186 and 80188—were unsuccessful. But incorporating system components into the CPU chip was an important idea for Intel because it led to faster, better chips, such as the 286.

The relationship between the 80186 and 80188 is the same as that of the 8086 and 8088; one is a slightly more advanced version of the other. Compared CPU to CPU, the 80186 is almost the same as the 8088 and has a full 16-bit design. The 80188 (like the 8088) is a hybrid chip that compromises the 16-bit design with an 8-bit external communications interface. The advantage of the 80186 and 80188 is that they combine on a single chip 15 to 20 of the 8086–8088 series system components—a fact that can greatly reduce the number of components in a computer design. The 80186 and 80188 chips were used for highly intelligent peripheral adapter cards of that age, such as network adapters.

8087 Coprocessor

Intel introduced the 8086 processor in 1976. The math coprocessor that was paired with the chip—the 8087—often was called the numeric data processor (NDP), the math coprocessor, or simply the math chip. The 8087 is designed to perform high-level math operations at many times the speed of the main processor. The primary advantage of using this chip is the increased execution speed in number-crunching programs, such as spreadsheet applications.

P2 (286) Second-Generation Processors

286 Processors

The Intel 80286 (normally abbreviated as 286) processor did not suffer from the compatibility problems that damned the 80186 and 80188. The 286 chip, first introduced in 1981, is the CPU behind the original IBM AT. Other computer makers manufactured what came to be known as IBM clones, many of these manufacturers calling their systems AT-compatible or AT-class computers.

When IBM developed the AT, it selected the 286 as the basis for the new system because the chip provided compatibility with the 8088 used in the PC and the XT. That means that software

written for those chips should run on the 286. The 286 chip is many times faster than the 8088 used in the XT, and it offered a major performance boost to PCs used in businesses. The processing speed, or throughput, of the original AT (which ran at 6MHz) was five times greater than that of the PC running at 4.77MHz. The die for the 286 is shown in Figure 3.30.

Figure 3.30 286 Processor die. Photograph used by permission of Intel Corporation.

286 systems are faster than their predecessors for several reasons. The main reason is that 286 processors are much more efficient in executing instructions. An average instruction takes 12 clock cycles on the 8086 or 8088, but an average 4.5 cycles on the 286 processor. Additionally, the 286 chip can handle up to 16 bits of data at a time through an external data bus twice the size of the 8088.

The 286 chip has two modes of operation: real mode and protected mode. The two modes are distinct enough to make the 286 resemble two chips in one. In real mode, a 286 acts essentially the same as an 8086 chip and is fully *object-code compatible* with the 8086 and 8088. (A processor with object-code compatibility can run programs written for another processor without modification and execute every system instruction in the same manner.)

In the protected mode of operation, the 286 was truly something new. In this mode, a program designed to take advantage of the chip's capabilities believes that it has access to 1GB of memory

(including virtual memory). The 286 chip, however, can address only 16MB of hardware memory. A significant failing of the 286 chip is that it cannot switch from protected mode to real mode without a hardware reset (a warm reboot) of the system. (It can, however, switch from real mode to protected mode without a reset.) A major improvement of the 386 over the 286 is that software can switch the 386 from real mode to protected mode, and vice versa. See the section “Processor Modes,” earlier in this chapter for more information.

Only a small amount of software that took advantage of the 286 chip was sold until Windows 3.0 offered standard mode for 286 compatibility; by that time, the hottest-selling chip was the 386. Still, the 286 was Intel’s first attempt to produce a CPU chip that supported multitasking, in which multiple programs run at the same time. The 286 was designed so that if one program locked up or failed, the entire system didn’t need a warm boot (reset) or cold boot (power off or on). Theoretically, what happened in one area of memory didn’t affect other programs. Before multitasked programs could be “safe” from one another, however, the 286 chip (and subsequent chips) needed an operating system that worked cooperatively with the chip to provide such protection.

80287 Coprocessor

The 80287, internally, is the same math chip as the 8087, although the pins used to plug them into the motherboard are different. Both the 80287 and the 8087 operate as though they were identical.

In most systems, the 80286 internally divides the system clock by two to derive the processor clock. The 80287 internally divides the system-clock frequency by three. For this reason, most AT-type computers run the 80287 at one-third the system clock rate, which also is two-thirds the clock speed of the 80286. Because the 286 and 287 chips are asynchronous, the interface between the 286 and 287 chips is not as efficient as with the 8088 and 8087.

In summary, the 80287 and the 8087 chips perform about the same at equal clock rates. The original 80287 is not better than the 8087 in any real way—unlike the 80286, which is superior to the 8086 and 8088. In most AT systems, the performance gain that you realize by adding the coprocessor is much less substantial than the same type of upgrade for PC- or XT-type systems or for the 80386.

286 Processor Problems

After you remove a math coprocessor from an AT-type system, you must rerun your computer’s Setup program. Some AT-compatible SETUP programs do not properly unset the math coprocessor bit. If you receive a POST error message because the computer cannot find the math chip, you might have to unplug the battery from the system board temporarily. All Setup information will be lost, so be sure to write down the hard drive type, floppy drive type, and memory and video configurations before unplugging the battery. This information is critical in reconfiguring your computer correctly.

P3 (386) Third-Generation Processors

386 Processors

The Intel 80386 (normally abbreviated as 386) caused quite a stir in the PC industry because of the vastly improved performance it brought to the personal computer. Compared with 8088 and 286 systems, the 386 chip offered greater performance in almost all areas of operation.

The 386 is a full 32-bit processor optimized for high-speed operation and multitasking operating systems. Intel introduced the chip in 1985, but the 386 appeared in the first systems in late 1986 and early 1987. The Compaq Deskpro 386 and systems made by several other manufacturers introduced the chip; somewhat later, IBM used the chip in its PS/2 Model 80. The 386 chip rose in popularity for several years, which peaked around 1991. Obsolete 386 processor systems are mostly retired or scrapped, having been passed down the user chain. If they are in operating condition, they can be useful for running old DOS or Windows 3.x-based applications, which they can do quite nicely.

The 386 can execute the real-mode instructions of an 8086 or 8088, but in fewer clock cycles. The 386 was as efficient as the 286 in executing instructions, which means that the average instruction took about 4.5 clock cycles. In raw performance, therefore, the 286 and 386 actually seemed to be at almost equal clock rates. Many 286 system manufacturers were touting their 16MHz and 20MHz 286 systems as being just as fast as 16MHz and 20MHz 386 systems, and they were right! The 386 offered greater performance in other ways, mainly because of additional software capability (modes) and a greatly enhanced memory management unit (MMU). The die for the 386 is shown in Figure 3.31.

The 386 can switch to and from protected mode under software control without a system reset—a capability that makes using protected mode more practical. In addition, the 386 has a new mode, called virtual real mode, which enables several real mode sessions to run simultaneously under protected mode.

The protected mode of the 386 is fully compatible with the protected mode of the 286. The protected mode for both chips often is called their native mode of operation, because these chips are designed for advanced operating systems such as OS/2 and Windows NT, which run only in protected mode. Intel extended the memory-addressing capabilities of 386 protected mode with a new MMU that provided advanced memory paging and program switching. These features were extensions of the 286 type of MMU, so the 386 remained fully compatible with the 286 at the system-code level.

The 386 chip's virtual real mode was new. In virtual real mode, the processor could run with hardware memory protection while simulating an 8086's real-mode operation. Multiple copies of DOS and other operating systems, therefore, could run simultaneously on this processor, each in a protected area of memory. If the programs in one segment crashed, the rest of the system was protected. Software commands could reboot the blown partition.

Numerous variations of the 386 chip exist, some of which are less powerful and some of which are less power-hungry. The following sections cover the members of the 386-chip family and their differences.

Figure 3.31 386 processor die. Photograph used by permission of Intel Corporation.

386DX Processors

The 386DX chip was the first of the 386 family members that Intel introduced. The 386 is a full 32-bit processor with 32-bit internal registers, a 32-bit internal data bus, and a 32-bit external data bus. The 386 contains 275,000 transistors in a VLSI (very large scale integration) circuit. The chip comes in a 132-pin package and draws approximately 400 milliamperes (ma), which is less power than even the 8086 requires. The 386 has a smaller power requirement because it is made of CMOS (complementary metal oxide semiconductor) materials. The CMOS design enables devices to consume extremely low levels of power.

The Intel 386 chip was available in clock speeds ranging from 16–33MHz; other manufacturers, primarily AMD and Cyrix, offered comparable versions with speeds up to 40MHz.

The 386DX can address 4GB of physical memory. Its built in virtual memory manager enables software designed to take advantage of enormous amounts of memory to act as though a system has 64TB of memory. (A terabyte (TB) is 1,099,511,627,776 bytes of memory, or about 1,000GB.)

386SX Processors

The 386SX was designed for systems designers who were looking for 386 capabilities at 286 system prices. Like the 286, the 386SX is restricted to only 16 bits when communicating with other system components, such as memory. Internally, however, the 386SX is identical to the DX chip;

the 386SX has 32-bit internal registers and can therefore run 32-bit software. The 386SX uses a 24-bit memory-addressing scheme like that of the 286, rather than the full 32-bit memory address bus of the standard 386. The 386SX, therefore, can address a maximum 16MB of physical memory rather than the 4GB of physical memory that the 386DX can address. Before it was discontinued, the 386SX was available in clock speeds ranging from 16–33MHz.

The 386SX signaled the end of the 286 because of the 386SX chip's superior MMU and the addition of the virtual real mode. Under a software manager such as Windows or OS/2, the 386SX can run numerous DOS programs at the same time. The capability to run 386-specific software is another important advantage of the 386SX over any 286 or older design. For example, Windows 3.1 runs nearly as well on a 386SX as it does on a 386DX.

Note

One common fallacy about the 386SX is that you can plug one into a 286 system and give the system 386 capabilities. This is not true; the 386SX chip is not pin-compatible with the 286 and does not plug into the same socket. Several upgrade products, however, have been designed to adapt the chip to a 286 system. In terms of raw speed, converting a 286 system to a 386 CPU chip results in little performance gain—286 motherboards are built with a restricted 16-bit interface to memory and peripherals. A 16MHz 386SX is not markedly faster than a 16MHz 286, but it does offer improved memory management capabilities on a motherboard designed for it, and the capability to run 386-specific software.

386SL Processors

The 386SL is another variation on the 386 chip. This low-power CPU had the same capabilities as the 386SX, but it was designed for laptop systems in which low power consumption was needed. The SL chips offered special power-management features that were important to systems that ran on batteries. The SL chip also offered several sleep modes to conserve power.

The chip included an extended architecture that contained a System Management Interrupt (SMI), which provided access to the power-management features. Also included in the SL chip was special support for LIM (Lotus Intel Microsoft) expanded memory functions and a cache controller. The cache controller was designed to control a 16–64KB external processor cache.

These extra functions account for the higher transistor count in the SL chips (855,000) compared with even the 386DX processor (275,000). The 386SL was available in 25MHz clock speed.

Intel offered a companion to the 386SL chip for laptops called the 82360SL I/O subsystem. The 82360SL provided many common peripheral functions such as serial and parallel ports, a direct memory access (DMA) controller, an interrupt controller, and power-management logic for the 386SL processor. This chip subsystem worked with the processor to provide an ideal solution for the small size and low power-consumption requirements of portable and laptop systems.

80387 Coprocessor

Although the 80387 chips ran asynchronously, 386 systems were designed so that the math chip runs at the same clock speed as the main CPU. Unlike the 80287 coprocessor, which was merely an 8087 with different pins to plug into the AT motherboard, the 80387 coprocessor was a high-performance math chip designed specifically to work with the 386.

All 387 chips used a low power-consumption CMOS design. The 387 coprocessor had two basic designs: the 387DX coprocessor, which was designed to work with the 386DX processor, and the 387SX coprocessor, which was designed to work with the 386SX, SL, or SLC processors.

Intel originally offered several speeds for the 387DX coprocessor. But when the company designed the 33MHz version, a smaller mask was required to reduce the lengths of the signal pathways in the chip. This increased the performance of the chip by roughly 20 percent.

Note

Because Intel lagged in developing the 387 coprocessor, some early 386 systems were designed with a socket for a 287 coprocessor. Performance levels associated with that union, however, leave much to be desired.

Installing a 387DX is easy, but you must be careful to orient the chip in its socket properly; otherwise, the chip will be destroyed. The most common cause of burned pins on the 387DX is incorrect installation. In many systems, the 387DX was oriented differently from other large chips. Follow the manufacturer's installation instructions carefully to avoid damaging the 387DX; Intel's warranty does not cover chips that are installed incorrectly.

Several manufacturers developed their own versions of the Intel 387 coprocessors, some of which were touted as being faster than the original Intel chips. The general compatibility record of these chips was very good.

Weitek Coprocessors

In 1981, several Intel engineers formed the Weitek Corporation. Weitek developed math coprocessors for several systems, including those based on Motorola processor designs. Intel originally contracted Weitek to develop a math coprocessor for the Intel 386 CPU, because Intel was behind in its own development of the 387 math coprocessor. The result was the Weitek 1167, a custom math coprocessor that uses a proprietary Weitek instruction set, which is incompatible with the Intel 387.

To use the Weitek coprocessor, your system must have the required additional socket, which was different from the standard Intel coprocessor sockets.

80386 Bugs

Some early 16MHz Intel 386DX processors had a small bug that appeared as a software problem. The bug, which apparently was in the chip's 32-bit multiply routine, manifested itself only when you ran true 32-bit code in a program such as OS/2 2.x, UNIX/386, or Windows in enhanced mode. Some specialized 386 memory-management software systems also may invoke this subtle bug, but 16-bit operating systems (such as DOS and OS/2 1.x) probably will not.

The bug usually causes the system to lock up. Diagnosing this problem can be difficult because the problem generally is intermittent and software-related. Running tests to find the bug is difficult; only Intel, with proper test equipment, can determine whether your chip has a bug. Some programs can diagnose the problem and identify a defective chip, but they cannot identify all defective chips. If a program indicates a bad chip, you certainly have a defective one; if the program passes the chip, you still might have a defective one.

Intel requested that its 386 customers return possibly defective chips for screening, but many vendors did not return them. Intel tested returned chips and replaced defective ones. The defective chips later were sold to bargain liquidators or systems houses that wanted chips that would not run 32-bit code. The defective chips were stamped with a 16-bit SW Only logo, indicating that they were authorized to run only 16-bit software.

Chips that passed the test, and all subsequent chips produced as bug-free, were marked with a double-sigma code (SS). 386DX chips that are not marked with either of these designations have not been tested by Intel and might be defective.

The following marking indicates that a chip has not yet been screened for the defect; it might be either good or bad.

80386-16

The following marking indicates that the chip has been tested and has the 32-bit multiply bug. The chip works with 16-bit software (such as DOS) but not with 32-bit, 386-specific software (such as Windows or OS/2).

80386-16

16-bit SW Only

The following mark on a chip indicates that it has been tested as defect-free. This chip fulfills all the capabilities promised for the 80386.

80386-16

SS

This problem was discovered and corrected before Intel officially added DX to the part number. So, if you have a chip labeled as 80386DX or 386DX, it does not have this problem.

Another problem with the 386DX can be stated more specifically. When 386-based versions of XENIX or other UNIX implementations are run on a computer that contains a 387DX math coprocessor, the computer locks up under certain conditions. The problem does not occur in the DOS environment, however. For the lockup to occur, all the following conditions must be in effect:

- Demand page virtual memory must be active.
- A 387DX must be installed and in use.
- DMA (direct memory access) must occur.
- The 386 must be in a wait state.

When all these conditions are true at the same instant, the 386DX ends up waiting for the 387DX and vice versa. Both processors will continue to wait for each other indefinitely. The problem is in certain versions of the 386DX, not in the 387DX math coprocessor.

Intel published this problem (Errata 21) immediately after it was discovered to inform its OEM customers. At that point, it became the responsibility of each manufacturer to implement a fix in

its hardware or software product. Some manufacturers, such as Compaq and IBM, responded by modifying their motherboards to prevent these lockups from occurring.

The Errata 21 problem occurs only in the B stepping version of the 386DX and not in the later D stepping version. You can identify the D stepping version of the 386DX by the letters DX in the part number (for example, 386DX-20). If DX is part of the chip's part number, the chip does not have this problem.

P4 (486) Fourth-Generation Processors

486 Processors

In the race for more speed, the Intel 80486 (normally abbreviated as 486) was another major leap forward. The additional power available in the 486 fueled tremendous growth in the software industry. Tens of millions of copies of Windows, and millions of copies of OS/2, have been sold largely because the 486 finally made the GUI of Windows and OS/2 a realistic option for people who work on their computers every day.

Four main features make a given 486 processor roughly twice as fast as an equivalent MHz 386 chip. These features are

- *Reduced instruction-execution time.* A single instruction in the 486 takes an average of only two clock cycles to complete, compared with an average of more than four cycles on the 386. Clock-multiplied versions such as the DX2 and DX4 further reduced this to about two cycles per instruction.
- *Internal (Level 1) cache.* The built-in cache has a hit ratio of 90–95 percent, which describes how often zero-wait-state read operations will occur. External caches can improve this ratio further.
- *Burst-mode memory cycles.* A standard 32-bit (4-byte) memory transfer takes two clock cycles. After a standard 32-bit transfer, more data up to the next 12 bytes (or three transfers) can be transferred with only one cycle used for each 32-bit (4-byte) transfer. Thus, up to 16 bytes of contiguous, sequential memory data can be transferred in as little as five cycles instead of eight cycles or more. This effect can be even greater when the transfers are only 8 bits or 16 bits each.

▶▶ See "Burst EDO," p. 428.

- *Built-in (synchronous) enhanced math coprocessor (some versions).* The math coprocessor runs synchronously with the main processor and executes math instructions in fewer cycles than previous designs did. On average, the math coprocessor built into the DX-series chips provides two to three times greater math performance than an external 387 chip.

The 486 chip is about twice as fast as the 386, which means that a 386DX-40 is about as fast as a 486SX-20. This made the 486 a much more desirable option, primarily because it could more easily be upgraded to a DX2 or DX4 processor at a later time. You can see why the arrival of the 486 rapidly killed off the 386 in the marketplace.

Before the 486, many people avoided GUIs because they didn't have time to sit around waiting for the hourglass, which indicates that the system is performing behind-the-scenes operations

that the user cannot interrupt. The 486 changed that situation. Many people believe that the 486 CPU chip spawned the widespread acceptance of GUIs.

With the release of its faster Pentium CPU chip, Intel began to cut the price of the 486 line to entice the industry to shift over to the 486 as the mainstream system. Intel later did the same thing with its Pentium chips, spelling the end of the 486 line. The 486 is now offered by Intel only for use in embedded microprocessor applications, used primarily in expansion cards.

Most of the 486 chips were offered in a variety of maximum speed ratings, varying from 16MHz up to 120MHz. Additionally, 486 processors have slight differences in overall pin configurations. The DX, DX2, and SX processors have a virtually identical 168-pin configuration, whereas the OverDrive chips have either the standard 168-pin configuration or a specially modified 169-pin OverDrive (sometimes also called 487SX) configuration. If your motherboard has two sockets, the primary one likely supports the standard 168-pin configuration, and the secondary (OverDrive) socket supports the 169-pin OverDrive configuration. Most newer motherboards with a single ZIF socket support any of the 486 processors except the DX4. The DX4 is different because it requires 3.3v to operate instead of 5v, like most other chips up to that time.

A processor rated for a given speed always functions at any of the lower speeds. A 100MHz-rated 486DX4 chip, for example, runs at 75MHz if it is plugged into a 25MHz motherboard. Note that the DX2/OverDrive processors operate internally at two times the motherboard clock rate, whereas the DX4 processors operate at two, two and a half, or three times the motherboard clock rate. Table 3.19 shows the different speed combinations that can result from using the DX2 or DX4 processors with different motherboard clock speeds.

Table 3.19 Intel DX2 and DX4 Operating Speeds Versus Motherboard Clock Speeds

Processor speed	DX2 (2× mode) Speed	DX4(2.5× mode) Speed	DX4 (3× mode) Speed	DX4
16MHz Motherboard	32MHz	32MHz	40MHz	48MHz
40MHz Motherboard	80MHz	80MHz	100MHz	120MHz
20MHz Motherboard	40MHz	40MHz	50MHz	60MHz
50MHz Motherboard	n/a	100MHz	n/a	n/a
25MHz Motherboard	50MHz	50MHz	63MHz	75MHz
33MHz Motherboard	66MHz	66MHz	83MHz	100MHz

The internal core speed of the DX4 processor is controlled by the CLKMUL (Clock Multiplier) signal at pin R-17 (Socket 1) or S-18 (Socket 2, 3, or 6). The CLKMUL input is sampled only during a reset of the CPU, and defines the ratio of the internal clock to the external bus frequency CLK signal at pin C-3 (Socket 1) or D-4 (Socket 2, 3, or 6). If CLKMUL is sampled low, the internal core speed will be two times the external bus frequency. If driven high or left floating (most motherboards would leave it floating), triple speed mode is selected. If the CLKMUL signal is connected to the BREQ (Bus Request) output signal at pin Q-15 (Socket 1) or R-16 (Socket 2, 3, or 6), the CPU internal core speed will be two and a half times the CLK speed. To summarize, here is how the socket has to be wired for each DX4 speed selection:

CPU Speed	CLKMUL (Sampled Only at CPU Reset)
2x	Low
2.5x	Connected to BREQ
3x	High or Floating

You will have to determine how your particular motherboard is wired and whether it can be changed to alter the CPU core speed in relation to the CLK signal. In most cases, there would be one or two jumpers on the board near the processor socket. The motherboard documentation should cover these settings if they can be changed.

One interesting capability here is to run the DX4-100 chip in a doubled mode with a 50MHz motherboard speed. This would give you a very fast memory bus, along with the same 100MHz processor speed, as if you were running the chip in a 33/100MHz tripled mode.

Note

One caveat is that if your motherboard has VL-Bus slots, they will have to be slowed down to 33 or 40MHz to operate properly.

Many VL-Bus motherboards can run the VL-Bus slots in a buffered mode, add wait states, or even selectively change the clock only for the VL-Bus slots to keep them compatible. In most cases, they will not run properly at 50MHz. Consult your motherboard—or even better, your chipset documentation—to see how your board is set up.

Caution

If you are upgrading an existing system, be sure that your socket will support the chip that you are installing. In particular, if you are putting a DX4 processor in an older system, you need some type of adapter to regulate the voltage down to 3.3v. If you put the DX4 in a 5v socket, you will destroy the chip! See the earlier section on processor sockets for more information.

The 486-processor family is designed for greater performance than previous processors because it integrates formerly external devices, such as cache controllers, cache memory, and math coprocessors. Also, 486 systems were the first designed for true processor upgradability. Most 486 systems can be upgraded by simple processor additions or swaps that can effectively double the speed of the system.

486DX Processors

The original Intel 486DX processor was introduced on April 10, 1989, and systems using this chip first appeared during 1990. The first chips had a maximum speed rating of 25MHz; later versions of the 486DX were available in 33MHz- and 50MHz-rated versions. The 486DX originally was available only in a 5v, 168-pin PGA version, but now is also available in 5v, 196-pin PQFP (Plastic Quad Flat Pack) and 3.3v, 208-pin SQFP (Small Quad Flat Pack). These latter form factors are available in SL Enhanced versions, which are intended primarily for portable or laptop applications in which saving power is important.

Two main features separate the 486 processor from older processors:

- The 486DX integrates functions such as the math coprocessor, cache controller, and cache memory into the chip.
- The 486 also was designed with upgradability in mind; double-speed OverDrive are upgrades available for most systems.

The 486DX processor is fabricated with low-power CMOS (complementary metal oxide semiconductor) technology. The chip has a 32-bit internal register size, a 32-bit external data bus, and a 32-bit address bus. These dimensions are equal to those of the 386DX processor. The internal register size is where the “32-bit” designation used in advertisements comes from. The 486DX chip contains 1.2 million transistors on a piece of silicon no larger than your thumbnail. This figure is more than four times the number of components on 386 processors and should give you a good indication of the 486 chip’s relative power. The die for the 486 is shown in Figure 3.32.

The standard 486DX contains a processing unit, a floating-point unit (math coprocessor), a memory-management unit, and a cache controller with 8KB of internal-cache RAM. Due to the internal cache and a more efficient internal processing unit, the 486 family of processors can execute individual instructions in an average of only two processor cycles. Compare this figure with the 286 and 386 families, both of which execute an average 4.5 cycles per instruction. Compare it also with the original 8086 and 8088 processors, which execute an average 12 cycles per instruction. At a given clock rate (MHz), therefore, a 486 processor is roughly twice as efficient as a 386 processor; a 16MHz 486SX is roughly equal to a 33MHz 386DX system; and a 20MHz 486SX is equal to a 40MHz 386DX system. Any of the faster 486s are way beyond the 386 in performance.

The 486 is fully instruction-set-compatible with previous Intel processors, such as the 386, but offers several additional instructions (most of which have to do with controlling the internal cache).

Like the 386DX, the 486 can address 4GB of physical memory and manage as much as 64TB of virtual memory. The 486 fully supports the three operating modes introduced in the 386: real mode, protected mode, and virtual real mode.

- *In real mode*, the 486 (like the 386) runs unmodified 8086-type software.
- *In protected mode*, the 486 (like the 386) offers sophisticated memory paging and program switching.

- *In virtual real mode*, the 486 (like the 386) can run multiple copies of DOS or other operating systems while simulating an 8086's real mode operation. Under an operating system such as Windows or OS/2, therefore, both 16-bit and 32-bit programs can run simultaneously on this processor with hardware memory protection. If one program crashes, the rest of the system is protected, and you can reboot the blown portion through various means, depending on the operating software.

Figure 3.32 486 processor die. Photograph used by permission of Intel Corporation.

The 486DX series has a built-in math coprocessor that sometimes is called an MCP (math coprocessor) or FPU (floating-point unit). This series is unlike previous Intel CPU chips, which required you to add a math coprocessor if you needed faster calculations for complex mathematics. The FPU in the 486DX series is 100 percent software-compatible with the external 387 math coprocessor used with the 386, but it delivers more than twice the performance. It runs in synchronization with the main processor and executes most instructions in half as many cycles as the 386.

486SL

The 486SL was a short-lived, standalone chip. The SL enhancements and features became available in virtually all the 486 processors (SX, DX, and DX2) in what are called SL enhanced versions. SL enhancement refers to a special design that incorporates special power-saving features.

The SL enhanced chips originally were designed to be installed in laptop or notebook systems that run on batteries, but they found their way into desktop systems, as well. The SL enhanced chips featured special power-management techniques, such as sleep mode and clock throttling, to reduce power consumption when necessary. These chips were available in 3.3v versions, as well.

Intel designed a power-management architecture called system management mode (SMM). This mode of operation is totally isolated and independent from other CPU hardware and software. SMM provides hardware resources such as timers, registers, and other I/O logic that can control and power down mobile-computer components without interfering with any of the other system resources. SMM executes in a dedicated memory space called system management memory, which is not visible and does not interfere with operating system and application software. SMM has an interrupt called system management interrupt (SMI), which services power-management events and is independent from, and higher priority than, any of the other interrupts.

SMM provides power management with flexibility and security that were not available previously. For example, an SMI occurs when an application program tries to access a peripheral device that is powered down for battery savings, which powers up the peripheral device and reexecutes the I/O instruction automatically.

Intel also designed a feature called suspend/resume in the SL processor. The system manufacturer can use this feature to provide the portable computer user with instant-on-and-off capability. An SL system typically can resume (instant on) in one second from the suspend state (instant off) to exactly where it left off. You do not need to reboot, load the operating system, load the application program, and then load the application data. Simply push the Suspend/Resume button and the system is ready to go.

The SL CPU was designed to consume almost no power in the suspend state. This feature means that the system can stay in the suspend state possibly for weeks and yet start up instantly right where it left off. An SL system can keep working data in normal RAM memory safe for a long time while it is in the suspend state, but saving to a disk still is prudent.

486SX

The 486SX, introduced in April 1991, was designed to be sold as a lower cost version of the 486. The 486SX is virtually identical to the full DX processor, but the chip does not incorporate the FPU or math coprocessor portion.

As you read earlier in this chapter, the 386SX was a scaled-down (some people would say crippled) 16-bit version of the full-blown 32-bit 386DX. The 386SX even had a completely different pinout and was not interchangeable with the more powerful DX version. The 486SX, however, is a different story. The 486SX is, in fact, a full-blown 32-bit 486 processor that is basically pin-compatible with the DX. A few pin functions are different or rearranged, but each pin fits into the same socket.

The 486SX chip is more a marketing quirk than new technology. Early versions of the 486SX chip actually were DX chips that showed defects in the math-coprocessor section. Instead of being

scrapped, the chips were packaged with the FPU section disabled and sold as SX chips. This arrangement lasted for only a short time; thereafter, SX chips got their own mask, which is different from the DX mask. (A *mask* is the photographic blueprint of the processor and is used to etch the intricate signal pathways into a silicon chip.) The transistor count dropped to 1.185 million (from 1.2 million) to reflect this new mask.

The 486SX chip is twice as fast as a 386DX with the same clock speed. Intel marketed the 486SX as being the ideal chip for new computer buyers, because fewer entry-level programs of that day used math-coprocessor functions.

The 486SX was normally available in 16, 20, 25, and 33MHz-rated speeds, and there was also a 486 SX/2 that ran at up to 50 or 66MHz. The 486SX normally comes in a 168-pin version, although other surface-mount versions are available in SL enhanced models.

Despite what Intel's marketing and sales information implies, no technical provision exists for adding a separate math coprocessor to a 486SX system; neither is a separate math coprocessor chip available to plug in. Instead, Intel wanted you to add a new 486 processor with a built-in math unit and disable the SX CPU that already was on the motherboard. If this situation sounds confusing, read on, because this topic brings you to the most important aspect of 486 design: upgradability.

487SX

The 487SX math coprocessor, as Intel calls it, really is a complete 25MHz 486DX CPU with an extra pin added and some other pins rearranged. When the 487SX is installed in the extra socket provided in a 486SX CPU-based system, the 487SX turns off the existing 486SX via a new signal on one of the pins. The extra key pin actually carries no signal itself and exists only to prevent improper orientation when the chip is installed in a socket.

The 487SX takes over all CPU functions from the 486SX and also provides math coprocessor functionality in the system. At first glance, this setup seems rather strange and wasteful, so perhaps further explanation is in order. Fortunately, the 487SX turned out to be a stopgap measure while Intel prepared its real surprise: the OverDrive processor. The DX2/OverDrive speed-doubling chips, which are designed for the 487SX 169-pin socket, have the same pinout as the 487SX. These upgrade chips are installed in exactly the same way as the 487SX; therefore, any system that supports the 487SX also supports the DX2/OverDrive chips.

Although in most cases you can upgrade a system by removing the 486SX CPU and replacing it with a 487SX (or even a DX or DX2/OverDrive), Intel originally discouraged this procedure. Instead, Intel recommended that PC manufacturers include a dedicated upgrade (OverDrive) socket in their systems, because several risks were involved in removing the original CPU from a standard socket. (The following section elaborates on those risks.) Now Intel recommends—or even insists on—the use of a single processor socket of a ZIF design, which makes upgrading an easy task physically.

Very few early 486 systems had a socket for the Weitek 4167 coprocessor chip for 486 systems that existed in November 1989.

DX2/OverDrive and DX4 Processors

On March 3, 1992, Intel introduced the DX2 speed-doubling processors. On May 26, 1992, Intel announced that the DX2 processors also would be available in a retail version called OverDrive. Originally, the OverDrive versions of the DX2 were available only in 169-pin versions, which meant that they could be used only with 486SX systems that had sockets configured to support the rearranged pin configuration.

On September 14, 1992, Intel introduced 168-pin OverDrive versions for upgrading 486DX systems. These processors could be added to existing 486 (SX or DX) systems as an upgrade, even if those systems did not support the 169-pin configuration. When you use this processor as an upgrade, you install the new chip in your system, which subsequently runs twice as fast.

The DX2/OverDrive processors run internally at twice the clock rate of the host system. If the motherboard clock is 25MHz, for example, the DX2/OverDrive chip runs internally at 50MHz; likewise, if the motherboard is a 33MHz design, the DX2/OverDrive runs at 66MHz. The DX2/OverDrive speed doubling has no effect on the rest of the system; all components on the motherboard run the same as they do with a standard 486 processor. Therefore, you do not have to change other components (such as memory) to accommodate the double-speed chip. The DX2/OverDrive chips have been available in several speeds. Three different speed-rated versions have been offered:

- 40MHz DX2/OverDrive for 16MHz or 20MHz systems
- 50MHz DX2/OverDrive for 25MHz systems
- 66MHz DX2/OverDrive for 33MHz systems

Notice that these ratings indicate the maximum speed at which the chip is capable of running. You could use a 66MHz-rated chip in place of the 50MHz- or 40MHz-rated parts with no problem, although the chip will run only at the slower speeds. The actual speed of the chip is double the motherboard clock frequency. When the 40MHz DX2/OverDrive chip is installed in a 16MHz 486SX system, for example, the chip will function only at 32MHz—exactly double the motherboard speed. Intel originally stated that no 100MHz DX2/OverDrive chip would be available for 50MHz systems—which technically has not been true, because the DX4 could be set to run in a clock-doubled mode and used in a 50MHz motherboard (see the discussion of the DX4 processor in this section).

The only part of the DX2 chip that doesn't run at double speed is the bus interface unit, a region of the chip that handles I/O between the CPU and the outside world. By translating between the differing internal and external clock speeds, the bus interface unit makes speed doubling transparent to the rest of the system. The DX2 appears to the rest of the system to be a regular 486DX chip, but one that seems to execute instructions twice as fast.

DX2/OverDrive chips are based on the 0.8 micron circuit technology that was first used in the 50MHz 486DX. The DX2 contains 1.1 million transistors in a three-layer form. The internal 8KB

cache, integer, and floating-point units all run at double speed. External communication with the PC runs at normal speed to maintain compatibility.

Besides upgrading existing systems, one of the best parts of the DX2 concept was the fact that system designers could introduce very fast systems by using cheaper motherboard designs, rather than the more costly designs that would support a straight high-speed clock. This means that a 50MHz 486DX2 system was much less expensive than a straight 50MHz 486DX system. The system board in a 486DX-50 system operates at a true 50MHz. The 486DX2 CPU in a 486DX2-50 system operates internally at 50MHz, but the motherboard operates at only 25MHz.

You may be thinking that a true 50MHz DX processor-based system still would be faster than a speed-doubled 25MHz system, and this generally is true. But, the differences in speed actually are very slight—a real testament to the integration of the 486 processor and especially to the cache design.

When the processor has to go to system memory for data or instructions, for example, it has to do so at the slower motherboard operating frequency (such as 25MHz). Because the 8KB internal cache of the 486DX2 has a hit rate of 90–95 percent, however, the CPU has to access system memory only 5–10 percent of the time for memory reads. Therefore, the performance of the DX2 system can come very close to that of a true 50MHz DX system and cost much less. Even though the motherboard runs only at 33.33MHz, a system with a DX2 66MHz processor ends up being faster than a true 50MHz DX system, especially if the DX2 system has a good L2 cache.

Many 486 motherboard designs also include a secondary cache that is external to the cache integrated into the 486 chip. This external cache allows for much faster access when the 486 chip calls for external-memory access. The size of this external cache can vary anywhere from 16KB to 512K or more. When you add a DX2 processor, an external cache is even more important for achieving the greatest performance gain. This cache greatly reduces the wait states that the processor will have to add when writing to system memory or when a read causes an internal cache miss. For this reason, some systems perform better with the DX2/OverDrive processors than others, usually depending on the size and efficiency of the external-memory cache system on the motherboard. Systems that have no external cache will still enjoy a near-doubling of CPU performance, but operations that involve a great deal of memory access will be slower.

This brings us to the DX4 processor. Although the standard DX4 technically was not sold as a retail part, it could be purchased from several vendors, along with the 3.3v voltage adapter needed to install the chip in a 5v socket. These adapters have jumpers that enable you to select the DX4 clock multiplier and set it to 2x, 2.5x, or 3x mode. In a 50MHz DX system, you could install a DX4/voltage-regulator combination set in 2x mode for a motherboard speed of 50MHz and a processor speed of 100MHz! Although you may not be able to take advantage of certain VL-Bus adapter cards, you will have one of the fastest 486-class PCs available.

Intel also sold a special DX4 OverDrive processor that included a built-in voltage regulator and heat sink that are specifically designed for the retail market. The DX4 OverDrive chip is essentially the same as the standard 3.3v DX4 with the main exception that it runs on 5v because it includes an on-chip regulator. Also, the DX4 OverDrive chip will run only in the tripled speed mode, and not the 2x or 2.5x modes of the standard DX4 processor.

Note

As of this writing, Intel has discontinued all 486 and DX2/DX4/OverDrive processors, including the so-called Pentium OverDrive processor.

Pentium OverDrive for 486SX2 and DX2 Systems

The Pentium OverDrive Processor became available in 1995. An OverDrive chip for 486DX4 systems had been planned, but poor marketplace performance of the SX2/DX2 chip meant that it never saw the light of day. One thing to keep in mind about the 486 Pentium OverDrive chip is that although it is intended primarily for SX2 and DX2 systems, it should work in any upgradable 486SX or DX system that has a Socket 2 or Socket 3. If in doubt, check Intel's online upgrade guide for compatibility.

The Pentium OverDrive processor is designed for systems that have a processor socket that follows the Intel Socket 2 specification. This processor also will work in systems that have a Socket 3 design, although you should ensure that the voltage is set for 5v rather than 3.3v. The Pentium OverDrive chip includes a 32KB internal L1 cache, and the same superscalar (multiple instruction path) architecture of the real Pentium chip. Besides a 32-bit Pentium core, these processors feature increased clock-speed operation due to internal clock multiplication and incorporate an internal write-back cache (standard with the Pentium). If the motherboard supports the write-back cache function, increased performance will be realized. Unfortunately, most motherboards, especially older ones with the Socket 2 design, only support write-through cache.

Most tests of these OverDrive chips show them to be only slightly ahead of the DX4-100 and behind the DX4-120 and true Pentium 60, 66, or 75. Unfortunately, these are the only solutions still offered by Intel for upgrading the 486. Based on the relative affordability of low-end "real" Pentiums (in their day), it was hard not to justify making the step up to a Pentium system. At the time, I did not recommend the 486 Pentium OverDrive chips as a viable solution for the future.

"Vacancy"—Secondary OverDrive Sockets

Perhaps you saw the Intel advertisements—both print and television—that featured a 486SX system with a neon Vacancy sign pointing to an empty socket next to the CPU chip. Unfortunately, these ads were not very informative, and they made it seem that only systems with the extra socket could be upgraded. I was worried when I first saw these ads because I had just purchased a 486DX system, and the advertisements implied that only 486SX systems with the empty OverDrive socket were upgradable. This, of course, was not true, but the Intel advertisements did not communicate that fact very well.

I later found that upgradability does not depend on having an extra OverDrive socket in the system and that virtually any 486SX or DX system can be upgraded. The secondary OverDrive socket was designed to make upgrading easier and more convenient. Even in systems that have the second socket, you can actually remove the primary SX or DX CPU and plug the OverDrive processor directly into the main CPU socket, rather than into the secondary OverDrive socket.

In that case, you would have an upgraded system with a single functioning CPU installed; you could remove the old CPU from the system and sell it or trade it in for a refund. Unfortunately, Intel does not offer a trade-in or core-charge policy; it does not want your old chip. For this reason, some people saw the OverDrive socket as being a way for Intel to sell more CPUs. Some valid reasons exist, however, to use the OverDrive socket and leave the original CPU installed.

One reason is that many PC manufacturers void the system warranty if the CPU has been removed from the system. Also, most manufacturers require that the system be returned with only the original parts when systems are serviced; you must remove all add-in cards, memory modules, upgrade chips, and similar items before sending the system in for servicing. If you replace the original CPU when you install the upgrade, returning the system to its original condition will be much more difficult.

Another reason for using the upgrade socket is that the system will not function if the main CPU socket is damaged when you remove the original CPU or install the upgrade processor. By contrast, if a secondary upgrade socket is damaged, the system still should work with the original CPU.

80487 Upgrade

The Intel 80486 processor was introduced in late 1989, and systems using this chip appeared during 1990. The 486DX integrated the math coprocessor into the chip.

The 486SX began life as a full-fledged 486DX chip, but Intel actually disabled the built-in math coprocessor before shipping the chip. As part of this marketing scheme, Intel marketed what it called a 487SX math coprocessor. Motherboard manufacturers installed an Intel-designed socket for this so-called 487 chip. In reality, however, the 487SX math chip was a special 486DX chip with the math coprocessor enabled. When you plugged this chip into your motherboard, it disabled the 486SX chip and gave you the functional equivalent of a full-fledged 486DX system.

AMD 486 (5x86)

AMD makes a line of 486-compatible chips that install into standard 486 motherboards. In fact, AMD makes the fastest 486 processor available, which they call the Am5x86(TM)-P75. The name is a little misleading, as the 5x86 part makes some people think that this is a fifth-generation Pentium-type processor. In reality, it is a fast clock-multiplied (4x clock) 486 that runs at four times the speed of the 33MHz 486 motherboard you plug it into.

The 5x85 offers high-performance features such as a unified 16KB write-back cache and 133MHz core clock speed; it is approximately comparable to a Pentium 75, which is why it is denoted with a P-75 in the part number. It is the ideal choice for cost-effective 486 upgrades, where changing the motherboard is difficult or impossible.

Not all motherboards support the 5x86. The best way to verify that your motherboard supports the chip is by checking with the documentation that came with the board. Look for keywords such as "Am5X86," "AMD-X5," "clock-quadrupled," "133MHz," or other similar wording. Another good way to determine whether your motherboard supports the AMD 5x86 is to look for it in the listed models on AMD's Web site.

There are a few things to note when installing a 5x86 processor into a 486 motherboard:

- The operating voltage for the 5x86 is 3.45v +/- 0.15v. Not all motherboards may have this setting, but most that incorporate a Socket 3 design should. If your 486 motherboard is a Socket 1 or 2 design, you cannot use the 5x86 processor directly. The 3.45 volt processor will not operate in a 5-volt socket and may be damaged. To convert a 5-volt motherboard to 3.45 volts, adapters can be purchased from several vendors including Kingston, Evergreen, and AMP. In fact, Kingston and Evergreen sell the 5x86 complete with a voltage regulator adapter attached in an easy-to-install package. These versions are ideal for older 486 motherboards that don't have a Socket 3 design.
- It is generally better to purchase a new motherboard with Socket 3 than to buy one of these adapters; however, 486 motherboards are hard to find these days, and your old board may be in a proprietary form factor for which it is impossible to find a replacement. Buying a new motherboard is also better than using an adapter because the older BIOS may not understand the requirements of the processor as far as speed is concerned. BIOS updates are often required with older boards.
- Most Socket 3 motherboards have jumpers, allowing you to set the voltage manually. Some boards don't have jumpers, but have voltage autodetect instead. These systems check the VOLDET pin (pin S4) on the microprocessor when the system is powered on.
- The VOLDET pin is tied to ground (Vss) internally to the microprocessor. If you cannot find any jumpers for setting voltage, you can check the motherboard as follows: Switch the PC off, remove the microprocessor, connect pin S4 to a Vss pin on the ZIF socket, power on, and check any Vcc pin with a voltmeter. This should read 3.45 (\pm 0.15) volts. See the previous section on CPU sockets for the pinout.
- The 5x86 requires a 33MHz motherboard speed, so be sure the board is set to that frequency. The 5x86 operates at an internal speed of 133MHz. Therefore, the jumpers must be set for "clock-quadrupled" or "4x clock" mode. By setting the jumpers correctly on the motherboard, the CLKMUL pin (pin R17) on the processor will be connected to ground (Vss). If there is no 4x clock setting, the standard DX2 2x clock setting should work.
- Some motherboards have jumpers that configure the internal cache in either write-back (WB) or write-through (WT) mode. They do this by pulling the WB/WT pin (pin B13) on the microprocessor to logic High (Vcc) for WB or to ground (Vss) for WT. For best performance, configure your system in WB mode; however, reset the cache to WT mode if there are problems running applications or the floppy drive doesn't work right (DMA conflicts).
- The 5x86 runs hot, so a heat sink is required; it normally must have a fan.

In addition to the 5x86, the AMD enhanced 486 product line includes 80MHz, 100MHz, and 1,20MHz CPUs. These are the A80486DX2-80SV8B (40MHz \times 2), A80486DX4-100SV8B (33MHz \times 3), and the A80486DX4-120SV8B (40MHz \times 3).

Cyrix/TI 486

The Cyrix 486DX2/DX4 processors were available in 100MHz, 80MHz, 75MHz, 66MHz, and 50MHz versions. Like the AMD 486 chips, the Cyrix versions are fully compatible with Intel's 486 processors and work in most 486 motherboards.

The Cx486DX2/DX4 incorporates an 8KB write-back cache, an integrated floating-point unit, advanced power management, and SMM, and was available in 3.3v versions.

Note

TI originally made all the Cyrix-designed 486 processors, and under their agreement they also sold them under the TI name. Eventually, TI and Cyrix had a falling out, and now IBM makes most of the Cyrix chips, although that might change since National Semiconductor has purchased Cyrix, and is now attempting to sell it.

P5 (586) Fifth-Generation Processors

Pentium Processors

On October 19, 1992, Intel announced that the fifth generation of its compatible microprocessor line (code-named P5) would be named the Pentium processor rather than the 586, as everybody had been assuming. Calling the new chip the 586 would have been natural, but Intel discovered that it could not trademark a number designation, and the company wanted to prevent other manufacturers from using the same name for any clone chips that they might develop. The actual Pentium chip shipped on March 22, 1993. Systems that use these chips were only a few months behind.

The Pentium is fully compatible with previous Intel processors, but it also differs from them in many ways. At least one of these differences is revolutionary: The Pentium features twin data pipelines, which enable it to execute two instructions at the same time. The 486 and all preceding chips can perform only a single instruction at a time. Intel calls the capability to execute two instructions at the same time superscalar technology. This technology provides additional performance compared with the 486.

The standard 486 chip can execute a single instruction in an average of two clock cycles—cut to an average of one clock cycle with the advent of internal clock multiplication used in the DX2 and DX4 processors. With superscalar technology, the Pentium can execute many instructions at a rate of two instructions per cycle. Superscalar architecture usually is associated with high-output RISC (Reduced Instruction Set Computer) chips. The Pentium is one of the first CISC (Complex Instruction Set Computer) chips to be considered superscalar. The Pentium is almost like having two 486 chips under the hood. Table 3.20 shows the Pentium processor specifications.

Table 3.20 Pentium Processor Specifications

Introduced	March 22, 1993 (first generation); March 7, 1994 (second generation)
Maximum rated speeds	60, 66, 75, 90, 100, 120, 133, 150, 166, 200MHz (second generation)
CPU clock multiplier	1x (first generation), 1.5x–3x (second generation)
Register size	32-bit
External data bus	64-bit
Memory address bus	32-bit
Maximum memory	4GB
Integral-cache size	8KB code, 8KB data
Integral-cache type	Two-way set associative, write-back Data
Burst-mode transfers	Yes

(continues)

Table 3.20 Continued

Number of transistors	3.1 million
Circuit size	0.8 micron (60/66MHz), 0.6 micron (75–100MHz), 0.35 micron (120MHz and up)
External package	273-pin PGA, 296-pin SPGA, tape carrier
Math coprocessor	Built-in FPU (floating-point unit)
Power management	SMM (system management mode), enhanced in second generation
Operating voltage	5v (first generation), 3.465v, 3.3v, 3.1v, 2.9v (second generation)

PGA = Pin Grid Array

SPGA = Staggered Pin Grid Array

The two instruction pipelines within the chip are called the *u-* and *v-*pipes. The *u-pipe*, which is the primary pipe, can execute all integer and floating-point instructions. The *v-pipe* is a secondary pipe that can execute only simple integer instructions and certain floating-point instructions. The process of operating on two instructions simultaneously in the different pipes is called *pairing*. Not all sequentially executing instructions can be paired, and when pairing is not possible, only the *u-pipe* is used. To optimize the Pentium's efficiency, you can recompile software to allow more instructions to be paired.

The Pentium is 100 percent software-compatible with the 386 and 486, and although all current software will run much faster on the Pentium, many software manufacturers want to recompile their applications to exploit even more of the Pentium's true power. Intel has developed new compilers that will take full advantage of the chip; the company will license the technology to compiler firms so that software developers can take advantage of the Pentium's superscalar (parallel processing) capability. This optimization rapidly started to appear in the software on the market. Optimized software improved performance by allowing more instructions to execute simultaneously in both pipes.

The Pentium processor has a Branch Target Buffer (BTB), which employs a technique called branch prediction. It minimizes stalls in one or more of the pipes caused by delays in fetching instructions that branch to nonlinear memory locations. The BTB attempts to predict whether a program branch will be taken, and then fetches the appropriate instructions. The use of branch prediction enables the Pentium to keep both pipelines operating at full speed. Figure 3.33 shows the internal architecture of the Pentium processor.

The Pentium has a 32-bit address bus width, giving it the same 4GB memory-addressing capabilities as the 386DX and 486 processors. But the Pentium expands the data bus to 64 bits, which means that it can move twice as much data into or out of the CPU, compared with a 486 of the same clock speed. The 64-bit data bus requires that system memory be accessed 64 bits wide, which means that each bank of memory is 64 bits.

On most motherboards, memory is installed via SIMMs (Single Inline Memory Modules) or DIMMs (Dual Inline Memory Modules). SIMMs are available in 8-bit-wide and 32-bit-wide versions, while DIMMs are 64 bits wide. There are also versions with additional bits for parity or ECC (error correcting code) data. Most Pentium systems use the 32-bit-wide SIMMs—two of these

SIMMs per bank of memory. Most Pentium motherboards have at least four of these 32-bit SIMM sockets, providing for a total of two banks of memory. The newest Pentium systems and most Pentium II systems today use DIMMs, which are 64 bits wide—just like the processor's external data bus so only one DIMM is used per bank. This makes installing or upgrading memory much easier because DIMMs can go in one at a time and don't have to be matched up in pairs.

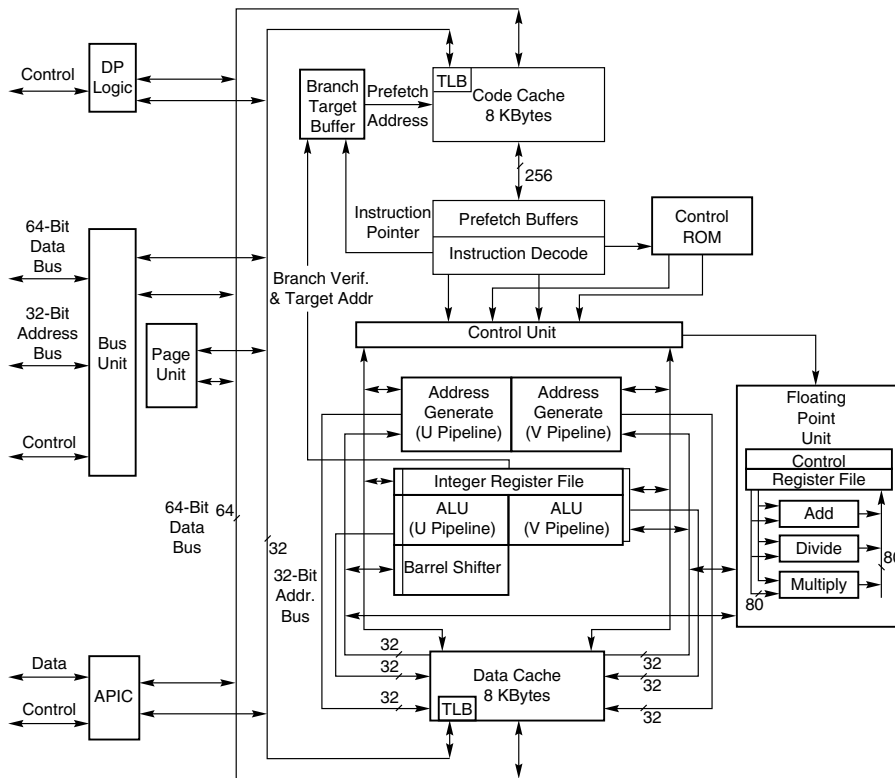

Figure 3.33 Pentium processor internal architecture.

►► See “SIMMs and DIMMs,” p. 437, and “Memory Banks,” p. 451.

Even though the Pentium has a 64-bit data bus that transfers information 64 bits at a time into and out of the processor, the Pentium has only 32-bit internal registers. As instructions are being processed internally, they are broken down into 32-bit instructions and data elements, and processed in much the same way as in the 486. Some people thought that Intel was misleading them by calling the Pentium a 64-bit processor, but 64-bit transfers do indeed take place. Internally, however, the Pentium has 32-bit registers that are fully compatible with the 486.

The Pentium has two separate internal 8KB caches, compared with a single 8KB or 16KB cache in the 486. The cache-controller circuitry and the cache memory are embedded in the CPU chip. The cache mirrors the information in normal RAM by keeping a copy of the data and code from different memory locations. The Pentium cache also can hold information to be written to

memory when the load on the CPU and other system components is less. (The 486 makes all memory writes immediately.)

The separate code and data caches are organized in a two-way set associative fashion, with each set split into lines of 32 bytes each. Each cache has a dedicated Translation Lookaside Buffer (TLB) that translates linear addresses to physical addresses. You can configure the data cache as write-back or write-through on a line-by-line basis. When you use the write-back capability, the cache can store write operations and reads, further improving performance over read-only write-through mode. Using write-back mode results in less activity between the CPU and system memory—an important improvement, because CPU access to system memory is a bottleneck on fast systems. The code cache is an inherently write-protected cache because it contains only execution instructions and not data, which is updated. Because burst cycles are used, the cache data can be read or written very quickly.

Systems based on the Pentium can benefit greatly from secondary processor caches (L2), which usually consist of up to 512KB or more of extremely fast (15ns or less) Static RAM (SRAM) chips. When the CPU fetches data that is not already available in its internal processor (L1) cache, wait states slow the CPU. If the data already is in the secondary processor cache, however, the CPU can go ahead with its work without pausing for wait states.

The Pentium uses a BiCMOS (bipolar complementary metal oxide semiconductor) process and superscalar architecture to achieve the high level of performance expected from the chip. BiCMOS adds about 10 percent to the complexity of the chip design, but adds about 30–35 percent better performance without a size or power penalty.

All Pentium processors are SL enhanced, meaning that they incorporate the SMM to provide full control of power-management features, which helps reduce power consumption. The second-generation Pentium processors (75MHz and faster) incorporate a more advanced form of SMM that includes processor clock control. This allows you to throttle the processor up or down to control power use. You can even stop the clock with these more advanced Pentium processors, putting the processor in a state of suspension that requires very little power. The second-generation Pentium processors run on 3.3v power (instead of 5v), reducing power requirements and heat generation even further.

Many current motherboards supply either 3.465v or 3.3v. The 3.465v setting is called VRE (Voltage Reduced Extended) by Intel and is required by some versions of the Pentium, particularly some of the 100MHz versions. The standard 3.3v setting is called STD (Standard), which most of the second-generation Pentiums use. STD voltage means anything in a range from 3.135v to 3.465v with 3.3v nominal. There is also a special 3.3v setting called VR (Voltage Reduced), which reduces the range from 3.300v to 3.465v with 3.38v nominal. Some of the processors require this narrower specification, which most motherboards provide. Here is a summary:

Voltage Specification	Nominal	Tolerance	Minimum	Maximum
STD (Standard)	3.30v	±0.165	3.135v	3.465v
VR (Voltage Reduced)	3.38v	±0.083	3.300v	3.465v
VRE (VR Extended)	3.50v	±0.100	3.400v	3.600v

For even lower power consumption, Intel introduced special Pentium processors with Voltage Reduction Technology in the 75 to 266MHz family; the processors are intended for mobile computer applications. They do not use a conventional chip package and are instead mounted using a new format called tape carrier packaging (TCP). The tape carrier packaging does not encase the chip in ceramic or plastic as with a conventional chip package, but instead covers the actual processor die directly with a thin, protective plastic coating. The entire processor is less than 1mm thick, or about half the thickness of a dime, and weighs less than 1 gram. They are sold to system manufacturers in a roll that looks very much like a filmstrip. The TCP processor is directly affixed (soldered) to the motherboard by a special machine, resulting in a smaller package, lower height, better thermal transfer, and lower power consumption. Special solder plugs on the circuit board located directly under the processor draw heat away and provide better cooling in the tight confines of a typical notebook or laptop system—no cooling fans are required. For more information on mobile processors and systems, see Chapter 23, “Portable PCs.”

The Pentium, like the 486, contains an internal math coprocessor or FPU. The FPU in the Pentium has been rewritten and performs significantly better than the FPU in the 486, yet it is fully compatible with the 486 and 387 math coprocessor. The Pentium FPU is estimated at two to as much as 10 times faster than the FPU in the 486. In addition, the two standard instruction pipelines in the Pentium provide two units to handle standard integer math. (The math coprocessor handles only more complex calculations.) Other processors, such as the 486, have only a single-standard execution pipe and one integer math unit. Interestingly, the Pentium FPU contains a flaw that received widespread publicity. See the discussion in the section “Pentium Defects,” later in this chapter.

First-Generation Pentium Processor

The Pentium has been offered in three basic designs, each with several versions. The first-generation design, which is no longer available, came in 60 and 66MHz processor speeds. This design used a 273-pin PGA form factor and ran on 5v power. In this design, the processor ran at the same speed as the motherboard—in other words, a 1x clock is used.

The first-generation Pentium was created through an 0.8 micron BiCMOS process. Unfortunately, this process, combined with the 3.1 million transistor count, resulted in a die that was overly large and complicated to manufacture. As a result, reduced yields kept the chip in short supply; Intel could not make them fast enough. The 0.8 micron process was criticized by other manufacturers, including Motorola and IBM, which had been using 0.6 micron technology for their most advanced chips. The huge die and 5v operating voltage caused the 66MHz versions to consume up to an incredible 3.2 amps or 16 watts of power, resulting in a tremendous amount of heat and problems in some systems that did not employ conservative design techniques. Fortunately, adding a fan to the processor would solve most cooling problems, as long as the fan kept running.

Much of the criticism leveled at Intel for the first-generation Pentium was justified. Some people realized that the first-generation design was just that; they knew that new Pentium versions, made in a more advanced manufacturing process, were coming. Many of those people advised against purchasing any Pentium system until the second-generation version became available.

Tip

A cardinal rule of computing is never buy the first generation of any processor. Although you can wait forever because something better always will be on the horizon, a little waiting is worthwhile in some cases.

If you do have one of these first-generation Pentiums, do not despair. As with previous 486 systems, Intel offers OverDrive upgrade chips that effectively double the processor speed of your Pentium 60 or 66. These are a single-chip upgrade, meaning they replace your existing CPU. Because subsequent Pentiums are incompatible with the Pentium 60/66 Socket 4 arrangement, these OverDrive chips were the only way to upgrade an existing first-generation Pentium without replacing the motherboard.

Rather than upgrading the processor with one only twice as fast, you should really consider a complete motherboard replacement, which would accept a newer design processor that would potentially be many times faster.

Second-Generation Pentium Processor

Intel announced the second-generation Pentium on March 7, 1994. This new processor was introduced in 90 and 100MHz versions, with a 75MHz version not far behind. Eventually, 120, 133, 150, 166, and 200MHz versions were also introduced. The second-generation Pentium uses 0.6 micron (75/90/100MHz) BiCMOS technology to shrink the die and reduce power consumption. The newer, faster 120MHz (and higher) second-generation versions incorporate an even smaller die built on a 0.35 micron BiCMOS process. These smaller dies are not changed from the 0.6 micron versions; they are basically a photographic reduction of the P54C die. The die for the Pentium is shown in Figure 3.34. Additionally, these new processors run on 3.3v power. The 100MHz version consumes a maximum 3.25 amps of 3.3v power, which equals only 10.725 watts. Further up the scale, the 150MHz chip uses 3.5 amps of 3.3v power (11.6 watts); the 166MHz unit draws 4.4 amps (14.5 watts); and the 200MHz processor uses 4.7 amps (15.5 watts).

The second-generation Pentium processors come in a 296-pin SPGA form factor that is physically incompatible with the first-generation versions. The only way to upgrade from the first generation to the second is to replace the motherboard. The second-generation Pentium processors also have 3.3 million transistors—more than the earlier chips. The extra transistors exist because additional clock-control SL enhancements were added, along with an on-chip Advanced Programmable Interrupt Controller (APIC) and dual-processor interface.

The APIC and dual-processor interface are responsible for orchestrating dual-processor configurations in which two second-generation Pentium chips can process on the same motherboard simultaneously. Many of the Pentium motherboards designed for file servers come with dual Socket 7 specification sockets, which fully support the multiprocessing capability of the new chips. Software support for what usually is called Symmetric Multi-Processing (SMP) is being integrated into operating systems such as Windows NT and OS/2.

Figure 3.34 Pentium processor die. *Photograph used by permission of Intel Corporation.*

The second-generation Pentium processors use clock-multiplier circuitry to run the processor at speeds faster than the bus. The 150MHz Pentium processor, for example, can run at 2.5 times the bus frequency, which normally is 60MHz. The 200MHz Pentium processor can run at a 3x clock in a system using a 66MHz bus speed.

Note

Some Pentium systems support 75MHz or even up to 100MHz with newer motherboard and chipset designs.

Virtually all Pentium motherboards have three speed settings: 50, 60, and 66MHz. Pentium chips are available with a variety of internal clock multipliers that cause the processor to operate at various multiples of these motherboard speeds. Table 3.21 lists the speeds of currently available Pentium processors and motherboards.

Table 3.21 Pentium CPU and Motherboard Speeds

CPU Type/Speed	CPU Clock	Motherboard Speed (MHz)
Pentium 75	1.5x	50
Pentium 90	1.5x	60
Pentium 100	1.5x	66
Pentium 120	2x	60
Pentium 133	2x	66

(continues)

Table 3.21 Continued

CPU Type/Speed	CPU Clock	Motherboard Speed (MHz)
Pentium 150	2.5x	60
Pentium 166	2.5x	66
Pentium 200	3x	66
Pentium 233	3.5x	66
Pentium 266	4x	66

The core-to-bus frequency ratio or clock multiplier is controlled in a Pentium processor by two pins on the chip labeled BF1 and BF2. Table 3.22 shows how the state of the BFx pins will affect the clock multiplication in the Pentium processor.

Table 3.22 Pentium BFx Pins and Clock Multipliers

BF1	BF2	Clock Multiplier	Bus Speed (MHz)	Core Speed (MHz)
0	1	3x	66	200
0	1	3x	60	180
0	1	3x	50	150
0	0	2.5x	66	166
0	0	2.5x	60	150
0	0	2.5x	50	125
1	0	2x/4x	66	133/266*
1	0	2x	60	120
1	0	2x	50	100
1	1	1.5x/3.5x	66	100/233*
1	1	1.5x	60	90
1	1	1.5x	50	75

**The 233 and 266MHz processors have modified the 1.5x and 2x multipliers to 3.5x and 4x, respectively.*

Not all chips support all the bus frequency (BF) pins or combinations of settings. In other words, some of the Pentium processors will operate only at specific combinations of these settings, or may even be fixed at one particular setting. Many of the newer motherboards have jumpers or switches that allow you to control the BF pins and, therefore, alter the clock multiplier ratio within the chip. In theory, you could run a 75MHz-rated Pentium chip at 133MHz by changing jumpers on the motherboard. This is called *overclocking*, and is discussed in the “Processor Speed Ratings” section of this chapter. What Intel has done to discourage overclockers in its most recent Pentiums is discussed near the end of the “Processor Manufacturing” section of this chapter.

A single-chip OverDrive upgrade is currently offered for second-generation Pentiums. These OverDrive chips are fixed at a 3x multiplier; they replace the existing Socket 5 or 7 CPU, increase processor speed up to 200MHz (with a 66MHz motherboard speed), and add MMX capability, as

well. Simply stated, this means that a Pentium 100, 133, or 166 system equipped with the OverDrive chip will have a processor speed of 200MHz. Perhaps the best feature of these Pentium OverDrive chips is that they incorporate MMX technology. MMX provides greatly enhanced performance while running the multimedia applications that are so popular today.

If you have a Socket 7 motherboard, you might not need the special OverDrive versions of the Pentium processor that have built-in voltage regulators. Instead, you can purchase a standard Pentium or Pentium-compatible chip and replace the existing processor with it. You will have to be sure to set the multiplier and voltage settings so that they are correct for the new processor.

Pentium-MMX Processors

A third generation of Pentium processors (code-named P55C) was released in January 1997, which incorporates what Intel calls MMX technology into the second-generation Pentium design (see Figure 3.35). These Pentium-MMX processors are available in clock rates of 66/166MHz, 66/200MHz, and 66/233MHz, and a mobile-only version, which is 66/266MHz. The MMX processors have a lot in common with other second-generation Pentiums, including superscalar architecture, multiprocessor support, on-chip local APIC controller, and power-management features. New features include a pipelined MMX unit, 16KB code, write-back cache (versus 8KB in earlier Pentiums), and 4.5 million transistors. Pentium-MMX chips are produced on an enhanced 0.35 micron CMOS silicon process that allows for a lower 2.8v voltage level. The newer mobile 233MHz and 266MHz processors are built on a 0.25 micron process and run on only 1.8 volts. With this newer technology, the 266 processor actually uses less power than the non-MMX 133.

Figure 3.35 Pentium MMX. The left side shows the underside of the chip with the cover plate removed exposing the processor die. *Photograph used by permission of Intel Corporation.*

To use the Pentium-MMX, the motherboard must be capable of supplying the lower (2.8v or less) voltage these processors use. To allow a more universal motherboard solution with respect to these changing voltages, Intel has come up with the Socket 7 with VRM. The VRM is a socketed module that plugs in next to the processor and supplies the correct voltage. Because the module is easily replaced, it is easy to reconfigure a motherboard to support any of the voltages required by the newer Pentium processors.

Of course, lower voltage is nice, but MMX is what this chip is really all about. MMX technology was developed by Intel as a direct response to the growing importance and increasing demands of multimedia and communication applications. Many such applications run repetitive loops of instructions that take vast amounts of time to execute. As a result, MMX incorporates a process Intel calls Single Instruction Multiple Data (SIMD), which allows one instruction to perform the same function on many pieces of data. Furthermore, 57 new instructions that are designed specifically to handle video, audio, and graphics data have been added to the chip.

If you want maximum future upgradability to the MMX Pentiums, make sure that your Pentium motherboard includes 321-pin processor sockets that fully meet the Intel Socket 7 specification. These would also include the VRM (Voltage Regulator Module) socket. If you have dual sockets, you can add a second Pentium processor to take advantage of SMP (Symmetric Multiprocessing) support in some newer operating systems.

Also make sure that any Pentium motherboard you buy can be jumpered or reconfigured for both 60 and 66MHz operation. This will enable you to take advantage of future Pentium OverDrive processors that will support the higher motherboard clock speeds. These simple recommendations will enable you to perform several dramatic upgrades without changing the entire motherboard.

Pentium Defects

Probably the most famous processor bug in history is the now legendary flaw in the Pentium FPU. It has often been called the FDIV bug, because it affects primarily the FDIV (floating-point divide) instruction, although several other instructions that use division are also affected. Intel officially refers to this problem as Errata No. 23, titled "Slight precision loss for floating-point divides on specific operand pairs." The bug has been fixed in the D1 or later steppings of the 60/66MHz Pentium processors, as well as the B5 and later steppings of the 75/90/100MHz processors. The 120MHz and higher processors are manufactured from later steppings, which do not include this problem. There are tables listing all the different variations of Pentium processors and steppings and how to identify them later in this chapter.

This bug caused a tremendous fervor when it first was reported on the Internet by a mathematician in October, 1994. Within a few days, news of the defect had spread nationwide, and even people who did not have computers had heard about it. The Pentium would incorrectly perform floating-point division calculations with certain number combinations, with errors anywhere from the third digit on up.

By the time the bug was publicly discovered outside of Intel, they had already incorporated the fix into the next stepping of both the 60/66MHz and the 75/90/100MHz Pentium processor, along with the other corrections they had made.

After the bug was made public and Intel admitted to already knowing about it, a fury erupted. As people began checking their spreadsheets and other math calculations, many discovered that they had also encountered this problem and did not know it. Others who had not encountered the problem had their faith in the core of their PCs very shaken. People had come to put so much trust in the PC that they had a hard time coming to terms with the fact that it might not even be capable of doing math correctly!

One interesting result of the fervor surrounding this defect is that people are less likely to implicitly trust their PCs, and are therefore doing more testing and evaluating of important results. The bottom line is that if your information and calculations are important enough, you should implement some results tests. Several math programs were found to have problems. For example, a bug was discovered in the yield function of Excel 5.0 that some were attributing to the Pentium

processor. In this case, the problem turned out to be the software, which has been corrected in later versions (5.0c and later).

Intel finally decided that in the best interest of the consumer and their public image, they would begin a lifetime replacement warranty on the affected processors. This means that if you ever encounter one of the Pentium processors with the Errata 23 floating-point bug, they will replace the processor with an equivalent one without this problem. Normally, all you have to do is call Intel and ask for the replacement. They will ship you a new part matching the ratings of the one you are replacing in an overnight shipping box. The replacement is free, including all shipping charges. You merely remove your old processor, replace it with the new one, and put the old one back in the box. Then you call the overnight service who will pick it up and send it back. Intel will take a credit card number when you first call for the replacement only to ensure that the original defective chip is returned. As long as they get the original CPU back within a specified amount of time, there will be no charges to you. Intel has indicated that these defective processors will be destroyed and will not be remarketed or resold in another form.

Testing for the FPU Bug

Testing a Pentium for this bug is relatively easy. All you have to do is execute one of the test division cases cited here and see if your answer compares to the correct result.

The division calculation can be done in a spreadsheet (such as Lotus 1-2-3, Microsoft Excel, or any other), in the Microsoft Windows built-in calculator, or in any other calculating program that uses the FPU. Make sure that for the purposes of this test the FPU has not been disabled. That would normally require some special command or setting specific to the application, and would, of course, ensure that the test came out correct, no matter whether the chip is flawed or not.

The most severe Pentium floating-point errors occur as early as the third significant digit of the result. Here is an example of one of the more severe instances of the problem:

$$962,306,957,033 / 11,010,046 = 87,402.6282027341 \text{ (correct answer)}$$

$$962,306,957,033 / 11,010,046 = 87,399.5805831329 \text{ (flawed Pentium)}$$

Note

Note that your particular calculator program may not show the answer to the number of digits shown here. Most spreadsheet programs limit displayed results to 13 or 15 significant digits.

As you can see in the previous case, the error turns up in the third most significant digit of the result. In an examination of over 5,000 integer pairs in the 5- to 15-digit range found to produce Pentium floating-point division errors, errors beginning in the sixth significant digit were the most likely to occur.

Here is another division problem that will come out incorrectly on a Pentium with this flaw:

$$4,195,835 / 3,145,727 = 1.33382044913624100 \text{ (correct answer)}$$

$$4,195,835 / 3,145,727 = 1.33373906890203759 \text{ (flawed Pentium)}$$

This one shows an error in the fifth significant digit. A variation on the previous calculation can be performed as follows:

$$x = 4,195,835$$

$$y = 3,145,727$$

$$z = x - (x/y) \times y$$

$$4,195,835 - (4,195,835 / 3,145,727) \times 3,145,727 = 0 \text{ (correct answer)}$$

$$4,195,835 - (4,195,835 / 3,145,727) \times 3,145,727 = 256 \text{ (flawed Pentium)}$$

With an exact computation, the answer here should be zero. In fact, you will get zero on most machines, including those using Intel 286, 386, and 486 chips. But, on the Pentium, the answer is 256!

Here is one more calculation you can try:

$$5,505,001 / 294,911 = 18.66665197 \text{ (correct answer)}$$

$$5,505,001 / 294,911 = 18.66600093 \text{ (flawed Pentium)}$$

This one represents an error in the sixth significant digit.

There are several workarounds for this bug, but they extract a performance penalty. Because Intel has agreed to replace any Pentium processor with this flaw under a lifetime warranty replacement program, the best workaround is a free replacement!

Power Management Bugs

Starting with the second-generation Pentium processors, Intel added functions that allow these CPUs to be installed in energy-efficient systems. These are usually called *Energy Star systems* because they meet the specifications imposed by the EPA Energy Star program, but they are also unofficially called *green PCs* by many users.

Unfortunately, there have been several bugs with respect to these functions, causing them to either fail or be disabled. These bugs are in some of the functions in the power-management capabilities accessed through SMM. These problems are applicable only to the second-generation 75/90/100MHz processors, because the first-generation 60/66MHz processors do not have SMM or power-management capabilities, and all higher speed (120MHz and up) processors have the bugs fixed.

Most of the problems are related to the STPCLK# pin and the HALT instruction. If this condition is invoked by the chipset, the system will hang. For most systems, the only workaround for this problem is to disable the power-saving modes, such as suspend or sleep. Unfortunately, this means that your green PC won't be so green anymore! The best way to repair the problem is to replace the processor with a later stepping version that does not have the bug. These bugs affect the B1 stepping version of the 75/90/100MHz Pentiums, and were fixed in the B3 and later stepping versions.

Pentium Processor Models and Steppings

We know that like software, no processor is truly ever perfect. From time to time, the manufacturers will gather up what problems they have found and put into production a new stepping, which consists of a new set of masks that incorporate the corrections. Each subsequent stepping is better and more refined than the previous ones. Although no microprocessor is ever perfect, they come closer to perfection with each stepping. In the life of a typical microprocessor, a manufacturer may go through half a dozen or more such steppings.

Table 3.23 shows all the versions of the Pentium processor Model 1 (60/66MHz version), indicating the various steppings that have been available.

Table 3.23 Pentium Processor Model 1 (60/66MHz Version) Steppings

Type	Family	Model	Stepping	Mfg. Stepping	Speed	Comments Specification	Number

All the Pentium MMX processors listed in this table run on a 66MHz bus except for 150MHz models, which run on a 60MHz bus.

Table 3.26 shows all the versions of the Pentium OverDrive processors, indicating the various steppings that have been available. Note that the Type 1 chips in this table are 486 Pentium OverDrive processors, which are designed to replace 486 chips in systems with Socket 2 or 3. The other OverDrive processors are designed to replace existing Pentium processors in Socket 4 or 5/7.

Table 3.26 Pentium OverDrive Steppings

Type	Family	Model	Stepping	Mfg. Stepping	Speed	Spec. Number	Product	Version
1	5	3	1	B1	63	SZ953	PODP5v63	1.0
1	5	3	1	B2	63	SZ990	PODP5v63	1.1
1	5	3	2	C0	83	SU014	PODP5v83	2.1
0	5	1	A	tA0	133	SU082	PODP5v133	1.0
0	5	2	C	aC0	125	SU081	PODP3v125	1.0
0	5	2	C	aC0	150	SU083	PODP3v150	1.0
0	5	2	C	aC0	166	SU084	PODP3v166	1.0
1	5	4	4	oxA3	125/50, 150/60	SL24V	PODPMT60X150	1.0
1	5	4	4	oxA3	166/66	SL24W	PODPMT66X166	1.0
1	5	4	3	oxB1	180/60	SL2FE	PODPMT60X180	2.0
1	5	4	3	oxB1	200/66	SL2FF	PODPMT66X200	2.0

The following list explains all the entries in the Comments columns of these Tables 3.22–3.24.

**These chips have no specification number.*

ES = Engineering Sample. These chips were not sold through normal channels but were designed for development and testing purposes.

HS = Heat Spreader Package. This indicates a chip with a metal plate on the top, which is used to spread heat away from the center part of the chip. The heat spreader helps the chip run cooler; however, most later chips use a smaller, more powerful and efficient die, and Intel has been able to eliminate the heat spreader from these.

DP = Dual Processor version where Type 0 is primary only, Type 2 is secondary only, and Type 0 or 2 is either.

MD = Minimum Delay timing restrictions on several processor signals.

STD = Standard voltage range. The range for the C2 and subsequent steppings of the Pentium processor is 3.135v to 3.6v. The voltage range for B-step parts remains at 3.135v–3.465v. Note that all E0-step production parts are standard voltage.

VR = Voltage Reduced (3.300v–3.465v).

VRE = VR and Extended (3.45v–3.60v).

VRT = Voltage Reduction Technology.

TCP = Tape Carrier Package.

BOX = A retail boxed processor with a standard passive heat sink.

BOXF = A retail boxed processor with an active (fan-cooled) heat sink.

The absence of a package type in the comments column means the processor is SPGA by default.

2.285v = This is a mobile Pentium processor with MMX technology with a core operating voltage of 2.285v–2.665v.

MAXF = The part may run only at the maximum specified frequency. Specifically, a 200MHz may be run at 200MHz +0/-5 MHz (195–200MHz), and a 166MHz may be run at 166MHz +0/-5MHz (161–166MHz).

BOXUF = This part also ships as a boxed processor with an unattached fan heat sink.

1.8v = This is a mobile Pentium processor with MMX technology with a core operating voltage of 1.665v–1.935v and an I/O operating voltage of 2.375v–2.625v.

2.2v = This Pentium processor with MMX technology with a core operating voltage of 2.10v–2.34v.

2.0v = This is a mobile Pentium processor with MMX technology with a core operating voltage of 1.850v–2.150v and an I/O operating voltage of 2.375v–2.625v.

STP = The cB1 stepping is logically equivalent to the C2-step, but on a different manufacturing process. The mcB1 step is logically equivalent to the cB1 step (except it does not support DP, APIC, or FRC). The mcB1, mA1, mA4, and mcC0-steps also use Intel's VRT (Voltage Reduction Technology), and are available in the TCP and SPGA package, primarily to support mobile applications. The mxA3 is logically equivalent to the xA3 stepping, except it does not support DP or APIC.

NO = Part meets the specifications but is not tested to support 82498/82493 and 82497/82492 cache timings.

In these tables, the processor Type heading refers to the dual processor capabilities of the Pentium. Versions indicated with a Type 0 can be used only as a primary processor, while those marked as Type 2 can be used only as the secondary processor in a pair. If the processor is marked as Type 0/2, it can serve as the primary or secondary processor, or both.

The Family designation for all Pentiums is 5 (for 586), while the model indicates the particular revision. Model 1 indicates the first-generation 60/66MHz version, whereas Model 2 or later indicates the second-generation 75+MHz version. The stepping number is the actual revision of the particular model. The family, model, and stepping number can be read by software such as the Intel CPUID program. These also correspond to a particular manufacturer stepping code, which is how Intel designates the chips in-house. These are usually an alphanumeric code. For example, stepping 5 of the Model 2 Pentium is also known as the C2 stepping inside Intel.

Manufacturing stepping codes that begin with an m indicate a mobile processor. Most Pentium processors come in a standard Ceramic Pin Grid Array (CPGA) package; however, the mobile processors also use the tape carrier package (TCP). Now there is also a Plastic Pin Grid Array (PPGA) package being used to reduce cost.

To determine the specifications of a given processor, you need to look up the S-spec number in the table of processor specifications. To find your S-spec number, you have to read it off of the chip directly. It can be found printed on both the top and bottom of the chip. If your heat sink is glued on, remove the chip and heat sink from the socket as a unit and read the numbers from the bottom of the chip. Then you can look up the S-spec number in the table; it will tell you the specifications of that particular processor. Intel is introducing new chips all the time, so visit their Web site and search for the Pentium processor “Quick Reference Guide” in the developer portion of their site. There you will find a complete listing of all current processor specifications by S-spec number.

One interesting item to note is that there are several subtly different voltages required by different Pentium processors. Table 3.27 summarizes the different processors and their required voltages:

Table 3.27 Pentium Processor Voltages

Model	Stepping	Voltage Spec.	Voltage Range
1	—	Std.	4.75–5.25v
1	—	5v1	4.90–5.25v
1	—	5v2	4.90–5.40v
1	—	5v3	5.15–5.40v
2+	B1-B5	Std.	3.135–3.465v
2+	C2+	Std.	3.135–3.600v
2+	—	VR	3.300–3.465v
2+	B1-B5	VRE	3.45–3.60v
2+	C2+	VRE	3.40–3.60v
4+	—	MMX	2.70–2.90v
4	3	Mobile	2.285–2.665v
4	3	Mobile	2.10–2.34v
8	1	Mobile	1.850–2.150v
8	1	Mobile	1.665–1.935v

Many of the newer Pentium motherboards have jumpers that allow for adjustments to the different voltage ranges. If you are having problems with a particular processor, it may not be matched correctly to your motherboard voltage output.

If you are purchasing an older, used Pentium system today, I recommend using only Model 2 (second generation) or later version processors that are available in 75MHz or faster speeds. I would definitely want stepping C2 or later. Virtually all the important bugs and problems were fixed in the C2 and later releases. The newer Pentium processors have no serious bugs to worry about.

AMD-K5

The AMD-K5 is a Pentium-compatible processor developed by AMD and available as the PR75, PR90, PR100, PR120, PR133, and PR-166. Because it is designed to be physically and functionally

compatible, any motherboard that properly supports the Intel Pentium should support the AMD-K5. However, a BIOS upgrade might be required to properly recognize the AMD-K5. AMD keeps a list of motherboards that have been tested for compatibility.

The K5 has the following features:

- 16KB instruction cache, 8KB write-back data cache
- Dynamic execution—branch prediction with speculative execution
- Five-stage RISC-like pipeline with six parallel functional units
- High-performance floating-point unit (FPU)
- Pin-selectable clock multiples of 1.5x and 2x

The K5 is sold under the P-Rating system, which means that the number on the chip does not indicate true clock speed, only apparent speed when running certain applications.

◀◀ See “AMD P-Ratings,” p. 49.

Note that several of these processors do not run at their apparent rated speed. For example, the PR-166 version actually runs at only 117 true MHz. Sometimes this can confuse the system BIOS, which may report the true speed rather than the P-Rating, which compares the chip against an Intel Pentium of that speed. AMD claims that because of architecture enhancements over the Pentium, they do not need to run the same clock frequency to achieve that same performance. Even with such improvements, AMD markets the K5 as a fifth-generation processor, just like the Pentium.

The AMD-K5 operates at 3.52 volts (VRE Setting). Some older motherboards default to 3.3 volts, which is below specification for the K5 and could cause erratic operation.

Pseudo Fifth-Generation Processors

There is at least one processor that, while generally regarded as a fifth-generation processor, lacks many of the functions of that class of chip—the IDT Centaur C6 Winchip. True fifth-generation chips would have multiple internal pipelines, which is called superscalar architecture, allowing more than one instruction to be processed at one time. They would also feature branch prediction, another fifth-generation chip feature. As it lacks these features, the C6 is more closely related to a 486; however, the performance levels and the pinout put it firmly in the class with Pentium processors. It has turned out to be an ideal Pentium Socket 7-compatible processor for low-end systems.

IDT Centaur C6 Winchip

The C6 processor is a recent offering from Centaur, a wholly owned subsidiary of IDT (Integrated Device Technologies). It is Socket 7-compatible with Intel's Pentium, includes MMX extensions, and is available at clock speeds of 180, 200, 225, and 240MHz. Pricing is below Intel on the Pentium MMX.

Centaur is led by Glenn Henry, who spent more than two decades as a computer architect at IBM and six years as chief technology officer at Dell Computer Corp. The company is a well-established semiconductor manufacturer well-known for SRAM and other components.

As a manufacturer, IDT owns its own fabs (semiconductor manufacturing plants), which will help keep costs low on the C6 Winchip. Their expertise in SRAM manufacturing may be applied in new versions of the C6, which integrate onboard L2 cache in the same package as the core processor, similar to the Pentium Pro.

The C6 has 32KB each of instruction and data cache, just like AMD's K6 and Cyrix's 6x86MX, yet it has only 5.4 million transistors, compared with the AMD chip's 8.8 million and the Cyrix chip's 6.5 million. This allows for a very small processor die, which also reduces power consumption. Centaur achieved this small size with a streamlined design. Unlike competitor chips, the C6 is not superscalar—it issues only one instruction per clock cycle like the 486. However, with large caches, an efficient memory-management unit, and careful performance optimization of commonly used instructions, the C6 achieves performance that's comparable to a Pentium. Another benefit of the C6's simple design is low power consumption—low enough for notebook PCs. Neither AMD nor Cyrix has a processor with power consumption low enough for most laptop designs.

To keep the design simple, Centaur compromised on floating-point and MMX speed and focused instead on typical application performance. As a result, the chip's performance trails the other competitors' on some multimedia applications and games.

Intel P6 (686) Sixth-Generation Processors

The P6 (686) processors represent a new generation with features not found in the previous generation units. The P6 processor family began when the Pentium Pro was released in November 1995. Since then, many other P6 chips have been released by Intel, all using the same basic P6 core processor as the Pentium Pro. Table 3.28 shows the variations in the P6 family of processors.

Table 3.28 Intel P6 Processor Variations

Pentium Pro	Original P6 processor, includes 256KB, 512KB, or 1MB of full core-speed L2 cache
Pentium II	P6 with 512KB of half core speed L2 cache
Pentium II Xeon	P6 with 512KB, 1MB, or 2MB of full-core speed L2 cache
Celeron	P6 with no L2 cache
Celeron-A	P6 with 128KB of on-die full-core speed L2 cache
Pentium III	P6 with SSE (MMX2), 512KB of half-core speed L2 cache
Pentium IIPE	P6 with 256KB of full-core speed L2 cache
Pentium III Xeon	P6 with SSE (MMX2), 512KB, 1MB, or 2MB of full-core speed L2 cache

Even more are expected in this family, including versions of the Pentium III with on-die full-core speed L2 cache, and faster versions of the Celeron.

The main new feature in the fifth-generation Pentium processors was the superscalar architecture, where two instruction execution units could execute instructions simultaneously in parallel. Later fifth-generation chips also added MMX technology to the mix, as well. So then what did Intel add in the sixth-generation to justify calling it a whole new generation of chip? Besides many minor improvements, the real key features of all sixth-generation processors are Dynamic Execution and the Dual Independent Bus (DIB) architecture, plus a greatly improved superscalar design.

Dynamic Execution enables the processor to execute more instructions on parallel, so that tasks are completed more quickly. This technology innovation is comprised of three main elements:

- *Multiple branch prediction*, to predict the flow of the program through several branches
- *Dataflow analysis*, which schedules instructions to be executed when ready, independent of their order in the original program
- *Speculative execution*, which increases the rate of execution by looking ahead of the program counter and executing instructions that are likely to be needed

Branch prediction is a feature formerly found only in high-end mainframe processors. It allows the processor to keep the instruction pipeline full while running at a high rate of speed. A special fetch/decode unit in the processor uses a highly optimized branch prediction algorithm to predict the direction and outcome of the instructions being executed through multiple levels of branches, calls, and returns. It is like a chess player working out multiple strategies in advance of game play by predicting the opponent's strategy several moves into the future. By predicting the instruction outcome in advance, the instructions can be executed with no waiting.

Dataflow analysis studies the flow of data through the processor to detect any opportunities for out-of-order instruction execution. A special dispatch/execute unit in the processor monitors many instructions and can execute these instructions in an order that optimizes the use of the multiple superscalar execution units. The resulting out-of-order execution of instructions can keep the execution units busy even when cache misses and other data-dependent instructions might otherwise hold things up.

Speculative execution is the processor's capability to execute instructions in advance of the actual program counter. The processor's dispatch/execute unit uses dataflow analysis to execute all available instructions in the instruction pool and store the results in temporary registers. A retirement unit then searches the instruction pool for completed instructions that are no longer data dependent on other instructions to run, or which have unresolved branch predictions. If any such completed instructions are found, the results are committed to memory by the retirement unit or the appropriate standard Intel architecture in the order they were originally issued. They are then retired from the pool.

Dynamic Execution essentially removes the constraint and dependency on linear instruction sequencing. By promoting out-of-order instruction execution, it can keep the instruction units working rather than waiting for data from memory. Even though instructions can be predicted and executed out of order, the results are committed in the original order so as not to disrupt or change program flow. This allows the P6 to run existing Intel architecture software exactly as the P5 (Pentium) and previous processors did, just a whole lot more quickly!

The other main P6 architecture feature is known as the Dual Independent Bus. This refers to the fact that the processor has two data buses, one for the system (motherboard) and the other just for cache. This allows the cache memory to run at speeds previously not possible.

Previous P5 generation processors have only a single motherboard host processor bus, and all data, including cache transfers, must flow through it. The main problem with that is the cache memory was restricted to running at motherboard bus speed, which was 66MHz until recently

and has now moved to 100MHz. We have cache memory today that can run 500MHz or more, and main memory (SDRAM) that runs at 66 and 100MHz, so a method was needed to get faster memory closer to the processor. The solution was to essentially build in what is called a backside bus to the processor, otherwise known as a dedicated cache bus. The L2 cache would then be connected to this bus and could run at any speed. The first implementation of this was in the Pentium Pro, where the L2 cache was built right into the processor package and ran at the full core processor speed. Later, that proved to be too costly, so the L2 cache was moved outside of the processor package and onto a cartridge module, which we now know as the Pentium II/III. With that design, the cache bus could run at any speed, with the first units running the cache at half-processor speed.

By having the cache on a backside bus directly connected to the processor, the speed of the cache is scalable to the processor. In current PC architecture—66MHz Pentiums all the way through the 333MHz Pentium IIs—the motherboard runs at a speed of 66MHz. Newer Pentium II systems run a 100MHz motherboard bus and have clock speeds of 350MHz and higher. If the cache were restricted to the motherboard as is the case with Socket 7 (P5 processor) designs, the cache memory would have to remain at 66MHz, even though the processor was running as fast as 333MHz. With newer boards, the cache would be stuck at 100MHz, while the processor ran as fast as 500MHz or more. With the Dual Independent Bus (DIB) design in the P6 processors, as the processor runs faster, at higher multiples of the motherboard speed, the cache would increase by the same amount that the processor speed increases. The cache on the DIB is coupled to processor speed, so that doubling the speed of the processor also doubles the speed of the cache.

The DIB architecture is necessary to have decent processor performance in the 300MHz and beyond range. Older Socket 7 (P5 processor) designs will not be capable of moving up to these higher speeds without suffering a tremendous performance penalty due to the slow motherboard-bound L2 cache. That is why Intel is not developing any Pentium (P5 class) processors beyond 266MHz; however, the P6 processors will be available in speeds of up to 500MHz or more.

Finally, the P6 architecture upgrades the superscalar architecture of the P5 processors by adding more instruction execution units, and by breaking down the instructions into special micro-ops. This is where the CISC (Complex Instruction Set Computer) instructions are broken down into more RISC (Reduced Instruction Set Computer) commands. The RISC-level commands are smaller and easier for the parallel instruction units to execute more efficiently. With this design, Intel has brought the benefits of a RISC processor—high-speed dedicated instruction execution—to the CISC world. Note that the P5 had only two instruction units, while the P6 has at least six separate dedicated instruction units. It is said to be three-way superscalar, because the multiple instruction units can execute up to three instructions in one cycle.

Other improvements in efficiency also are included in the P6 architecture: built-in multiprocessor support, enhanced error detection and correction circuitry, and optimization for 32-bit software.

Rather than just being a faster Pentium, the Pentium Pro, Pentium II/III, and other sixth-generation processors have many feature and architectural improvements. The core of the chip is very RISC-like, while the external instruction interface is classic Intel CISC. By breaking down the CISC instructions into several different RISC instructions and running them down parallel execution pipelines, the overall performance is increased.

Compared to a Pentium at the same clock speed, the P6 processors are faster—as long as you're running 32-bit software. The P6 Dynamic Execution is optimized for performance primarily when running 32-bit software such as Windows NT. If you are using 16-bit software, such as Windows 95 or 98 (which operate part time in a 16-bit environment) and most older applications, the P6 will not provide as marked a performance improvement over similarly speed-rated Pentium and Pentium-MMX processors. That's because the Dynamic Execution capability will not be fully exploited. Because of this, Windows NT is often regarded as the most desirable operating system for use with Pentium Pro/II/III/Celeron processors. While this is not exactly true (a Pentium Pro/II/III/Celeron will run fine under Windows 95/98), Windows NT does take better advantage of the P6's capabilities. Note that it is really not so much the operating system but which applications you use. Software developers can take steps to gain the full advantages of the sixth-generation processors. This includes using modern compilers that can improve performance for all current Intel processors, writing 32-bit code where possible, and making code as predictable as possible to take advantage of the processor's Dynamic Execution multiple branch prediction capabilities.

Pentium Pro Processors

Intel's successor to the Pentium is called the Pentium Pro. The Pentium Pro was the first chip in the P6 or sixth-generation processor family. It was introduced in November 1995, and became widely available in 1996. The chip is a 387-pin unit that resides in Socket 8, so it is not pin-compatible with earlier Pentiums. The new chip is unique among processors as it is constructed in a Multi-Chip Module (MCM) physical format, which Intel is calling a Dual Cavity PGA (Pin Grid Array) package. Inside the 387-pin chip carrier are two dies. One contains the actual Pentium Pro processor (shown in Figure 3.36), and the other a 256KB (the Pentium Pro with 256KB cache is shown in Figure 3.37), 512KB, or 1MB (the Pentium Pro with 1MB cache is shown in Figure 3.37) L2 cache. The processor die contains 5.5 million transistors, the 256KB cache die contains 15.5 million transistors, and the 512KB cache die(s) have 31 million transistors each, for a potential total of nearly 68 million transistors in a Pentium Pro with 1MB of internal cache! A Pentium Pro with 1MB cache has two 512KB cache die and a standard P6 processor die (see Figure 3.38).

The main processor die includes a 16KB split L1 cache with an 8KB two-way set associative cache for primary instructions, and an 8KB four-way set associative cache for data.

Another sixth-generation processor feature found in the Pentium Pro is the Dual Independent Bus (DIB) architecture, which addresses the memory bandwidth limitations of previous-generation processor architectures. Two buses make up the DIB architecture: the L2 cache bus (contained entirely within the processor package) and the processor-to-main memory system bus. The speed of the dedicated L2 cache bus on the Pentium Pro is equal to the full core speed of the processor. This was accomplished by embedding the cache chips directly into the Pentium Pro package. The DIB processor bus architecture addresses processor-to-memory bus bandwidth limitations. It offers up to three times the performance bandwidth of the single-bus, "Socket 7" generation processors, such as the Pentium.

Figure 3.37 Pentium Pro processor with 256KB L2 cache (the cache is on the left side of the processor die). *Photograph used by permission of Intel Corporation.*

Figure 3.38 Pentium Pro processor with 1MB L2 cache (the cache is in the center and right portions of the die). *Photograph used by permission of Intel Corporation.*

Table 3.29 shows Pentium Pro processor specifications. Table 3.30 shows the specifications for each model within the Pentium Pro family, as there are many variations from model to model.

Table 3.29 Pentium Pro Family Processor Specifications

Introduced	November 1995
Maximum rated speeds	150, 166, 180, 200MHz
CPU	2.5x, 3x
Internal registers	32-bit
External data bus	64-bit
Memory address bus	36-bit
Addressable memory	64GB
Virtual memory	64TB
Integral L1-cache size	8KB code, 8KB data (16KB total)
Integrated L2-cache bus	64-bit, full core-speed
Socket/Slot	Socket 8
Physical package	387-pin Dual Cavity PGA
Package dimensions	2.46 (6.25cm) × 2.66 (6.76cm)
Math coprocessor	Built-in FPU
Power management	SMM (system management mode)
Operating voltage	3.1v or 3.3v

Table 3.30 Pentium Pro Processor Specifications by Processor Model

Pentium Pro Processor (200MHz) with 1MB Integrated Level 2 Cache	
Introduction date	August 18, 1997
Clock speeds	200MHz (66MHz × 3)
Number of transistors	5.5 million (0.35 micron process), plus 62 million in 1MB L2 cache (0.35 micron)
Cache Memory	8Kx2 (16KB) L1, 1MB core-speed L2
Die Size	0.552 (14.0mm)
Pentium Pro Processor (200MHz)	
Introduction date	November 1, 1995
Clock speeds	200MHz (66MHz × 3)
iCOMP Index 2.0 rating	220
Number of transistors	5.5 million (0.35 micron process), plus 15.5 million in 256KB L2 cache (0.6 micron), or 31 million in 512KB L2 cache (0.35 micron)
Cache Memory	8Kx2 (16KB) L1, 256KB or 512KB core-speed L2
Die Size	0.552 inches per side (14.0mm)
Pentium Pro Processor (180MHz)	
Introduction date	November 1, 1995
Clock speeds	180MHz (60MHz × 3)
iCOMP Index 2.0 rating	197
Number of transistors	5.5 million (0.35 micron process), plus 15.5 million in 256KB L2 cache (0.6 micron)
Cache Memory	8Kx2 (16KB) L1, 256KB core-speed L2
Die Size	0.552 inches per side (14.0mm)
Pentium Pro Processor (166MHz)	
Introduction date	November 1, 1995
Clock speeds	166MHz (66MHz × 2.5)
Number of transistors	5.5 million (0.35 micron process), plus 31 million in 512KB L2 cache (0.35 micron)
Cache Memory	8Kx2 L1, 512KB core-speed L2
Die Size	0.552 inches per side (14.0mm)
Pentium Pro Processor (150MHz)	
Introduction date	November 1, 1995
Clock speeds	150MHz (60MHz × 2.5)
Number of transistors	5.5 million (0.6 micron process), plus 15.5 million in 256KB L2 cache (0.6 micron)
Cache Memory	8Kx2 speed L2
Die Size	0.691 inches per side (17.6mm)

As you saw in Table 3.3, performance comparisons on the iCOMP 2.0 Index rate a classic Pentium 200MHz at 142, whereas a Pentium Pro 200MHz scores an impressive 220. Just for comparison,

note that a Pentium MMX 200MHz falls right about in the middle in regards to performance at 182. Keep in mind that using a Pentium Pro with any 16-bit software applications will nullify much of the performance gain shown by the iCOMP 2.0 rating.

Like the Pentium before it, the Pentium Pro runs clock multiplied on a 66MHz motherboard. The following table lists speeds for Pentium Pro processors and motherboards.

CPU Type/Speed	CPU Clock	Motherboard Speed
Pentium Pro 150	2.5x	60
Pentium Pro 166	2.5x	66
Pentium Pro 180	3x	60
Pentium Pro 200	3x	66

The integrated L2 cache is one of the really outstanding features of the Pentium Pro. By building the L2 cache into the CPU and getting it off the motherboard, they can now run the cache at full processor speed rather than the slower 60 or 66MHz motherboard bus speeds. In fact, the L2 cache features its own internal 64-bit backside bus, which does not share time with the external 64-bit frontside bus used by the CPU. The internal registers and data paths are still 32-bit, as with the Pentium. By building the L2 cache into the system, motherboards can be cheaper because they no longer require separate cache memory. Some boards may still try to include cache memory in their design, but the general consensus is that L3 cache (as it would be called) would offer less improvement with the Pentium Pro than with the Pentium.

One of the features of the built-in L2 cache is that multiprocessing is greatly improved. Rather than just SMP, as with the Pentium, the Pentium Pro supports a new type of multiprocessor configuration called the Multiprocessor Specification (MPS 1.1). The Pentium Pro with MPS allows configurations of up to four processors running together. Unlike other multiprocessor configurations, the Pentium Pro avoids cache coherency problems because each chip maintains a separate L1 and L2 cache internally.

Pentium Pro-based motherboards are pretty much exclusively PCI and ISA bus-based, and Intel is producing their own chipsets for these motherboards. The first chipset was the 450KX/GX (code-named Orion), while the most recent chipset for use with the Pentium Pro is the 440LX (Natoma). Due to the greater cooling and space requirements, Intel designed the new ATX motherboard form factor to better support the Pentium Pro and other future processors, such as the Pentium II. Even so, the Pentium Pro can be found in all types of motherboard designs; ATX is not mandatory.

- ▶▶ See "Motherboard Form Factors," p. 204, and "Sixth-Generation (P6 Pentium Pro/Pentium II Class) Chipsets," p. 252.

Some Pentium Pro system manufacturers have been tempted to stick with the Baby-AT form factor. The big problem with the standard Baby-AT form factor is keeping the CPU properly cooled. The massive Pentium Pro processor consumes more than 25 watts and generates an appreciable amount of heat.

Four special Voltage Identification (VID) pins are on the Pentium Pro processor. These pins can be used to support automatic selection of power supply voltage. This means that a Pentium Pro

motherboard does not have voltage regulator jumper settings like most Pentium boards, which greatly eases the setup and integration of a Pentium Pro system. These pins are not actually signals, but are either an open circuit in the package or a short circuit to voltage. The sequence of opens and shorts define the voltage required by the processor. In addition to allowing for automatic voltage settings, this feature has been designed to support voltage specification variations on future Pentium Pro processors. The VID pins are named VID0 through VID3 and the definition of these pins is shown in Table 3.31. A 1 in this table refers to an open pin and 0 refers to a short to ground. The voltage regulators on the motherboard should supply the voltage that is requested or disable itself.

Table 3.31 Pentium Pro Voltage Identification Definition

VID[3:0]	Voltage Setting	VID[3:0]	Voltage Setting
0000	3.5	1000	2.7
0001	3.4	1001	2.6
0010	3.3	1010	2.5
0011	3.2	1011	2.4
0100	3.1	1100	2.3
0101	3.0	1101	2.2
0110	2.9	1110	2.1
0111	2.8	1111	No CPU present

Most Pentium Pro processors run at 3.3v, but a few run at 3.1v. Although those are the only versions available now, support for a wider range of VID settings will benefit the system in meeting the power requirements of future Pentium Pro processors. Note that the 1111 (or all opens) ID can be used to detect the absence of a processor in a given socket.

The Pentium Pro never did become very popular on the desktop, but has found a niche in file server applications due primarily to the full core-speed high-capacity internal L2 cache. It is expected that Intel will introduce only one or two more variations of the Pentium Pro, primarily as upgrade processors for those who want to install a faster CPU in their existing Pentium Pro motherboard. In most cases, it would be wiser to install a new Pentium II motherboard instead.

The following tables list the unique specifications of the different models of the Pentium Pro.

As with other processors, the Pentium Pro has been available in a number of different revisions and steppings. The following table shows all the versions of the Pentium Pro. They can be identified by the Specification number printed on the top and bottom of the chip.

Type	Family	Model	Stepping	Mfg. Stepping	L2 Size/Stepping	Speed Core/Bus	Spec. (+/-5%)	Voltage	Notes

1. L2 cache stepping refers to the silicon revision of the 256KB, 512KB, or 1MB on-chip L2 cache. The "a" designation refers to the first production steppings; the "b" to the second production steppings, and so on.

2. The sA0 stepping is logically equivalent to the C0 stepping, but on a different manufacturing process.

3. The VID pins are not supported on these parts.

4. These are engineering samples only, provided under a Pentium Pro processor nondisclosure loan agreement.

5. The VID pins are functional but not tested on these parts.

6. These sample parts are equipped with a preproduction 512KB L2 cache.

7. These components have additional specification changes associated with them:

a. Primary Voltage = 3.5v

b. Max Thermal Design Power = 39.4W @ 200MHz, 256KB L2

c. Max Current = 11.9A

d. The VID pins are not supported on these parts.

8. This is a boxed Pentium Pro processor with an unattached fan heat sink.

9. This part also ships as a boxed processor with an unattached fan heat sink.

Pentium II Processors

Intel revealed the Pentium II in May 1997. Prior to its official unveiling, the Pentium II processor was popularly referred to by its code name Klamath, and was surrounded by much speculation throughout the industry. The Pentium II is essentially the same sixth-generation processor as the Pentium Pro, with MMX technology added (which included double the L1 cache and 57 new MMX instructions); however, there are a few twists to the design. The Pentium II processor die is shown in Figure 3.39.

Figure 3.39 Pentium II Processor die. *Photograph used by permission of Intel Corporation.*

From a physical standpoint, it is truly something new. Abandoning the chip in a socket approach used by virtually all processors up until this point, the Pentium II chip is characterized by its Single Edge Contact (SEC) cartridge design. The processor, along with several L2 cache chips, is mounted on a small circuit board (much like an oversized-memory SIMM) as shown in Figure 3.40, which is then sealed in a metal and plastic cartridge. The cartridge is then plugged into the motherboard through an edge connector called Slot 1, which looks very much like an adapter card slot.

There are two variations on these cartridges, called SECC (Single Edge Contact Cartridge) and SECC2. Figure 3.41 shows a diagram of the SECC package. Figure 3.42 shows the SECC2 package.

Figure 3.40 Pentium II Processor Board (inside SEC cartridge). *Photograph used by permission of Intel Corporation.*

Figure 3.41 SECC components showing enclosed processor board.

Figure 3.42 2 Single Edge Contact Cartridge, rev. 2 components showing half-enclosed processor board.

As you can see from these figures, the SECC2 version is cheaper to make because it uses fewer overall parts. It also allows for a more direct heat sink attachment to the processor for better cooling. Intel transitioned from SECC to SECC2 in the beginning of 1999; all newer PII/PIII cartridge processors use the improved SECC2 design.

By using separate chips mounted on a circuit board, Intel can build the Pentium II much less expensively than the multiple die within a package used in the Pentium Pro. They can also use cache chips from other manufacturers, and more easily vary the amount of cache in future processors compared to the Pentium Pro design.

At present, Intel is offering Pentium II processors with the following speeds:

CPU Type/Speed	CPU Clock	Motherboard Speed
Pentium II 233MHz	3.5x	66MHz
Pentium II 266MHz	4x	66MHz
Pentium II 300MHz	4.5x	66MHz
Pentium II 333MHz	5x	66MHz
Pentium II 350MHz	3.5x	100MHz
Pentium II 400MHz	4x	100MHz
Pentium II 450MHz	4.5x	100MHz

The Pentium II processor core has 7.5 million transistors and is based on Intel's advanced P6 architecture. The Pentium II started out using .35 micron process technology, although the 333MHz and faster Pentium IIs are based on 0.25 micron technology. This enables a smaller die, allowing increased core frequencies and reduced power consumption. At 333MHz, the Pentium II processor delivers a 75–150 percent performance boost, compared to the 233MHz Pentium processor with MMX technology, and approximately 50 percent more performance on multimedia benchmarks. These are very fast processors, at least for now. As shown in Table 3.3, the iCOMP 2.0 Index rating for the Pentium II 266MHz chip is more than twice as fast as a classic Pentium 200MHz.

Aside from speed, the best way to think of the Pentium II is as a Pentium Pro with MMX technology instructions and a slightly modified cache design. It has the same multiprocessor scalability as the Pentium Pro, as well as the integrated L2 cache. The 57 new multimedia-related instructions carried over from the MMX processors and the capability to process repetitive loop commands more efficiently are also included. Also included as a part of the MMX upgrade is double the internal L1 cache from the Pentium Pro (from 16KB total to 32KB total in the Pentium II).

The original Pentium II processors were manufactured using a 0.35 micron process. More recent models, starting with the 333MHz version, have been manufactured using a newer 0.25 micron process. Intel is considering going to a 0.18 micron process in the future. By going to the smaller process, power draw is greatly reduced.

Maximum power usage for the Pentium II is shown in the following table.

Core Speed	Power Draw	Process	Voltage
450MHz	27.1w	0.25 micron	2.0v
400MHz	24.3w	0.25 micron	2.0v
350MHz	21.5w	0.25 micron	2.0v
333MHz	23.7w	0.25 micron	2.0v
300MHz	43.0w	0.35 micron	2.8v
266MHz	38.2w	0.35 micron	2.8v
233MHz	34.8w	0.35 micron	2.8v

You can see that the highest speed 450MHz version of the Pentium II actually uses less power than the slowest original 233MHz version! This was accomplished by using the smaller 0.25 micron process and running the processor on a lower voltage of only 2.0v. Future Pentium III processors will use the 0.25- and 0.18 micron processes and even lower voltages to continue this trend.

The Pentium II includes Dynamic Execution, which describes unique performance-enhancing developments by Intel and was first introduced in the Pentium Pro processor. Major features of Dynamic Execution include Multiple Branch Prediction, which speeds execution by predicting the flow of the program through several branches; Dataflow Analysis, which analyzes and modifies the program order to execute instructions when ready; and Speculative Execution, which looks ahead of the program counter and executes instruction that are likely to be needed. The Pentium II processor expands on these capabilities in sophisticated and powerful new ways to deliver even greater performance gains.

Like the Pentium Pro, the Pentium II also includes DIB architecture. The term *Dual Independent Bus* comes from the existence of two independent buses on the Pentium II processor—the L2 cache bus and the processor-to-main-memory system bus. The Pentium II processor can use both buses simultaneously, thus getting as much as 2× more data in and out of the Pentium II processor than a single-bus architecture processor. The DIB architecture enables the L2 cache of the 333MHz Pentium II processor to run 2 1/2 times as fast as the L2 cache of Pentium processors. As the frequency of future Pentium II processors increases, so will the speed of the L2 cache. Also,

the pipelined system bus enables simultaneous parallel transactions instead of singular sequential transactions. Together, these DIB architecture improvements offer up to three times the bandwidth performance over a single-bus architecture as with the regular Pentium.

Table 3.32 shows the general Pentium II processor specifications. Table 3.33 shows the specifications that vary by model for the models that have been introduced to date.

Table 3.32 Pentium II General Processor Specifications

Bus Speeds	66MHz, 100MHz
CPU clock multiplier	3.5x, 4x, 4.5x, 5x
CPU Speeds	233MHz, 266MHz, 300MHz, 333MHz, 350MHz, 400MHz, 450MHz
Cache Memory	16Kx2 (32KB) L1, 512KB 1/2-speed L2
Internal Registers	32-bit
External Data Bus	64-bit system bus w/ ECC; 64-bit cache bus w/ optional ECC
Memory Address Bus	36-bit
Addressable Memory	64GB
Virtual Memory	64TB
Physical package	Single Edge Contact Cartridge (S.E), 242 pins
Package Dimensions	5.505 in. (12.82cm)x2.473 inches (6.28cm)x0.647 in. (1.64cm)
Math coprocessor	Built-in FPU (floating-point unit)
Power management	SMM (System Management Mode)

Table 3.33 Pentium II Specifications by Model

Pentium II MMX Processor (350, 400 and 450MHz)	
Introduction date	April 15, 1998
Clock speeds	350MHz (100MHzx3.5), 400MHz (100MHz x4), and 450MHz (100MHzx4.5)
iCOMP Index 2.0 rating	386 (350MHz), 440 (400MHz), and 483 (450MHz)
Number of transistors	7.5 million (0.25 micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	4GB
Operating voltage	2.0v
Slot	Slot 2
Die Size	0.400 inches per side (10.2mm)
Mobile Pentium II Processor (266, 300, 333, and 366MHz)	
Introduction date	January 25, 1999
Clock speeds	266, 300, 333, and 366MHz
Number of transistors	27.4 million (0.25 micron process), 256KB on-die L2 cache
Ball Grid Array (BGA)	Number of balls = 615
Dimensions	Width = 31mm; Length = 35mm
Core voltage	1.6 volts
Thermal design power ranges by frequency	366MHz = 9.5 watts; 333MHz = 8.6 watts; 300MHz = 7.7 watts; 266MHz = 7.0 watts

Pentium II MMX Processor (333MHz)

Introduction date	January 26, 1998
Clock speeds	333MHz (66MHzx5)
iCOMP Index 2.0 rating	366
Number of transistors	7.5 million (0.25 micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Operating voltage	2.0v
Slot	Slot 1
Die Size	0.400 inches per side (10.2mm)

Pentium II MMX Processor (300MHz)

Introduction date	May 7, 1997
Clock speeds	300MHz (66MHzx4.5)
iCOMP Index 2.0 rating	332
Number of transistors	7.5 million (0.35 micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Die Size	0.560 inches per side (14.2mm)

Pentium II MMX Processor (266MHz)

Introduction date	May 7, 1997
Clock speeds	266MHz (66MHzx4)
iCOMP Index 2.0 rating	303
Number of transistors	7.5 million (0.35 micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Slot	Slot 1
Die Size	0.560 inches per side (14.2mm)

Pentium II MMX Processor (233MHz)

Introduction date	May 7, 1997
Clock speeds	233MHz (66MHzx3.5)
iCOMP Index 2.0 rating	267
Number of transistors	7.5 million (0.35 micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Slot	Slot 1
Die Size	0.560 inches per side (14.2mm)

As you can see from the table, the Pentium II can handle up to 64GB of physical memory. Like the Pentium Pro, the CPU incorporates Dual Independent Bus architecture. This means the chip has two independent buses: one for accessing the L2 cache, the other for accessing main memory. These dual buses can operate simultaneously, greatly accelerating the flow of data within the system. The L1 cache always runs at full core speeds because it is mounted directly on the processor die. The L2 cache in the Pentium II normally runs at 1/2-core speed, which saves money and allows for less expensive cache chips to be utilized. For example, in a 333MHz Pentium II, the L1 cache runs at a full 333MHz, while the L2 cache runs at 167MHz. Even though the L2 cache is

not at full core speed as it was with the Pentium Pro, this is still far superior to having cache memory on the motherboard running at the 66MHz motherboard speed of most Socket 7 Pentium designs. Intel claims that the DIB architecture in the Pentium II allows up to three times the bandwidth of normal single-bus processors like the original Pentium.

By removing the cache from the processor's internal package and using external chips mounted on a substrate and encased in the cartridge design, Intel can now use more cost-effective cache chips and more easily scale the processor up to higher speeds. The Pentium Pro was limited in speed to 200MHz, largely due to the inability to find affordable cache memory that runs any faster. By running the cache memory at 1/2-core speed, the Pentium II can run up to 400MHz while still using 200MHz rated cache chips. To offset the 1/2-core speed cache used in the Pentium II, Intel doubled the basic amount of integrated L2 cache from 256KB standard in the Pro to 512KB standard in the Pentium II.

Note that the tag-RAM included in the L2 cache will allow up to 512MB of main memory to be cacheable in PII processors from 233MHz to 333MHz. The 350MHz, 400MHz, and faster versions include an enhanced tag-RAM that allows up to 4GB of main memory to be cacheable. This is very important if you ever plan on adding more than 512MB of memory. In that case, you would definitely want the 350MHz or faster version; otherwise, memory performance would suffer.

The system bus of the Pentium II provides "glueless" support for up to two processors. This enables low-cost, two-way on the L2 cache bus. These system buses are designed especially for servers or other mission-critical system use where reliability and data integrity are important. All Pentium IIs also include parity-protected address/request and response system bus signals with a retry mechanism for high data integrity and reliability.

To install the Pentium II in a system, a special processor-retention mechanism is required. This consists of a mechanical support that attaches to the motherboard and secures the Pentium II processor in Slot 1 to prevent shock and vibration damage. Retention mechanisms should be provided by the motherboard manufacturer. (For example, the Intel Boxed AL440FX and DK440LX motherboards include a retention mechanism, plus other important system integration components.)

The Pentium II can generate a significant amount of heat that must be dissipated. This is accomplished by installing a heat sink on the processor. Many of the Pentium II processors will use an active heat sink that incorporates a fan. Unlike heat sink fans for previous Intel boxed processors, the Pentium II fans draw power from a three-pin power header on the motherboard. Most motherboards provide several fan connectors to supply this power.

Special heat sink supports are needed to furnish mechanical support between the fan heat sink and support holes on the motherboard. Normally, a plastic support is inserted into the heat sink holes in the motherboard next to the CPU, before installing the CPU/heat sink package. Most fan heat sinks have two components: a fan in a plastic shroud and a metal heat sink. The heat sink is attached to the processor's thermal plate and should not be removed. The fan can be removed and replaced if necessary, for example, if it has failed. Figure 3.43 shows the SEC assembly with fan, power connectors, mechanical supports, and the slot and support holes on the motherboard.

Figure 3.43 Pentium II processor and heat sink assembly.

The following tables show the specifications unique to certain versions of the Pentium II processor.

To identify exactly which Pentium II processor you have and what its capabilities are, look at the specification number printed on the SEC cartridge. You will find the specification number in the dynamic mark area on the top of the processor module. See Figure 3.44 to locate these markings.

After you have located the specification number (actually, it is an alphanumeric code), you can look it up in Table 3.34 to see exactly which processor you have.

For example, a specification number of SL2KA identifies the processor as a Pentium II 333MHz running on a 66MHz system bus, with an ECC L2 cache—and that this processor runs on only 2.0 volts. The stepping is also identified, and by looking in the Pentium II Specification Update Manual published by Intel, you could figure out exactly which bugs were fixed in that revision.

Figure 3.44 Pentium II single edge contact cartridge.

Table 3.34 Basic Pentium II Processor Identification Information

S-spec	Core Stepping	CPUID	Core/Bus Speed (MHz)	L2 Cache Size (MB)	L2 Cache Type	CPU Package	Notes (see footnotes)
SL264	C0	0633h	233/66	512	non-ECC	SECC 3.00	5

SECC = Single Edge Contact Cartridge

SECC2 = Single Edge Contact Cartridge revision 2

PLGA = Plastic Land Grid Array

OLGA = Organic Land Grid Array

CPUID = The internal ID returned by the CPUID instruction

ECC = Error Correcting Code

1. This is a boxed Pentium II processor with an attached fan heat sink.
2. These processors have an enhanced L2 cache, which can cache up to 4GB of main memory. Other standard PII processors can only cache up to 512MB of main memory.
3. These boxed processors may have packaging which incorrectly indicates ECC support in the L2 cache.
4. This is a boxed Pentium II OverDrive processor with an attached fan heat sink, designed for upgrading Pentium Pro (Socket 8) systems.
5. These parts will only operate at the specified clock multiplier frequency ratio at which they were manufactured. They can only be overclocked by increasing bus speed.

The two variations of the SECC2 cartridge vary by the type of processor core package on the board. The PLGA (Plastic Land Grid Array) is the older type of packaging used in previous SECC cartridges as well, and is being phased out. Taking its place is the newer OLGA (Organic Land Grid Array), which is a processor core package that is smaller and easier to manufacture. It also allows better thermal transfer between the processor die and the heat sink, which is attached directly to the top of the OLGA chip package. Figure 3.45 shows the open back side (where the heat sink would be attached) of SECC2 processors with PLGA and OLGA cores.

Figure 3.45 SECC2 processors with PLGA and OLGA cores.

Pentium II motherboards have an onboard voltage regulator circuit that is designed to power the CPU. Currently, there are Pentium II processors that run at several different voltages, so the regulator must be set to supply the correct voltage for the specific processor you are installing. As with the Pentium Pro and unlike the older Pentium, there are no jumpers or switches to set; the voltage setting is handled completely automatically through the Voltage ID (VID) pins on the processor cartridge. Table 3.35 shows the relationship between the pins and the selected voltage.

Table 3.35 Pentium II Voltage ID Definition

Processor Pins					
VID4	VID3	VID2	VID1	VID0	Voltage

1 = Open on processor

To ensure the system is ready for all Pentium II processor variations, the values in **bold** must be supported. Most Pentium II processors run at 2.8v, with some newer ones at 2.0v.

The Pentium II Mobile Module is a Pentium II for notebooks that includes the North Bridge of the high-performance 440BX chipset. This is the first chipset on the market that allows 100MHz processor bus operation, although that is currently not supported in the mobile versions. The 440BX chipset was released at the same time as the 350 and 400MHz versions of the Pentium II; it is the recommended minimum chipset for any new Pentium II motherboard purchases.

▶▶ See “Mobile Pentium II,” p. 1218.

Newer variations on the Pentium II include the Pentium IIPE, which is a mobile version that includes 256KB of L2 cache directly integrated into the die. This means that it runs at full core speed, making it faster than the desktop Pentium II, because the desktop chips use half-speed L2 cache.

Celeron

The Celeron processor is a P6 with the same processor core as the Pentium II. It is mainly designed for lower cost PCs in the \$1,000 or less price category. The best “feature” is that although the cost is low, the performance is not. In fact, due to the superior cache design, the Celeron outperforms the Pentium II at the same speed and at a lower cost.

Most of the features for the Celeron are the same as the Pentium II because it uses the same internal processor core. The main differences are in packaging and L2 cache design.

Up until recently, all Celeron processors were available in a package called the Single Edge Processor Package (SEPP or SEP package). The SEP package is basically the same Slot 1 design as the SECC (Single Edge Contact Cartridge) used in the Pentium II/III, with the exception of the fancy plastic cartridge cover. This cover is deleted in the Celeron, making it cheaper to produce and sell. Essentially the Celeron uses the same circuit board as is inside the Pentium II package.

◀◀ See “Single Edge Contact (SEC) and Single Edge Processor (SEP) Packaging,” p. 71.

Even without the plastic covers, the Slot 1 packaging was more expensive than it should be. This was largely due to the processor retention mechanisms (stands) required to secure the processor into Slot 1 on the motherboard, as well as the larger and more complicated heat sinks required. This, plus competition from the lower end Socket 7 systems using primarily AMD processors, led Intel to introduce the Celeron in a socketed form. The socket is called PGA-370 or Socket 370, because it has 370 pins. The processor package designed for this socket is called the Plastic Pin Grid Array (PPGA) package (see Figure 3.46). The PPGA package plugs into the 370 pin socket and allows for lower cost, lower profile, and smaller systems because of the less expensive processor retention and cooling requirements of the socketed processor.

◀◀ See “Socket PGA-370,” p. 85.

Figure 3.46 Celeron processors in the PPGA and SEP packages.

All Celeron processors at 433MHz and lower have been available in the SEPP that plugs into the 242-contact slot connector. The 300MHz and higher versions are also available in the PPGA package. This means that the 300MHz–433MHz have been available in both packages, while the 466MHz and higher speed versions are only available in the PPGA.

Motherboards that include Socket 370 cannot accept Slot 1 versions of the Celeron, and would also be unable to accept Pentium II or III processors. I normally recommend people use Slot 1 motherboards even for Celerons, because they can later upgrade to Pentium III processors without changing the board. That is because most motherboards that include a Slot 1 can accept Pentium II, Pentium III, or SEPP (Slot 1 board type) Celeron processors. Since the newest and fastest Celerons are only available in the socketed form, you would think this would make them unusable in a Slot 1 motherboard. Fortunately, there are slot-to-socket adapters (usually called slot-kets) available for about \$10 that plug into Slot 1 and incorporate a Socket 370 on the card. Figure 3.47 shows a typical slot-ket adapter.

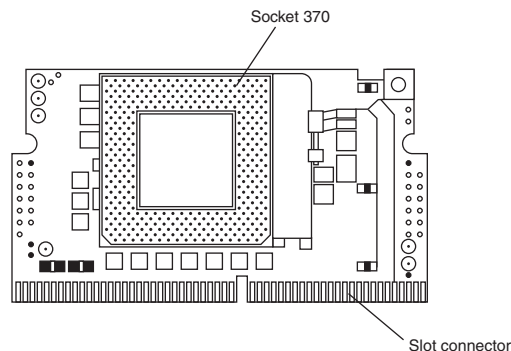

Figure 3.47 Slot-ket adapter for installing PPGA processors in Slot 1 motherboards.

Highlights of the Celeron include

- Available at 300MHz (300A) and higher core frequencies with 128KB L2 cache; 300MHz and 266MHz core frequencies without L2 cache
- Uses same P6 core processor as the Pentium Pro and Pentium II
- Dynamic execution microarchitecture

- Operates on a 66MHz CPU bus (future versions will likely also use the 100MHz bus)
- Specifically designed for lower cost value PC systems
- Includes MMX technology
- More cost-effective packaging technology including Single Edge Processor (SEP) or Plastic Pin Grid Array (PPGA) packages
- Integrated 32KB L1 cache, implemented as separate 16KB instruction and 16KB data caches
- Integrated thermal diode for temperature monitoring

Table 3.36 shows the specifications for all the Celeron processors.

Table 3.36 Intel Celeron Processor Specifications

Intel Celeron Processor (466MHz)	
Introduction date	April 26, 1999
Clock speeds	466MHz
Number of transistors	19 million (0.25 micron process)
Cache: 128KB on-die packaging	Plastic Pin Grid Array (PPGA), 370 pins
Bus Speed	66MHz
Bus Width	64-bit system bus
Addressable Memory	4GB
Typical Use	Value PCs
Mobile Intel Celeron Processor (366MHz)	
Introduction date	May 17, 1999
Clock speeds	366MHz
Number of transistors	18.9 million (0.25 micron process), 128KB on-die L2 cache
Ball Grid Array (BGA) number of balls	615
Dimensions	Width = 32mm; Length = 37mm
Core voltage	1.6 volts
Thermal design power	300MHz = 8.6 watts
Typical use	Value/low-cost mobile PCs
Mobile Intel Celeron Processor (333MHz)	
Introduction date	April 5, 1999
Clock speeds	333MHz
Number of transistors	18.9 million (0.25 micron process), 128KB on-die L2 cache
Ball Grid Array (BGA) number of balls	615
Dimensions	Width = 31mm; Length = 35mm
Core voltage	1.6 volts
Thermal design power	300MHz = 8.6 watts
Typical use	Value/low-cost mobile PCs

Intel Celeron Processor (433MHz)

Introduction date	March 22, 1999
Clock speeds	433MHz
Number of transistors	19 million (0.25 micron process)
Cache	128KB on-die Single Edge Processor Package (SEPP), 242 pins
Plastic Pin Grid Array (PPGA)	370 pins
Bus Speed	66MHz
Bus Width	64 bit system bus
Addressable Memory	4GB
Typical Use	Value PCs

Mobile Intel Celeron Processor (266 and 300MHz)

Introduction date	January 25, 1999
Clock speeds	266 and 300MHz
Number of transistors	18.9 million (0.25 micron process), 128KB on-die L2 cache
Ball Grid Array (BGA) number of balls	615
Dimensions	Width = 31mm; Length = 35mm
Core voltage	1.6 volts
Thermal design power	300MHz = 7.7 watts; 266MHz = 7.0 watts
Typical use	Value/low-cost mobile PCs

Intel Celeron Processor (400, 366MHz)

Introduction date	January 4, 1999
Clock speeds	400, 366MHz
Number of transistors	19 million (0.25 micron process)
Single Edge Processor Package (SEPP)	242 pins
Plastic Pin Grid Array (PPGA)	370 pins
Bus Speed	66MHz
Bus Width	64-bit system bus
Addressable Memory	4GB
Typical Use	Low-cost PCs

Intel Celeron Processor (333MHz)

Introduction date	August 24, 1998
Clock speeds	333MHz
Number of transistors	19 million (0.25 micron process)
Single Edge Processor Package (SEPP)	242 pins
Bus Speed	66MHz
Bus Width	64-bit system bus
Addressable Memory	4GB
Package Dimensions	5" x 2.275" x .208"
Typical Use	Low-cost PCs

(continues)

Table 3.36 Continued

Intel Celeron Processor (300A-MHz)	
Introduction date	August 24, 1998
Clock speeds	300MHz
Number of transistors	19 million (0.25 micron process)
Single Edge Processor Package (SEPP)	242 pins
Bus Speed	66MHz
Bus Width	64-bit system bus
Addressable Memory	4GBs
Package Dimensions	5" × 2.275" × .208"
Typical Use	Low-cost PCs
Intel Celeron Processor (300 MHz)	
Introduction date	June 8, 1998
Clock speeds	300 MHz
Number of transistors	7.5 million (0.25 micron process)
Single Edge Processor Package (SEPP)	242 pins
Bus Speed	66MHz
Bus Width	64-bit system bus
Addressable Memory	4GB
Virtual Memory	64TB
Package Dimensions	5" × 2.275" × .208"
Typical Use	Low-cost PCs
Intel Celeron Processor (266MHz)	
Introduction date	April 15, 1998
Clock speeds	266MHz
Number of transistors	7.5 million (0.25 micron process)
Single Edge Processor Package (SEPP)	242 pins
Bus Speed	66MHz
Bus Width	64-bit system bus
Addressable Memory	4GB
Virtual Memory	64TB
Package Dimensions	5" × 2.275" × .208"
Typical Use	Low-cost PCs

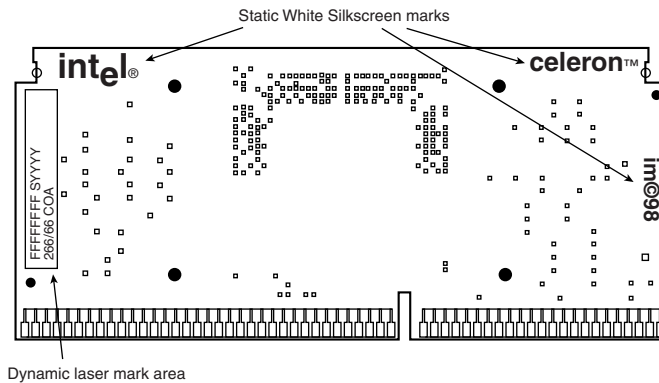

The Intel Celeron processors at 466, 433, 400, 366, 333, and 300A-MHz include integrated L2 cache 128KB. The core for the 466, 433, 400, 366, 333, and 300A-MHz processors have a whopping 19 million transistors due to the addition of the integrated 128KB L2 cache.

All the Celerons are manufactured using the .25 micron process, which reduces processor heat and enables the Intel Celeron processor to use a smaller heat sink compared to some of the Pentium II processors. Table 3.37 shows the power consumed by the various Celeron processors.

Table 3.37 Intel Celeron Processor Power Consumption

Processor Speed	Current (amps)	Voltage	Watts
266MHz	8.2	2.0	16.4
300MHz	9.3	2.0	18.6
300A-MHz	9.3	2.0	18.6
333MHz	10.1	2.0	20.2
366MHz	11.2	2.0	22.4
400MHz	12.2	2.0	24.4
433MHz	12.6	2.0	25.2
466MHz	13.4	2.0	26.8

Figure 3.48 shows the Intel Celeron processor identification information. Figure 3.49 shows the Celeron's PPGA processor markings.

**Figure 3.48** Celeron SEPP (Single Edge Processor Package) processor markings.**Note**

The markings on the processor identify the following information:

SYYYY = S-spec. number

FFFFFFF = FPO # (test lot tracability #)

COA = Country of assembly

**Figure 3.49** Celeron PPGA processor markings.

Note

The PPGA processor markings identify the following information:

AAAAAAA = Product code

ZZZ = Processor speed (MHz)

LLL = Integrated L2 cache size (in Kilobytes)

SYYYY = S-spec. number

FFFFFFF-XXXX = Assembly lot tracking number

Table 3.38 shows all the available variations of the Celeron, indicated by the S-specification number.

2. Boxed processor with an unattached fan heat sink
3. Also available as a boxed processor with an attached fan heat sink

Pentium III

The Pentium III processor, shown in Figure 3.50, was released in February 1999 and introduced several new features to the P6 family. The most important advancements are the streaming SIMD extensions (SSE), consisting of 70 new instructions that dramatically enhance the performance and possibilities of advanced imaging, 3D, streaming audio, video, and speech-recognition applications.

Figure 3.50 Pentium III processor. Photograph used by permission of Intel Corporation.

Based on Intel's advanced 0.25 micron CMOS process technology, the PIII core has over 9.5 million transistors. The Pentium III is available in 450MHz, 500MHz, and 550MHz versions, as well as in 500MHz and 550MHz Xeon versions. The Pentium III also incorporates advanced features such as a 32KB L1 cache and half core speed 512KB L2 cache with cacheability for up to 4GB of addressable memory space. The PIII also can be used in dual-processing systems with up to 64GB of physical memory. A self-reportable processor serial number gives security, authentication, and system management applications a powerful new tool for identifying individual systems.

Pentium III processors are available in Intel's Single Edge Contact Cartridge 2 (SECC2) form factor, which is replacing the more expensive older SEC packaging. The SECC2 package covers only one side of the chip, and allows for better heat sink attachment and less overall weight. It is also less expensive.

Architectural features of the Pentium III processor include

- *Streaming SIMD Extensions.* Seventy new instructions for dramatically faster processing and improved imaging, 3D streaming audio and video, Web access, speech recognition, new user interfaces, and other graphics and sound rich applications.
- *Intel Processor Serial Number.* The processor serial number, the first of Intel's planned building blocks for PC security, serves as an electronic serial number for the processor and, by extension, its system or user. This enables the system/user to be identified by networks and applications. The processor serial number will be used in applications that benefit from stronger forms of system and user identification, such as the following:
 - *Applications using security capabilities.* Managed access to new Internet content and services; electronic document exchange
 - *Manageability applications.* Asset management; remote system load and configuration
 - *Intel MMX Technology*
 - *Dynamic Execution Technology*
 - *Incorporates an on-die diode.* This can be used to monitor the die temperature for thermal management purposes.

Most of the Pentium III processors will be made in the improved SECC2 packaging, which is less expensive to produce and allows for a more direct attachment of the heat sink to the processor core for better cooling.

All Pentium III processors have 512KB of L2 cache, which runs at half of the core processor speed. Xeon versions have 512KB, 1MB, or 2MB of L2 cache that runs at full core speed. These are more expensive versions designed for servers and workstations.

All PIII processor L2 caches can cache up to 4GB of addressable memory space, and include Error Correction Code (ECC) capability.

Table 3.39 shows the Pentium III specifications by model.

Table 3.39 Pentium III Processor Specifications

Pentium III Processor (550MHz)	
Introduction date	May 17, 1999
Clock Speeds	450, 500MHz
Number of transistors	9.5 million (0.25 micron process)
L2 cache	512KB
Processor Package Style	Single Edge Contact (SEC) Cartridge 2
System Bus Speed	100MHz
System Bus Width	64-bit system bus
Addressable Memory	64GB
Typical Use	Business and consumer PCs, one- and two-way servers and workstations

Pentium III Processor (450 and 500MHz)

Introduction date	February 26, 1999
Clock Speeds	450, 500MHz
Number of transistors	9.5 million (0.25 micron process)
L2 cache	512KB
Processor Package Style	Single Edge Contact (SEC) Cartridge 2
System Bus Speed	100MHz
System Bus Width	64-bit system bus
Addressable Memory	64GB
Typical Use	Business and consumer PCs, one- and two-way servers and workstations

Pentium III processors can be identified by their markings, which are found on the top edge of the processor cartridge. Figure 3.51 shows the format and meaning of the markings.

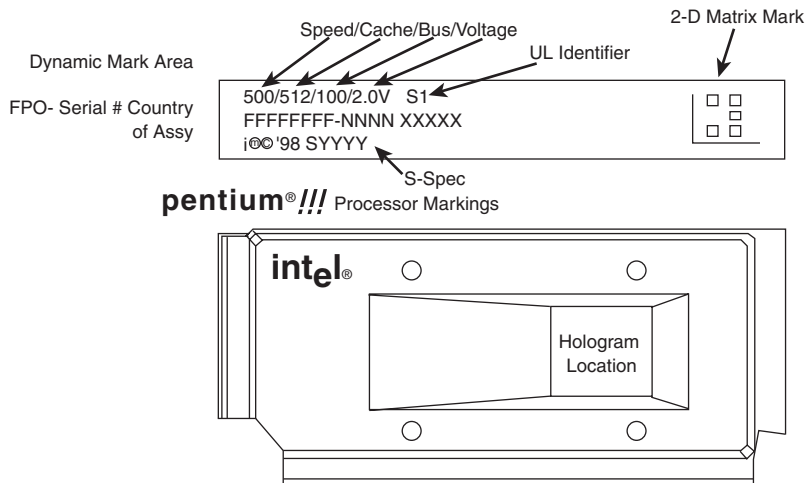

Figure 3.51 Pentium III processor markings.

Table 3.40 shows the available variations of the Pentium III, indicated by the S-specification number.

Table 3.40 Intel Pentium III Processor Variations

S-Spec	Core Stepping	CPUID	Core/Bus Speed (MHz)	L2 Cache Size	L2 Cache Type	Package	Notes (see footnotes)
SL364	kB0	672	450/100	512	ECC	SECC2	
SL365	kB0	672	500/100	512	ECC	SECC2	
SL3CC	kB0	672	450/100	512	ECC	SECC2	1

SECC = Single Edge Contact Cartridge

SECC2 = Single Edge Contact Cartridge revision 2

CPUID = The internal ID returned by the CPUID instruction

ECC = Error Correcting Code

1. This is a boxed processor with an attached heat sink

Pentium III processors are all clock multiplier locked. This is a means to prevent processor fraud and overclocking by making the processor work only at a given clock multiplier. Unfortunately, this feature can be bypassed by making modifications to the processor under the cartridge cover, and unscrupulous individuals have been selling lower speed processors remarked as higher speeds. It pays to purchase your systems or processors from direct Intel distributors or high-end dealers that do not engage in these practices.

Pentium II/III Xeon

The Pentium II and III processors are available in special high-end versions called Xeon processors. These differ from the standard Pentium II and III in three ways: packaging, cache size, and cache speed.

Xeon processors use a larger SEC (Single Edge Contact) cartridge than the standard PII/III processors, mainly to house a larger internal board with more cache memory. The Xeon processor is shown in Figure 3.52; the Xeon's SEC is shown in Figure 3.53.

Figure 3.52 Pentium III Xeon processor. Photograph used by permission of Intel.

Figure 3.53 Xeon processor internal components.

Besides the larger package, the Xeon processors also include more L2 cache. They are available in three variations, with 512KB, 1MB, or 2MB of L2 cache. This cache is costly; the list price of the 2MB version is over \$3,000!

Even more significant than the size of the cache is its speed. All the cache in the Xeon processors run at the full core speed. This is difficult to do considering that the cache chips are separate chips on the board; they are not integrated into the processor die like the Celeron. With the amount of cache, that would be impossible today but might be possible in the future.

Table 3.41 shows the Xeon processor specifications for each model.

Table 3.41 Intel Pentium II and III Xeon Specifications

Pentium III Xeon Processor (500 and 550MHz)	
Introduction date	March 17, 1999
Clock Speeds	500, 550MHz
Number of transistors	9.5 million (0.25 micron process)
L2 cache	512KB, 1 and 2MB for 500MHz
Processor Package Style	Single Edge Contact (SEC) Cartridge 2
System Bus Speed	100MHz
System Bus Width	64-bit system bus
Addressable Memory	64GB
Typical Use	Business PCs, two-, four- and eight-way (and higher) servers and workstations

(continues)

Table 3.41 Continued

Pentium II Xeon Processor (450MHz)	
Introduction date	January 5, 1999
Clock speed	450MHz
L2 cache	512KB, 1MB, and 2MB
Number of transistors	7.5 million
Processor Package Style	Single Edge Contact (SEC) Cartridge
System Bus Speed	100MHz
System Bus Width	8 bytes
Addressable Memory	64GB
Virtual Memory	64TB
Package Dimensions	Height 4.8" × Width 6.0" × Depth .73"
Typical Use	Four-way servers and workstations
Pentium II Xeon Processor (450MHz)	
Introduction date	October 6, 1998
Clock speed	450MHz
L2 cache	512KB
Number of transistors	7.5 million
Processor Package Style	Single Edge Contact (SEC) Cartridge
System Bus Speed	100MHz
System Bus Width	8 bytes
Addressable Memory	64GB
Virtual Memory	64TB
Package Dimensions	Height 4.8" × Width 6.0" × Depth .73"
Typical Use	Dual-processor workstations and servers
Pentium II Xeon Processor (400MHz)	
Introduction date	June 29, 1998
Clock speed	400MHz
L2 cache versions	512KB and 1MB
Number of transistors	7.5 million
Processor Package Style	Single Edge Contact (SEC) Cartridge
System Bus Speed	100MHz
System Bus Width	8 bytes
Addressable Memory	64GB
Virtual Memory	64TB
Package Dimensions	Height 4.8" × Width 6.0" × Depth .73"
Typical Use	Midrange and higher servers and workstations

Note that the Slot 2 Xeon processors do not replace the Slot 1 processors. Xeon processors for Slot 2 are targeted at the mid-range to high-end server and workstation market segments, offering larger, full-speed L2 caches and four-way multiprocessor support. Pentium III processors for Slot 1

will continue to be the processor used in the business and home desktop market segments, and for entry-level servers and workstations (single and dual processor systems).

Pentium III Future

There are several new developments on target for the Pentium III processors. The primary trend seems to be the integration of L2 cache into the processor die, which also means it runs at full core speed.

There will also be further reductions in the process size used to manufacture the processors. Pentium II processors at 333MHz and up were the first members of the Pentium II processor family to be based on the “Deschutes” core (0.25 micron technology). Currently, through the Pentium III 550, they are still using a 0.25 micron process, but will be shifting to a 0.18, and then 0.13 micron process in the future. The shift to the 0.13 micron process will also include a shift from aluminum interconnects on the chip die to copper instead.

Other Sixth-Generation Processors

Besides Intel, many other manufacturers are now making P6 type processors, but often with a difference. Most of them are designed to interface with P5 class motherboards and for the lower end markets. AMD has recently offered up the K7, which is a true sixth-generation design using its own proprietary connection to the system.

This section examines the various sixth-generation processors from manufacturers other than Intel.

Nexgen Nx586

Nexgen was founded by Thampy Thomas who hired some of the people formerly involved with the 486 and Pentium processors at Intel. At Nexgen, they created the Nx586, a processor that was functionally the same as the Pentium but not pin compatible. As such, it was always supplied with a motherboard; in fact, it was normally soldered in. Nexgen did not manufacture the chips or the motherboards they came in; for that they hired IBM Microelectronics. Later Nexgen was bought by AMD, right before they were ready to introduce the Nx686, a greatly improved design done by Greg Favor, and a true competitor for the Pentium. AMD took the Nx686 design and combined it with a Pentium electrical interface to create a drop-in Pentium compatible chip called the K6, which actually outperformed the original from Intel.

The Nx586 had all the standard fifth-generation processor features, such as superscalar execution with two internal pipelines and a high performance integral L1 cache with separate code and data caches. One advantage is that the Nx586 includes separate 16KB instruction and 16KB data caches compared to 8KB each for the Pentium. These caches keep key instruction and data close to the processing engines to increase overall system performance.

The Nx586 also included branch prediction capabilities, which are one of the hallmarks of a sixth-generation processor. Branch prediction means the processor has internal functions to predict program flow to optimize the instruction execution.

The Nx586 processor also featured an RISC (Reduced Instruction Set Computer) core. A translation unit dynamically translates x86 instructions into RISC86 instructions. These RISC86 instructions were specifically designed with direct support for the x86 architecture while obeying RISC performance principles. They are thus simpler and easier to execute than the complex x86 instructions. This type of capability is another feature normally found only in P6 class processors.

The Nx586 was discontinued after the merger with AMD, who then took the design for the successor Nx686 and released it as the AMD-K6.

AMD-K6 Series

The AMD-K6 processor is a high-performance sixth-generation processor that is physically installable in a P5 (Pentium) motherboard. It was essentially designed for them by Nexgen, and was first known as the Nx686. The Nexgen version never appeared because they were purchased by AMD before the chip was due to be released. The AMD-K6 delivers performance levels somewhere between the Pentium and Pentium II processor due to its unique hybrid design. Because it is designed to install in Socket 7, which is a fifth-generation processor socket and motherboard design, it cannot perform quite as a true sixth-generation chip because the Socket 7 architecture severely limits cache and memory performance. However, with this processor, AMD is giving Intel a lot of competition in the low- to mid-range market, where the Pentium is still popular.

The K6 processor contains an industry-standard, high-performance implementation of the new multimedia instruction set (MMX), enabling a high level of multimedia performance. The K6-2 introduced an upgrade to MMX AMD calls 3DNow, which adds even more graphics and sound instructions. AMD designed the K6 processor to fit the low-cost, high-volume Socket 7 infrastructure. This enables PC manufacturers and resellers to speed time to market and deliver systems with an easy upgrade path for the future. AMD's state-of-the-art manufacturing facility in Austin, Texas (Fab 25) makes the AMD-K6 series processors. Initially they used AMD's 0.35 micron, five-metal layer process technology; newer variations use the 0.25 micron processor to increase production quantities because of reduced die size, as well as to decrease power consumption.

AMD-K6 processor technical features include

- Sixth-generation internal design, fifth-generation external interface
- Internal RISC core, translates x86 to RISC instructions
- Superscalar parallel execution units (seven)
- Dynamic execution
- Branch prediction
- Speculative execution
- Large 64KB L1 cache (32KB instruction cache plus 32KB write-back dual-ported data cache)
- Built-in floating-point unit (FPU)
- Industry-standard MMX instruction support
- System Management Mode (SMM)
- Ceramic Pin Grid Array (CPGA) Socket 7 design
- Manufactured using a 0.35 micron and 0.25 micron, five-layer design

The K6-2 adds

- Higher clock speeds
- Higher bus speeds of up to 100MHz (Super7 motherboards)
- 3DNow; 21 new graphics and sound processing instructions

The K6-3 adds

- 256KB of on-die full core speed L2 cache

The addition of the full speed L2 cache in the K6-3 is significant. It brings the K6 series to a level where it can fully compete with the Intel Celeron and Pentium II processors. The 3DNow capability added in the K6-2/3 is also being exploited by newer graphics programs, making these processors ideal for lower cost gaming systems.

The AMD-K6 processor architecture is fully x86 binary code compatible, which means it runs all Intel software, including MMX instructions. To make up for the lower L2 cache performance of the Socket 7 design, AMD has beefed up the internal L1 cache to 64KB total, twice the size of the Pentium II or III. This, plus the dynamic execution capability, allows the K6 to outperform the Pentium and come close to the Pentium II in performance for a given clock rate. The K6-3 is even better with the addition of full core speed L2 cache.

Both the AMD-K5 and AMD-K6 processors are Socket 7 bus-compatible. However, certain modifications might be necessary for proper voltage setting and BIOS revisions. To ensure reliable operation of the AMD-K6 processor, the motherboard must meet specific voltage requirements.

The AMD processors have specific voltage requirements. Most older split-voltage motherboards default to 2.8v Core/3.3v I/O, which is below specification for the AMD-K6 and could cause erratic operation. To work properly, the motherboard must have Socket 7 with a dual-plane voltage regulator supplying 2.9v or 3.2v (233MHz) to the CPU core voltage (Vcc2) and 3.3v for the I/O (Vcc3). The voltage regulator must be capable of supplying up to 7.5A (9.5A for the 233MHz) to the processor. When used with a 200MHz or slower processor, the voltage regulator must maintain the core voltage within 145 mv of nominal (2.9v+/-145 mv). When used with a 233MHz processor, the voltage regulator must maintain the core voltage within 100 mv of nominal (3.2v+/-100 mv).

If the motherboard has a poorly designed voltage regulator that cannot maintain this performance, unreliable operation can result. If the CPU voltage exceeds the absolute maximum voltage range, the processor can be permanently damaged. Also note that the K6 can run hot. Ensure your heat sink is securely fitted to the processor and the thermally conductive grease or pad is properly applied.

The motherboard must have an AMD-K6 processor-ready BIOS with support for the K6 built in. Award has that support in their March 1, 1997 or later BIOS, AMI had K6 support in any of their BIOS with CPU Module 3.31 or later, and Phoenix supports the K6 in version 4.0, release 6.0, or release 5.1 with build dates of 4/7/97 or later.

Because these specifications can be fairly complicated, AMD keeps a list of motherboards that have been verified to work with the AMD-K6 processor on their Web site. All the motherboards on that list have been tested to work properly with the AMD-K6. So, unless these requirements can be verified elsewhere, it is recommended that you only use a motherboard from that list with the AMD-K6 processor.

The multiplier, bus speed, and voltage settings for the K6 are shown in Table 3.42. You can identify which AMD-K6 you have by looking at the markings on this chip, as shown in Figure 3.57.

Table 3.42 AMD-K6 Processor Speeds and Voltages

Processor	Core Speed	Clock Multiplier	Bus Speed	Core Voltage	I/O Voltage
K6-III	450MHz	4.5x	100MHz	2.4v	3.3v
K6-III	400MHz	4x	100MHz	2.4v	3.3v
K6-2	475MHz	5x	95MHz	2.4v	3.3v
K6-2	450MHz	4.5x	100MHz	2.4v	3.3v
K6-2	400MHz	4x	100MHz	2.2v	3.3v
K6-2	380MHz	4x	95MHz	2.2v	3.3v
K6-2	366MHz	5.5x	66MHz	2.2v	3.3v
K6-2	350MHz	3.5x	100MHz	2.2v	3.3v
K6-2	333MHz	3.5x	95MHz	2.2v	3.3v
K6-2	333MHz	5.0x	66MHz	2.2v	3.3v
K6-2	300MHz	3x	100MHz	2.2v	3.3v
K6-2	300MHz	4.5x	66MHz	2.2v	3.3v
K6-2	266MHz	4x	66MHz	2.2v	3.3v
K6	300MHz	4.5x	66MHz	2.2v	3.45v
K6	266MHz	4x	66MHz	2.2v	3.3v
K6	233 MHz	3.5x	66MHz	3.2v	3.3v
K6	200MHz	3x	66MHz	2.9v	3.3v
K6	166MHz	2.5x	66MHz	2.9v	3.3v

Figure 3.54 AMD-K6 processor markings.

Older motherboards achieve the 3.5x setting by setting jumpers for 1.5x. The 1.5x setting for older motherboards equates to a 3.5x setting for the AMD-K6 and newer Intel parts. To get the 4x and higher setting requires a motherboard that controls three BF (bus frequency) pins, including BF2. Older motherboards can only control two BF pins. The settings for the multipliers are shown in Table 3.43.

Table 3.43 AMD-K6 Multiplier Settings

Multiplier Setting	BF0	BF1	BF2
2.5x	Low	Low	High
3x	High	Low	High
3.5x	High	High	High
4x	Low	High	Low
4.5x	Low	Low	Low
5x	High	Low	Low
5.5x	High	High	Low

These settings are normally controlled by jumpers on the motherboard. Consult your motherboard documentation to see where they are and how to set them for the proper multiplier and bus speed settings.

Unlike Cyrix and some of the other Intel competitors, AMD is a manufacturer and a designer. This means they design and build their chips in their own fabs. Like Intel, AMD is migrating to 0.25 micron process technology and beyond. The original K6 has 8.8 million transistors and is built on a 0.35 micron, five-layer process. The die is 12.7mm on each side, or about 162 square mm. The K6-3 uses a 0.25 micron process and now incorporates 21.3 million transistors on a die only 10.9mm on each side, or about 118 square mm. Further process improvements will enable even more transistors, smaller die, higher yields, and greater numbers of processors. AMD has recently won contracts with several high-end system suppliers, which gives them an edge on the other Intel competitors. AMD has delivered more than 50 million Windows-compatible CPUs in the last five years.

Because of its performance and compatibility with the Socket 7 interface, the K6 series is often looked at as an excellent processor upgrade for motherboards currently using older Pentium or Pentium MMX processors. Although they do work in Socket 7, the AMD-K6 processors have different voltage and bus speed requirements than the Intel processors. Before attempting any upgrades, you should check the board documentation or contact the manufacturer to see if your board will meet the necessary requirements. In some cases, a BIOS upgrade will also be necessary.

3DNow

3DNow technology was introduced in May 1998 in the K6-2 as a set of instructions that extend the multimedia capabilities of the AMD chips. This allows greater performance for 3D graphics, multimedia, and other floating-point-intensive PC applications.

3DNow technology is a set of 21 instructions that use SIMD (Single Instruction Multiple Data) techniques to operate on arrays of data rather than single elements. Positioned as an extension to MMX technology, 3DNow is similar to the SSE (streaming SIMD extensions) found in the Pentium III processors from Intel. SSE consists of 70 new SIMD type instructions.

3DNow is well supported by software including Microsoft Windows 95/98, Windows NT 4.0, and all newer Microsoft operating systems. Application programming interfaces such as Microsoft's DirectX 6.x API and SGI's Open GL API have been optimized for 3DNow technology, as have the drivers for many leading 3D graphic accelerator suppliers, including 3Dfx, ATI, Matrox, and nVidia.

AMD-K7

The K7 is AMD's successor to the K6 series. The K7 is a whole new chip from the ground up and does not interface via the Socket 7 or Super7 sockets like their previous chips. Instead AMD seems to be taking a lesson from Intel, as the K7 looks almost exactly like a Pentium II/III cartridge. Unfortunately it doesn't plug into the same motherboards as the Pentium II/III; instead the K7 slot is a proprietary design requiring specific K7 motherboards with specific K7 chipsets.

The K7 is available in speeds from 550MHz and up, and uses a sideways 200MHz bus called the EV6 to connect to the motherboard North Bridge chip as well as other processors. Licensed from Digital Equipment, the EV6 bus is the same as that used for the Alpha 21264 processor, now owned by Compaq.

The K7 has a very large 128KB of L1 cache on the processor die, and 200MHz L2 cache from 512KB to 8MB in the cartridge. As expected, the K7 has support for MMX and 3DNow instructions, but not for the newer SSE (streaming SIMD extensions) instructions from Intel.

The initial production will utilize 0.25 micron technology, and clock speeds will exceed 500MHz. Subsequent versions will use a 0.18 micron process, and speeds will continue to increase. AMD chairman and CEO William J. (Jerry) Sanders III has previously stated the goal of delivering 1GHz K7 chips by 2000, utilizing copper interconnect manufacturing.

Cyrix MediaGX

The Cyrix MediaGX is designed for low-end sub-\$1,000 retail store systems that must be highly integrated and low priced. The MediaGX integrates the sound, graphics, and memory control by putting these functions directly within the processor. With all these functions pulled "on chip," MediaGX-based PCs are priced lower than other systems with similar features.

The MediaGX processor integrates the PCI interface, coupled with audio, graphics, and memory control functions, right into the processor unit. As such, a system with the MediaGX doesn't require a costly graphics or sound card. Not only that, but on the motherboard level, the MediaGX and its companion chip replace the processor, North and South Bridge chips, the memory control hardware, and L2 cache found on competitive Pentium boards. Finally, the simplified PC design of the MediaGX, along with its low-power and low-heat characteristics, allow the OEM PC manufacturer to design a system in a smaller form factor with a reduced power-supply requirement.

The MediaGX processor is not a Socket 7 processor; in fact, it does not go in a socket at all—it is permanently soldered into its motherboard. Because of the processor's high level of integration, motherboards supporting MediaGX processors and its companion chip (Cx5510) are of a different design than conventional Pentium boards. As such, a system with the MediaGX processor is more of a disposable system than an upgradable system. You will not be able to easily upgrade most components in the system, but that is often not important in the very low-end market. If upgradability is important, look elsewhere. On the other hand, if you need the lowest-priced system possible, one with the MediaGX might fill the bill.

The MediaGX is fully Windows-compatible and will run the same software as an equivalent Pentium. You can expect a MediaGX system to provide equivalent performance as a given Pentium system at the same megahertz. The difference with the MediaGX is that this performance level is achieved at a much lower cost. Because the MediaGX processor is soldered into the motherboard and requires a custom chipset, it is only sold in a complete motherboard form.

There is also an improved MMX-enhanced MediaGX processor that features MPEG1 support, Microsoft PC97 compliance for Plug-and-Play access, integrated game port control, and AC97 audio compliance. It supports Windows 95 and DOS-based games, and MMX software as well. Such systems will also include two universal serial bus (USB) ports, which will accommodate the new generation of USB peripherals such as printers, scanners, joysticks, cameras, and more.

The MediaGX processor is offered at 166 and 180MHz, while the MMX-enhanced MediaGX processor is available at 200MHz and 233 MHz. Compaq is using the MMX-enhanced MediaGX processor in its Presario 1220 notebook PCs, which is a major contract win for Cyrix. Other retailers and resellers are offering low-end, low-cost systems in retail stores nationwide.

Cyrix/IBM 6x86 (M1) and 6x86MX (MII)

The Cyrix 6x86 processor family consists of the now-discontinued 6x86 and the newer 6x86MX processors. They are similar to the AMD-K5 and K6 in that they offer sixth-generation internal designs in a fifth-generation P5 Pentium compatible Socket 7 exterior.

The Cyrix 6x86 and 6x86MX (renamed MII) processors incorporate two optimized superpipelined integer units and an on-chip floating-point unit. These processors include the dynamic execution capability that is the hallmark of a sixth-generation CPU design. This includes branch prediction and speculative execution.

The 6x86MX/MII processor is compatible with MMX technology to run the latest MMX games and multimedia software. With its enhanced memory-management unit, a 64KB internal cache, and other advanced architectural features, the 6x86MX processor achieves higher performance and offers better value than competitive processors.

Features and benefits of the 6x86 processors include

- *Superscalar architecture.* Two pipelines to execute multiple instructions in parallel.
- *Branch prediction.* Predicts with high accuracy the next instructions needed.

- *Speculative execution.* Allows the pipelines to continuously execute instructions following a branch without stalling the pipelines.
- *Out-of-order completion.* Lets the faster instruction exit the pipeline out of order, saving processing time without disrupting program flow.

The 6x86 incorporates two caches: a 16KB dual-ported unified cache and a 256-byte instruction line cache. The unified cache is supplemented with a small quarter-K sized high-speed, fully associative instruction line cache. The improved 6x86MX design quadruples the internal cache size to 64KB, which significantly improves performance.

The 6x86MX also includes the 57 MMX instructions that speed up the processing of certain computing-intensive loops found in multimedia and communication applications.

All 6x86 processors feature support for System Management Mode (SMM). This provides an interrupt that can be used for system power management or software transparent emulation of I/O peripherals. Additionally, the 6x86 supports a hardware interface that allows the CPU to be placed into a low-power suspend mode.

The 6x86 is compatible with x86 software and all popular x86 operating systems, including Windows 95/98, Windows NT, OS/2, DOS, Solaris, and UNIX. Additionally, the 6x86 processor has been certified Windows 95 compatible by Microsoft.

As with the AMD-K6, there are some unique motherboard requirements for the 6x86 processors. Cyrix maintains a list of recommended motherboards on their Web site that should be consulted if you are considering installing one of these chips in a board.

When installing or configuring a system with the 6x86 processors, you have to set the correct motherboard bus speed and multiplier settings. The Cyrix processors are numbered based on a P-rating scale, which is not the same as the true megahertz clock speed of the processor.

See “Cyrix P-Ratings” earlier in this chapter to see the correct and true speed settings for the Cyrix 6x86 processors.

Note that because of the use of the P-rating system, the actual speed of the chip is not the same number at which it is advertised. For example, the 6x86MX-PR300 is not a 300MHz chip; it actually runs at only 263MHz or 266MHz, depending on exactly how the motherboard bus speed and CPU clock multipliers are set. Cyrix says it runs as fast as a 300MHz Pentium, hence the P-rating. Personally, I wish they would label the chips at the correct speed, and then say that it runs faster than a Pentium at the same speed.

To install the 6x86 processors in a motherboard, you also have to set the correct voltage. Normally, the markings on top of the chip indicate which voltage setting is appropriate. Various versions of the 6x86 run at 3.52v (use VRE setting), 3.3v (VR setting), or 2.8v (MMX) settings. The MMX versions use the standard split-plane 2.8v core 3.3v I/O settings.

P7 (786) Seventh-Generation Processors

What is coming after the Pentium III? The next processor is code-named either P7 or Merced.

Intel has indicated that the new 64-bit Merced processor will be available in sample volumes in 1999, with planned production volumes moving from 1999 to mid-2000. The Merced processor will be the first processor in Intel's IA-64 (Intel Architecture 64-bit) product family, and will incorporate innovative performance-enhancing architecture techniques, such as predication and speculation.

Merced

The most current generation of processor is the P6, which was first seen in the Pentium Pro introduced in November of 1995, and most recently found in the latest Pentium III processors. Obviously, then, the next generation processor from Intel will be called the P7.

Although the Merced processor program is still far from being released, the program has made considerable progress to date according to Intel, including

- Definition of the 64-bit instruction set architecture with Hewlett-Packard
- Completion of the fundamental microarchitecture design
- Completion of functional model and initial physical layout
- Completion of mechanical and thermal design and validation with system vendors
- Specifications complete and designs underway for chipset and other system components
- Progress on 64-bit compiler development and IA-64 software development kits
- Real-time software emulation capability to speed the development of IA-64 optimized software
- Multiple operating systems running in Merced simulation environment
- All required platform components planned for alignment with 1999 Merced processor samples for initial system assembly and testing

Intel's IA-64 product family is expected to expand the capabilities of the Intel architecture to address the high-performance server and workstation market segments. A variety of industry players—among them leading workstation and server-system manufacturers, leading operating system vendors, and dozens of independent software vendors—have already publicly committed their support for the Merced processor and the IA-64 product family.

As with previous new processor introductions, the P7 will not replace the P6 or P5, at least not at first. It will feature an all new design that will be initially expensive and found only in the highest end systems such as file servers or workstations. Intel expects the P7 will become the mainstream processor by the year 2004 and that the P6 will likely be found in low-end systems only. Intel is already developing an even more advanced P7 processor, due to ship in 2001, which will be significantly faster than Merced.

Intel and Hewlett-Packard began jointly working on the P7 processor in 1994. It was then that they began a collaboration on what will eventually become Intel's next-generation CPU. Although we don't know exactly what the new CPU will be like, Intel has begun slowly releasing information about the new processor to prepare the industry for its eventual release. In October of 1997, more than three years after they first disclosed their plan to work together on a new microprocessor architecture, Intel and HP officially announced some of the new processor's technical details.

The first chip to implement the P7 architecture won't ship until late 1999.

Merced will be the first microprocessor that will be based on the 64-bit, next-generation Intel architecture-64 (IA-64) specification. IA-64 is a completely different processor design, which will use Very Long Instruction Words (VLIW), instruction prediction, branch elimination, speculative loading, and other advanced processes for enhancing parallelism from program code. The new chip will feature elements of both CISC and RISC design.

There is also a new architecture Intel calls Explicitly Parallel Instruction Computing (EPIC), which will let the processor execute *parallel instructions*—several instructions at the same time. In the P7, three instructions will be encoded in one 128-bit word, so that each instruction has a few more bits than today's 32-bit instructions. The extra bits let the chip address more registers and tell the processor which instructions to execute in parallel. This approach simplifies the design of processors with many parallel-execution units and should let them run at higher clock rates. In other words, besides being capable of executing several instructions in parallel within the chip, the P7 will have the capability to be linked to other P7 chips in a parallel processing environment.

Besides having new features and running a completely new 64-bit instruction set, Intel and HP promise full backward compatibility between the Merced, the current 32-bit Intel x86 software, and even HP's own PA-RISC software. The P7 will incorporate three different kinds of processors in one and therefore be capable of running advanced IA-64 parallel processing software and IA-32 Windows and HP-RISC UNIX programs at the same time. In this way, Merced will support 64-bit instructions while retaining compatibility with today's 32-bit applications. This backward compatibility will be a powerful selling point.

To use the IA-64 instructions, programs will have to be recompiled for the new instruction set. This is similar to what happened in 1985, when Intel introduced the 80386, the first 32-bit PC processor. The 386 was to give IBM and Microsoft a platform for an advanced 32-bit operating system that tapped this new power. To ensure immediate acceptance, the 386 and future 32-bit processors still ran 16-bit code. To take advantage of the 32-bit capability first found in the 386, new software would have to be written. Unfortunately, software evolves much more slowly than hardware. It took Microsoft a full 10 years after the 386 debuted to release Windows 95, the first mainstream 32-bit operating system for Intel processors.

Intel claims that won't happen with the P7. Despite that, it will likely take several years before the software market shifts to 64-bit operating systems and software. The installed base of 32-bit processors is simply too great, and the backward compatible 32-bit mode of the P7 will allow it to run 32-bit software very well, because it will be done in the hardware rather than through software emulation.

Merced will use 0.18 micron technology, which is one generation beyond the 0.25 micron process used today. This will allow them to pack many more transistors in the same space. Early predictions have the Merced sporting between 10 and 12 million transistors!

Intel's initial goal with IA-64 is to dominate the workstation and server markets, competing with chips such as the Digital Alpha, Sun Sparc, and Motorola PowerPC. Microsoft will provide a

version of Windows NT that runs on the P7, and Sun plans to provide a version of Solaris, its UNIX operating-system software, to support Merced as well. NCR has already announced that it will build Merced-powered systems that use Solaris.

Merced will be available in a new package called the Pin Array Cartridge (PAC). This cartridge will include cache and will plug into a socket on the motherboard and not a slot. The package is about the size of a standard index card, weighs about 6oz (170g), and has an alloy metal on its base to dissipate the heat. Merced has clips on its sides, allowing four to be hung from a motherboard, both below and above.

Merced will have three levels of cache. A new L0 cache will be closely tied to the execution unit. It will be backed by on-chip L1 cache. The multimegabyte L2 cache will be housed on a separate die but contained within the cartridge.

Merced will be followed in late 2001 by a second IA-64 processor code-named McKinley. McKinley will have large, on-chip L2 cache and target clock speeds of more than 1GHz, offering more than twice the performance of Merced, according to Intel reps. Following McKinley will be Madison, based on 0.13 micron technology. Both Merced and McKinley are based on 0.18 micron technology.

Processor Upgrades

Since the 486, processor upgrades have been relatively easy for most systems. With the 486 and later processors, Intel designed in the capability to upgrade by designing standard sockets that would take a variety of processors. Thus, if you have a motherboard with Socket 3, you can put virtually any 486 processor in it; if you have a Socket 7 motherboard, it should be capable of accepting virtually any Pentium processor.

To maximize your motherboard, you can almost always upgrade to the fastest processor your particular board will support. Normally, that can be determined by the type of socket on the motherboard. Table 3.44 lists the fastest processor upgrade solution for a given processor socket.

Table 3.44 Maximum Processor Speeds by Socket

Socket Type	Fastest Processor Supported
Socket 1	5x86–133MHz with 3.3v adapter
Socket 2	5x86–133MHz with 3.3v adapter
Socket 3	5x86–133MHz
Socket 4	Pentium OverDrive 133MHz
Socket 5	Pentium MMX 233MHz or AMD-K6 with 2.8v adapter
Socket 7	AMD-K6-2, K6-3, up to 475MHz
Socket 8	Pentium Pro OverDrive (333MHz Pentium II performance)
Slot 1	Celeron 466MHz (66MHz bus)
Slot 1	Pentium III 550MHz (100MHz bus)
Slot 2	Pentium III Xeon 550MHz (100MHz bus)

For example, if your motherboard has a Pentium Socket 5, you can install a Pentium MMX 233MHz processor with a 2.8v voltage regulator adapter, or optionally an AMD-K6, also with a voltage regulator adapter. If you have Socket 7, your motherboard should be capable of supporting the lower voltage Pentium MMX or AMD-K6 series directly without any adapters. The K6-2 and K6-3 are the fastest and best processors for Socket 7 motherboards.

Rather than purchasing processors and adapters separately, I normally recommend you purchase them together in a module from companies such as Kingston or Evergreen (see the Vendor List on the CD).

Upgrading the processor can, in some cases, double the performance of a system, such as if you were going from a Pentium 100 to an MMX 233. However, if you already have a Pentium 233, you already have the fastest processor that goes in that socket. In that case, you really should look into a complete motherboard change, which would let you upgrade to a Pentium II processor at the same time. If your chassis design is not proprietary and your system uses an industry standard Baby-AT or ATX motherboard design, I normally recommend changing the motherboard and processor rather than trying to find an upgrade processor that will work with your existing board.

OverDrive Processors

Intel has stated that all its future processors will have OverDrive versions available for upgrading at a later date. Often these are repackaged versions of the standard processors, sometimes including necessary voltage regulators and fans. Usually they are more expensive than other solutions, but they are worth a look.

OverDrive Processor Installation

You can upgrade many systems with an OverDrive processor. The most difficult aspect of the installation is having the correct OverDrive processor for your system. Currently, 486 Pentium OverDrive processors are available for replacing 486SX and 486DX processors. Pentium and Pentium-MMX OverDrive processors are also available for some Pentium processors. Unfortunately, Intel no longer offers upgrade chips for 168-pin socket boards. Table 3.45 lists the current OverDrive processors offered by Intel.

Table 3.45 Intel OverDrive Processors

Processor Designation	Replaces	Socket	Heat Sink
486 Pentium OverDrive	486SX/DX/SX2/DX2	Socket 2 or 3	Active
120/133 Pentium	Pentium 60/66	Socket 4	Active OverDrive
200MHz Pentium OverDrive	Pentium 75/90/100	Socket 5/7	Active with MMX

Upgrades that use the newer OverDrive chips for Sockets 2–7 are likely to be much easier because these chips almost always go into a ZIF socket and, therefore, require no tools. In most cases, special configuration pins in the socket and on the new OverDrive chips take care of any jumper settings for you. In some cases, however, you might have to set some jumpers on the motherboard

to configure the socket for the new processor. If you have an SX system, you also will have to run your system's Setup program because you must inform the CMOS memory that a math coprocessor is present. (Some DX systems also require you to run the setup program.) Intel provides a utility disk that includes a test program to verify that the new chip is installed and functioning correctly.

After verifying that the installation functions correctly, you have nothing more to do. You do not need to reconfigure any of the software on your system for the new chip. The only difference that you should notice is that everything works nearly twice as fast as it did before the upgrade.

OverDrive Compatibility Problems

Although you can upgrade many older 486SX or 486DX systems with the OverDrive processors, some exceptions exist. Four factors can make an OverDrive upgrade difficult or impossible:

- BIOS routines that use CPU-dependent timing loops
- Lack of clearance for the OverDrive heat sink (25MHz and faster)
- Inadequate system cooling
- A 486 CPU that is soldered in rather than socketed

In some rare cases, problems may occur in systems that should be upgradable but are not. One of these problems is related to the ROM BIOS. A few 486 systems have a BIOS that regulates hardware operations by using timing loops based on how long it takes the CPU to execute a series of instructions. When the CPU suddenly is running twice as fast, the prescribed timing interval is too short, resulting in improper system operation or even hardware lockups. Fortunately, you usually can solve this problem by upgrading the system's BIOS. Intel offers BIOS updates with the OverDrive processors it sells.

Another problem is related to physical clearance. All OverDrive chips have heat sinks glued or fastened to the top of the chip. The heat sink can add 0.25 to 1.2 inches to the top of the chip. This extra height can interfere with other components in the system, especially in small desktop systems and portables. Solutions to this problem must be determined on a case-by-case basis. You can sometimes relocate an expansion card or disk drive, or even modify the chassis slightly to increase clearance. In some cases, the interference cannot be resolved, leaving you only the option of running the chip without the heat sink. Needless to say, removing the glued-on heat sink will at best void the warranty provided by Intel and will at worst damage the chip or the system due to overheating. I do not recommend removing the heat sink.

The OverDrive chips can generate up to twice the heat of the chips that they replace. Even with the active heat sink/fan built into the faster OverDrive chips, some systems do not have enough airflow or cooling capability to keep the OverDrive chip within the prescribed safe operating-temperature range. Small desktop systems or portables are most likely to have cooling problems. Unfortunately, only proper testing can indicate whether a system will have a heat problem. For this reason, Intel has been running an extensive test program to certify systems that are properly designed to handle an OverDrive upgrade.

Finally, some systems have a proprietary design that precludes the use of the OverDrive processor. This would, for example, include virtually all portable, laptop, or notebook computers that have their processor soldered into the motherboard. Some of the newer ones use the Intel Mobile Module, which is potentially upgradable.

To clarify which systems are tested to be upgradable without problems, Intel has compiled an extensive list of compatible systems. To determine whether a PC is upgradable with an OverDrive processor, contact Intel via its FAXback system (see the Vendor List on the CD) and ask for the OverDrive Processor Compatibility Data documents. The information is also available on Intel's Web site. These documents list the systems that have been tested with the OverDrive processors and indicate which other changes you might have to make for the upgrade to work (for example, a newer ROM BIOS or Setup program).

Note

If your system is not on the list, the warranty on the OverDrive processor is void. Intel recommends OverDrive upgrades only for systems that are in the compatibility list. The list also includes notes about systems that may require a ROM upgrade, a jumper change, or perhaps a new setup disk.

After upgrading your system, I suggest running a diagnostic program such as the Norton Utilities to verify that the new processor is running correctly.

▶▶ See "Norton Utilities Diagnostics," p. 1296.

Processor Benchmarks

People love to know how fast (or slow) their computers are. We have always been interested in speed; it is human nature. To help us with this quest, various benchmark test programs can be used to measure different aspects of processor and system performance. Although no single numerical measurement can completely describe the performance of a complex device like a processor or a complete PC, benchmarks can be useful tools for comparing different components and systems.

However, the only truly accurate way to measure your system's performance is to test the system using the actual software applications you use. Though you think you might be testing one component of a system, often other parts of the system can have an effect. It is inaccurate to compare systems with different processors, for example, if they also have different amounts or types of memory, different hard disks, video cards, and so on. All these things and more will skew the test results.

Benchmarks can normally be divided into two kinds: component or system tests. Component benchmarks measure the performance of specific parts of a computer system, such as a processor, hard disk, video card, or CD-ROM drive, while system benchmarks typically measure the performance of the entire computer system running a given application or test suite.

Benchmarks are, at most, only one kind of information that you can use during the upgrading or purchasing process. You are best served by testing the system using your own set of software operating systems and applications, and in the configuration you will be running.

There are several companies that specialize in benchmark tests and software. The following table lists the company and the benchmarks they are known for. You can contact these companies via the information in the Vendor List on the CD.

Company	Benchmarks Published	Benchmark Type
Intel	iCOMP index 2.0	Processor
Intel	iCOMP index 2.0	System Intel Media Benchmark
Business Applications Performance Corporation	SYSmark/NT (BAPCo)	System
Business Applications Performance Corporation for Windows	SYSmark/NT, SYSmark95 (BAPCo)	System
Standard Performance Evaluation Corporation	SPECint95 (SPEC)	Processor
Standard Performance Evaluation Corporation	SPECint95, SPECfp95	Processor (SPEC)
Ziff-Davis Benchmark	CPUmark32	Processor Operation
Ziff-Davis Benchmark	Winstone 98	System Operation
Ziff-Davis Benchmark	WinBench 98	System Operation
Ziff-Davis Benchmark	CPUmark32, Winstone 98, WinBench 98, 3D WinBench 98	System Operation
Symantec Corporation	Norton SI32	Processor
Symantec Corporation	Norton SI32, Norton Multimedia Benchmark	System

Processor Troubleshooting Techniques

Processors are normally very reliable. Most PC problems will be with other devices, but if you suspect the processor, there are some steps you can take to troubleshoot it. The easiest thing to do is to replace the microprocessor with a known good spare. If the problem goes away, the original processor is defective. If the problem persists, the problem is likely elsewhere.

Table 3.46 provides a general troubleshooting checklist for processor-related PC problems.

Table 3.46 Troubleshooting Processor-Related Problems

Problem Identification	Possible Cause	Resolution
System is dead, no cursor, no beeps, no fan	Power cord failure	Plug in or replace power cord. Power cords can fail even though they look fine.
	Power supply Failure	Replace the power supply. Use a known-good spare for testing.

(continues)

Table 3.46 Troubleshooting Processor-Related Problems

Problem Identification	Possible Cause	Resolution
	Motherboard failure	Replace motherboard. Use a known good spare for testing.
	Memory failure	Remove all memory except 1 bank and retest. If the system still won't boot replace bank 1.
System is dead, no beeps, or locks up before POST begins	All components either not installed or incorrectly installed	Check all peripherals, especially memory and graphics adapter. Reseat all boards and socketed components.
System beeps on startup, fan is running, no cursor on screen.	Improperly Seated or Failing Graphics Adapter	Reseat or replace graphics adapter. Use known good spare for testing.
Locks up during or shortly after POST	Poor Heat Dissipation	Check CPU heat sink/fan; replace if necessary, use one with higher capacity
	Improper voltage settings	Set motherboard for proper core processor voltage
	Wrong motherboard bus speed	Set motherboard for proper speed
	Wrong CPU clock multiplier	Jumper motherboard for proper clock multiplier
Improper CPU identification during POST	Old BIOS	Update BIOS from manufacturer
	Board is not configured properly	Check manual and jumper board accordingly to proper bus and multiplier settings
Operating system will not boot	Poor heat dissipation	Check CPU fan; replace if necessary, may need higher capacity heat sink
	Improper voltage settings	Jumper motherboard for proper core voltage
	Wrong motherboard bus speed	Jumper motherboard for proper speed
	Wrong CPU clock multiplier	Jumper motherboard for proper clock multiplier
	Applications will not install or run	Improper drivers or incompatible hardware; update drivers and check for compatibility issues
System appears to work, but no video is displayed	Monitor turned off or failed	Check monitor and power to monitor. Replace with known, good spare for testing

If during the POST the processor is not identified correctly, your motherboard settings might be incorrect or your BIOS might need to be updated. Check that the motherboard is jumpered or configured correctly for the processor that you have, and make sure that you have the latest BIOS for your motherboard.

If the system seems to run erratically after it warms up, try setting the processor to a lower speed setting. If the problem goes away, the processor might be defective or overclocked.

Many hardware problems are really software problems in disguise. Make sure you have the latest BIOS for your motherboard, as well as the latest drivers for all your peripherals. Also it helps to use the latest version of your given operating system since there will normally be fewer problems.

Motherboards and Buses

Motherboard Form Factors

Without a doubt, the most important component in a PC system is the main board or motherboard. Some companies refer to the motherboard as a system board or planar. The terms, *motherboard*, *main board*, *system board*, and *planar* are interchangeable. In this chapter, we will examine the different types of motherboards available and those components usually contained on the motherboard and motherboard interface connectors.

There are several common form factors used for PC motherboards. The form factor refers to the physical dimensions and size of the board, and dictates what type of case the board will fit into. Some are true standards (meaning that all boards with that form factor are interchangeable), while others are not standardized enough to allow for true interchangeability. Unfortunately these nonstandard form factors preclude any easy upgrade, which generally means they should be avoided. The more commonly known PC motherboard form factors include the following:

Obsolete Form Factors

- Baby-AT
- Full-size AT
- LPX (semi-proprietary)

All Others

- Proprietary Designs (Compaq, Packard Bell, Hewlett-Packard, notebook/portable systems, etc.)

Modern Form Factors

- ATX
- Micro-ATX
- Flex-ATX
- NLX
- WTX

Motherboards have evolved over the years from the original Baby-AT size and shape boards used in the original IBM PC and XT, to the current ATX, NLX, and WTX boards used in most full-size desktop and tower systems. ATX has a number of variants, including Micro-ATX (which is a smaller version of the ATX form factor used in the smaller systems) to Flex-ATX (an even smaller version for the lowest-cost home PCs). NLX is designed for corporate desktop type systems; WTX is for workstations and medium duty servers. The following table shows the modern industry-standard form factors and their recommended uses.

Form Factor	Use
ATX	Standard desktop, mini-tower and full-tower systems, most common form factor today, most flexible design
Micro-ATX	Lower cost desktop or mini-tower systems
Flex-ATX	Least expensive small desktop or mini-tower systems
NLX	Corporate desktop or mini-tower systems, integrated 10/100 Ethernet, easiest and quickest to service
WTX	High performance workstations, midrange servers

Although the Baby-AT, Full-size AT, and LPX boards were once popular, they have all but been replaced by more modern and interchangeable form factors. The modern form factors are true standards, which guarantees improved interchangeability within each type. This means that ATX boards will interchange with other ATX boards, NLX with other NLX and so on. The additional features found on these boards as compared to the obsolete form factors, combined with true interchangeability, has made the migration to these newer form factors quick and easy. Today I only recommend purchasing systems with one of the modern industry-standard form factors.

Anything that does not fit into one of the industry standard form factors is considered proprietary. Unless there are special circumstances, I do not recommend purchasing systems with proprietary board designs. They will be virtually impossible to upgrade and very expensive to repair later, because the motherboard, case, and often power supply will not be interchangeable with other models. I call proprietary form factor systems “disposable” PCs, since that’s what you must normally do with them when they are too slow or need repair out of warranty.

The following sections detail each of the standard form factors.

Baby-AT

The first popular PC motherboard was, of course, the original IBM PC released in 1981. Figure 4.1 shows how this board looked. IBM followed the PC with the XT motherboard in 1983, which had the same basic shape as the PC board, but had eight slots instead of five. Also, the slots were spaced 0.8 inch apart instead of 1 inch apart as in the PC (see Figure 4.2). The XT also eliminated the weird cassette port in the back, which was supposed to be used to save BASIC programs on cassette tape instead of the much more expensive (at the time) floppy drive.

- ▶▶ See “An Introduction to the PC (5150),” in “IBM Personal Computer Family Hardware” on the CD
- ▶▶ See “An Introduction to the XT (5160),” in “IBM Personal Computer Family Hardware” on the CD

The minor differences in the slot positions and the now lonesome keyboard connector on the back required a minor redesign of the case. This motherboard became very popular and many other PC motherboard manufacturers of the day copied IBM’s XT design and produced similar boards. By the time most of these clones or compatible systems came out, IBM had released their AT system, which initially used a larger form factor motherboard. Due to the advances in circuit miniaturization, these companies found they could fit all the additional circuits found on the 16-bit AT motherboard into the XT motherboard form factor. Rather than call these boards XT-sized, which may have made people think they were 8-bit designs, they referred to them as Baby-AT, which ended up meaning an XT-sized board with AT motherboard design features (16-bit or greater).

Figure 4.1 IBM PC motherboard (circa 1981).

Thus, the Baby-AT form factor is essentially the same as the original IBM XT motherboard. The only difference is a slight modification in one of the screw hole positions to fit into an AT-style case (see Figure 4.3). These motherboards also have specific placement of the keyboard and slot connectors to match the holes in the case. Note that virtually all full-size AT and Baby-AT motherboards use the standard 5-pin DIN type connector for the keyboard. Baby-AT motherboards can be used to replace full-sized AT motherboards and will fit into a number of different case designs. Because of their flexibility, from 1983 into early 1996 the Baby-AT form factor was the most popular motherboard type. Starting in mid-1996, Baby-AT was replaced by the superior ATX motherboard design, which is not directly interchangeable. Most systems sold since 1996 have used the improved ATX, micro-ATX, or NLX designs, and Baby-AT is getting harder and harder to come by. Figure 4.3 shows the dimensions and layout of a Baby-AT motherboard.

Figure 4.2 IBM PC-XT motherboard (circa 1983).

Any case that accepts a full-sized AT motherboard will also accept a Baby-AT design. Since its debut in the IBM XT motherboard in 1983 and lasting well into 1996, the Baby-AT motherboard form factor was, for that time, the most popular design. You can get a PC motherboard with virtually any processor from the original 8088 to the fastest Pentium III in this design, although the pickings are slim in the Pentium II/III category. As such, systems with Baby-AT motherboards are virtually by definition upgradable systems. Because any Baby-AT motherboard can be replaced with any other Baby-AT motherboard, this is an interchangeable design.

Until mid-1996 I had recommended to most people that they make sure any PC system they purchased had a Baby-AT motherboard. They would sometimes say, "I've never heard of that brand before." "Of course," I'd tell them, "that's not a brand, but a shape!" The point being that if they had a Baby-AT board in their system, when a year or so goes by and they longed for something

faster, it would be easy and inexpensive to purchase a newer board with a faster processor and simply swap it in. If they purchased a system with a proprietary or semi-proprietary board, they would be out of luck when it came time to upgrade, because they had a disposable PC. Disposable PCs may be cheaper initially, but they are usually much more expensive in the long run because they can't easily or inexpensively be upgraded or repaired.

Figure 4.3 Baby-AT motherboard form factor dimensions.

The easiest way to identify a Baby-AT form factor system without opening it is to look at the rear of the case. In a Baby-AT motherboard, the cards plug directly into the board at a 90-degree angle; in other words, the slots in the case for the cards are perpendicular to the motherboard. Also, the Baby-AT motherboard has only one visible connector directly attached to the board, which is the keyboard connector. Normally this connector is the full-sized 5-pin DIN type connector; although, some Baby-AT systems will use the smaller 6-pin min-DIN connector (sometimes called a PS/2 type connector) and may even have a mouse connector. All other connectors will be mounted on the case or on card edge brackets and attached to the motherboard via cables.

Figure 4.4 shows the connector profile at the rear of Baby-AT boards. The keyboard connector is visible through an appropriately placed hole in the case.

►► See "Keyboard/Mouse Interface Connectors," p. 920.

Figure 4.4 The Baby-AT motherboard rear connector profile showing keyboard connector position.

Baby-AT boards all conform to specific width, screw hole, slot, and keyboard connector locations, but one thing that can vary is the length of the board. Versions have been built that are shorter than the full 13-inch length; these are often called Mini-AT, Micro-AT, or even things such as 2/3-Baby or 1/2-Baby. Even though they may not have the full length, they still bolt directly into the same case as a standard Baby-AT board, and can be used as a direct replacement for one.

Full-Size AT

The full-size AT motherboard matches the original IBM AT motherboard design. This allows for a very large board of up to 12 inches wide by 13.8 inches deep. When the full-size AT board debuted in 1984, IBM needed more room for additional circuits when they migrated from the 8-bit architecture of the PC/XT to the 16-bit architecture of the AT. So, IBM started with an XT board and extended it in two directions (see Figure 4.5).

The board was redesigned to make it slightly smaller a little over a year after being introduced. Then it was redesigned again as IBM shrank it down to XT-size in a system they called the XT-286 (see Figure 28.14 in Chapter 28). The XT-286 board size was virtually identical to the original XT, and was adopted by most PC-compatible manufacturers when it became known as Baby-AT.

- ▶▶ See “An Introduction to the AT,” in “IBM Personal Computer Family Hardware” on the CD
- ▶▶ See “An Introduction to the XT Model 286,” in “IBM Personal Computer Family Hardware” on the CD

The keyboard connector and slot connectors in the full-sized AT boards still conformed to the same specific placement requirements to fit the holes in the XT cases already in use, but a larger case was still required to fit the larger board. Due to the larger size of the board, a full-size AT motherboard will fit into full-size AT desktop or Tower cases only. Because these motherboards will not fit into the smaller Baby-AT or Mini-Tower cases, and because of advances in component miniaturization, they are no longer being produced by most motherboard manufacturers, except in some cases for dual processor server applications.

Note that you can always replace a full-size AT motherboard with a Baby-AT board, but the opposite is not true unless the case is large enough to accommodate the full-size AT design.

Figure 4.5 IBM AT motherboard (circa 1984).

LPX

The LPX and Mini-LPX form factor boards are a semi-proprietary design originally developed by Western Digital in 1987 for some of their motherboards. The LP in LPX stands for Low Profile, which is so named because these boards incorporated slots that were parallel to the main board, allowing the expansion cards to install sideways. This allowed for a slim or low profile case design and overall a smaller system than the Baby-AT.

Although Western Digital no longer produces PC motherboards, the form factor lives on and has been duplicated by many other motherboard manufacturers. Unfortunately, because the specifications were never laid out in exact detail—especially with regard to the bus riser card portion of the design—these boards are termed semi-proprietary and are not interchangeable between manufacturers. This means that if you have a system with an LPX board, in most cases you will not be able to replace the motherboard with a different LPX board later. You essentially have a system that you cannot upgrade or repair by replacing the motherboard with something better. In other words, you have what I call a disposable PC, something I would not normally recommend that anybody purchase.

Most people are not aware of the semi-proprietary nature of the design of these boards, and they have been extremely popular in what I call “retail store” PCs from the late ‘80s through the late ‘90s. This would include primarily Compaq and Packard Bell systems, as well as any others who used this form factor. These boards were most often used in Low Profile or Slimline case systems, but can also be found in Tower cases, too. These are often lower cost systems such as those sold at retail electronics superstores. Due to their proprietary nature, I recommend staying away from any system that uses an LPX motherboard.

LPX boards are characterized by several distinctive features (see Figure 4.6). The most noticeable is that the expansion slots are mounted on a bus riser card that plugs into the motherboard. Expansion cards must plug sideways into the riser card. This sideways placement allows for the low profile case design. Slots will be located on one or both sides of the riser card depending on the system and case design.

Figure 4.6 Typical LPX system chassis and motherboard.

Another distinguishing feature of the LPX design is the standard placement of connectors on the back of the board. An LPX board will have a row of connectors for video (VGA 15-pin), parallel

(25-pin), two serial ports (9-pin each), and mini-DIN PS/2 style mouse and keyboard connectors. All these connectors are mounted across the rear of the motherboard and protrude through a slot in the case. Some LPX motherboards may have additional connectors for other internal ports such as Network or SCSI adapters. Figure 4.7 shows the standard form factors for the LPX and Mini-LPX motherboards used in many systems today.

Figure 4.7 LPX motherboard dimensions.

I am often asked, “How can I tell if a system has an LPX board before I purchase it?” Fortunately, this is easy, and you don’t even have to open the system up or remove the cover. LPX motherboards have a very distinctive design with the bus slots on a riser card that plugs into the motherboard. This means that any card slots will be parallel to the motherboard, because the cards stick out sideways from the riser. Looking at the back of a system, you should be able to tell whether the card slots are parallel to the motherboard. This implies a bus riser card is used, which also normally implies that the system is an LPX design.

The use of a riser card no longer directly implies that the motherboard is an LPX design. More recently, a newer form factor called NLX has been released which also uses a riser card.

On an LPX board, the riser is placed in the middle of the motherboard while NLX boards have the riser to the side (the motherboard actually plugs into the riser in NLX).

Because the riser card is no longer used only on LPX boards, perhaps the easiest feature to distinguish is the single height row of connectors along the bottom of the board. The NLX boards have a different connector area with both single-row and double-row connector areas.

See the section on NLX motherboards later in this chapter for more information on NLX.

See Figure 4.8 for an example of the connectors on the back of an LPX board. There are two connector arrangements shown, for systems without or with USB ports. Note that not all LPX boards will have the built-in audio, so those connectors might be missing. Other ports can be missing from what is shown in these diagrams, depending on exactly what options are included on a specific board.

Figure 4.8 LPX motherboard back panel connectors.

The connectors along the rear of the board prevent expansion cards from being plugged directly into the motherboard, which accounts for why riser cards are used for adding expansion boards.

While the built-in connectors on the LPX boards were a good idea, unfortunately, the LPX design was proprietary (not a fully interchangeable standard) and thus, not a good choice. Newer motherboard form factors such as ATX, Micro-ATX, and NLX have both built-in connectors and use a standard board design. In fact, the NLX form factor was developed as a modern replacement for LPX.

ATX

The ATX form factor was the first of a dramatic evolution in motherboard form factors. ATX is a combination of the best features of the Baby-AT and LPX motherboard designs, with many new enhancements and features thrown in. The ATX form factor is essentially a Baby-AT motherboard turned sideways in the chassis, along with a modified power supply location and connector. The most important thing to know initially about the ATX form factor is that it is physically incompatible with either the previous Baby-AT or LPX designs. In other words, a different case and power supply are required to match the ATX motherboard. These new case and power supply designs have become common, and can be found in many new systems.

The official ATX specification was initially released by Intel in July 1995 and was written as an open specification for the industry. ATX boards didn't hit the market in force until mid-1996 when they rapidly began replacing Baby-AT boards in new systems. The ATX specification was updated to version 2.01 in February 1997. The latest revision is ATX version 2.03, released in December 1998. Intel has published detailed specifications so other manufacturers can use the ATX design in their systems. Currently, ATX is the most popular motherboard form factor for new systems, and it is the one I recommend most people get in their systems today. An ATX system will be upgradable for many years to come, exactly like Baby-AT was in the past.

ATX improves on the Baby-AT and LPX motherboard designs in several major areas:

- *Built-in double high external I/O connector panel.* The rear portion of the motherboard includes a stacked I/O connector area that is 6 1/4-inches wide by 1 3/4-inches tall. This allows external connectors to be located directly on the board and negates the need for cables running from internal connectors to the back of the case as with Baby-AT designs.
- *Single keyed internal power supply connector.* This is a boon for the average end user who always had to worry about interchanging the Baby-AT power supply connectors and subsequently blowing the motherboard! The ATX specification includes a single keyed and shrouded power connector that is easy to plug in, and which cannot be installed incorrectly. This connector also features pins for supplying 3.3v to the motherboard, which means that ATX motherboards will not require built-in voltage regulators that are susceptible to failure.

▶▶ See "Power Supply Connectors," p. 1102.

- *Relocated CPU and memory.* The CPU and memory modules are relocated so they cannot interfere with any bus expansion cards, and they can easily be accessed for upgrade without removing any of the installed bus adapters. The CPU and memory are relocated next to the power supply, which is where the primary system fan is located. The improved airflow

concentrated over the processor often eliminates the need for extra-cost and sometimes failure-prone CPU cooling fans. There is room for a large passive heat sink on the CPU with more than adequate clearance provided in that area.

Note

Note that systems from smaller vendors might still include CPU fans even in ATX systems, as Intel supplies processors with attached high-quality (ball bearing) fans for CPUs sold to smaller vendors. These are so-called “boxed” processors because they are sold in single-unit box quantities instead of pallets of 100 or more like the raw CPUs sold to the larger vendors. Intel includes the fan as insurance because most smaller vendors and system assemblers lack the engineering knowledge necessary to perform thermal analysis, temperature measurements, and the testing required to select the properly sized passive heat sink. By putting a fan on these “boxed” processors, Intel is covering their bases, as the fan will ensure adequate CPU cooling. This allows them to put a warranty on the boxed processors that is independent of the system warranty. Larger vendors have the engineering talent to select the proper passive heat sink, thus reducing the cost of the system as well as increasing reliability. With an OEM non-boxed processor, the warranty is with the system vendor and not Intel directly. Intel normally includes heat sink mounting instructions with their motherboards if non-boxed processors are used.

- *Relocated internal I/O connectors.* The internal I/O connectors for the floppy and hard disk drives are relocated to be near the drive bays and out from under the expansion board slot and drive bay areas. This means that internal cables to the drives can be much shorter, and accessing the connectors will not require card or drive removal.
- *Improved cooling.* The CPU and main memory are positioned so they can be cooled directly by the power supply fan, eliminating the need for separate case or CPU cooling fans. Note that the ATX specification originally specified that the ATX power supply fan blows into the system chassis instead of outward. This reverse flow, or positive pressure design, pressurizes the case, which greatly minimizes dust and dirt intrusion. With the positive pressurized reverse flow design, an air filter can be easily added to the air intake vents on the power supply, creating a system that is even more immune to dirt and dust. More recently, the ATX specification was revised to allow the more normal standard flow, which negatively pressurizes the case by having the fan blow outward. Because the specification technically allows either type of airflow, and because some overall cooling efficiency is lost with the reverse flow design, most power supply manufacturers provide ATX power supplies with standard airflow fans that exhaust air from the system, otherwise called a negative pressure design.
- *Lower cost to manufacture.* The ATX specification eliminates the need for the rat’s nest of cables to external port connectors found on Baby-AT motherboards, additional CPU or chassis cooling fans, or onboard 3.3v voltage regulators. Instead, ATX uses a single power supply connector and allows for shorter internal drive cables. These all conspire to greatly reduce the cost of the motherboard the cost of a complete system—including the case and power supply.

Figure 4.9 shows the new ATX system layout and chassis features, as you would see them looking in with the lid off on a desktop, or sideways in a tower with the side panel removed. Notice how virtually the entire motherboard is clear of the drive bays, and how the devices such as CPU, memory, and internal drive connectors are easy to access and do not interfere with the bus slots. Also notice the power supply orientation and the single power supply fan that blows into the case directly over the high heat, cooling items such as the CPU and memory.

Figure 4.9 ATX system chassis layout and features.

The ATX motherboard is basically a Baby-AT design rotated sideways. The expansion slots are now parallel to the shorter side dimension and do not interfere with the CPU, memory, or I/O connector sockets. There are actually two basic sizes of ATX boards. In addition to a full-sized ATX layout, Intel also has specified a mini-ATX design, which is a fully compatible subset in size and will fit into the same case. A full size ATX board is 12" wide \times 9.6" deep (305mm \times 244mm). The mini-ATX board is 11.2" \times 8.2" (284mm \times 208mm).

Although the case holes are similar to the Baby-AT case, cases for the two formats are generally not compatible. The power supplies would require a connector adapter to be interchangeable, but the basic ATX power supply design is similar to the standard Slimline power supply. The ATX and mini-ATX motherboard dimensions are shown in Figure 4.10. Clearly, the advantages of the ATX form factor make it the best choice for new systems. For backward compatibility, you can still find Baby-AT boards for use in upgrading older systems, but the choices are becoming slimmer every day. I would never recommend building or purchasing a new system with a Baby-AT motherboard, as you will severely limit your future upgrade possibilities. In fact, I have been recommending only ATX systems for new system purchases since late 1996 and will probably continue to do so for the next several years.

The best way to tell whether your system has an ATX-board design without removing the lid is to look at the back of the system. There are two distinguishing features that identify ATX. One is that the expansion boards plug directly into the motherboard. There is no riser card like with LPX or NLX and so the slots will be perpendicular to the plane of the motherboard. Also, ATX boards have a unique double-high connector area for all the built-in connectors on the motherboard (see Figure 4.11). This will be found just to the side of the bus slot area, and can be used to easily identify an ATX board.

Figure 4.10 ATX specification version 2.03, showing ATX and mini-ATX dimensions.

The specification and related information about the ATX, mini-ATX, micro-ATX, flex-ATX, or NLX form factor specifications are available from the Platform Development Support Web site at <http://www.teleport.com/~ffsupprt/>. This single public site replaces the previous independent sites dedicated to those form factors. The Platform Developer site provides form factor specifications and design guides, as well as design considerations for new technologies, information on initiative supporters, vendor products through a “One-Stop-Shopping” mall link, and a form factor bulletin board.

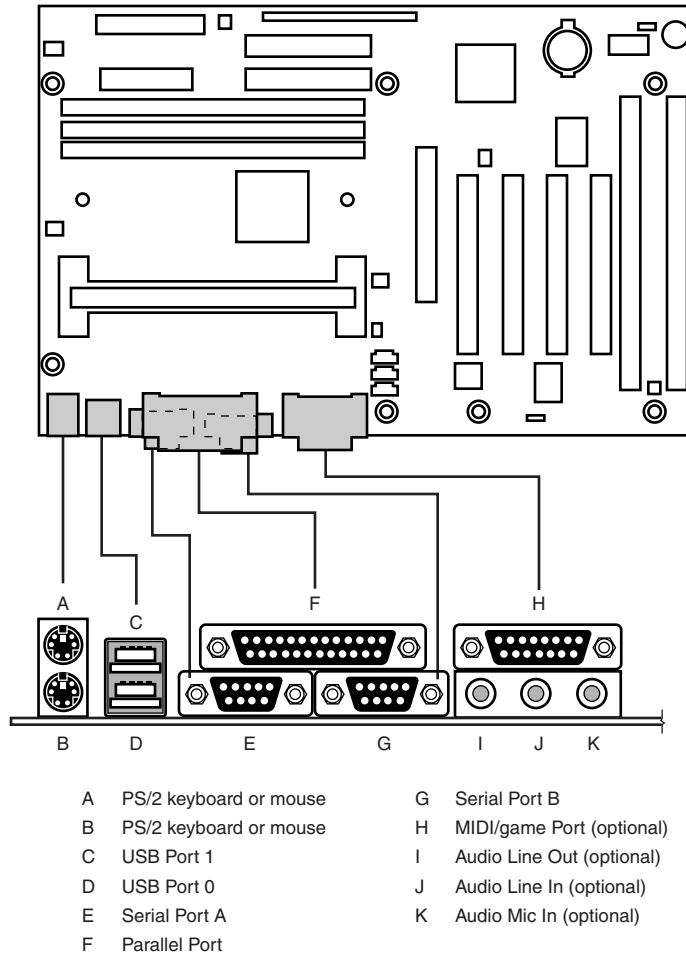

Figure 4.11 Typical ATX motherboard rear panel connectors.

Micro-ATX

Micro-ATX is a motherboard form factor originally introduced by Intel in December of 1997 as an evolution of the ATX form factor for smaller and lower cost systems. The reduced size as compared to standard ATX allows for a smaller chassis, motherboard, and power supply, reducing the cost of entire system. The micro-ATX form factor is also backward compatible with the ATX form factor and can be used in full-size ATX cases. During early 1999 this form factor began to really catch on in the low-cost, sub-\$1,000 PC market.

The main differences between micro-ATX and standard or mini-ATX are as follows:

- Reduced width motherboard (9.6" [244mm] instead of 12" [305mm] or 11.2" [284mm])
- Fewer I/O bus expansion slots
- Smaller power supply (SFX form factor)

The micro-ATX motherboard maximum size is only 9.6" \times 9.6" (244 \times 244 mm) as compared to the full-size ATX size of 12" \times 9.6" (305 \times 244 mm) or the mini-ATX size of 11.2" \times 8.2" (284mm \times 208mm). Even smaller boards can be designed as long as they conform to the location of the mounting holes, connector positions, etc. as defined by the standard. Fewer slots aren't a problem because more components such as sound and video are likely to be integrated on the motherboard and therefore won't require separate slots. This higher integration reduces motherboard and system costs. External buses such as USB, 10/100 Ethernet, and optionally 1394 (FireWire) will provide additional expansion out of the box.

The specifications for micro-ATX motherboard dimensions are shown in Figure 4.12.

Figure 4.12 Micro-ATX specification 1.0 motherboard dimensions.

A new, small form factor (called SFX) power supply has been defined for use with micro-ATX systems. The smaller size of this power supply encourages flexibility in choosing mounting locations within the chassis, and will allow for smaller systems which consume less power overall.

►► See "SFX Style (micro-ATX Motherboards)," p. 1099.

The micro-ATX form factor is similar to ATX for compatibility. The similarities include the following:

- Standard ATX 20-pin power connector
- Standard ATX I/O panel
- Mounting holes are a subset of ATX

These similarities will ensure that a micro-ATX motherboard will easily work in a standard ATX chassis with a standard ATX power supply, as well as the smaller micro-ATX chassis and SFX power supply.

The overall system size for a micro-ATX is very small. A typical case will be only 12" to 14" tall, about 7" wide, and 12" deep. This results in a kind of micro-tower or desktop size. A typical micro-ATX tower is shown in Figure 4.13.

Figure 4.13 Micro-ATX system side view showing typical internal layout.

As with ATX, micro-ATX was released to the public domain by Intel so as to facilitate adoption as a de facto standard. The specification and related information on micro-ATX are available through the Platform Developer Web site (<http://www.teleport.com/~ffsupprt/>).

Flex-ATX

In March of 1999, Intel released the flex-ATX addendum to the micro-ATX specification. This added a new and even smaller variation of the ATX form factor to the motherboard scene. Flex-ATX is smaller design intended to allow a variety of new PC designs, especially extremely inexpensive, smaller, consumer-oriented, appliance type systems.

Flex-ATX defines a board that is only 9.0" × 7.5" (229mm × 191mm) in size, which is the smallest of the ATX family boards. Besides the smaller size, the other biggest difference between the flex-ATX form factor and the micro-ATX is that flex-ATX will only support socketed processors. This means that a flex-ATX board will not have a Slot 1 or Slot 2 type connector for the cartridge versions of the Pentium II/III processors. However, it can have Socket 7 or the newer Socket 370, which supports up through the AMD K6-3 and Intel Celeron (Pentium II/III class) processors. Future versions of the Pentium III will most likely become available in the Socket 370 design and will be usable in flex-ATX boards.

Besides the smaller size and socketed-processor only requirement, the rest of flex-ATX is backward compatible with standard ATX, using a subset of the mounting holes and the same I/O and power supply connector specifications (see Figure 4.14).

Form factor	Mounting hole locations	Notes
• FlexATX	B, C, F, H, J, S	
• microATX	B, C, F, H, J, L, M, R, S	Holes R and S were added for microATX form factor. Hole B was defined in Full AT format.
• ATX	A, C, F, G, H, J, K, L, M	Hole F must be implemented in all ATX 2.03-compliant chassis assemblies. The hole was optional in the ATX 1.1 specification.

Figure 4.14 Size and mounting hole comparison between ATX, micro-ATX, and flex-ATX motherboards.

Most flex-ATX systems will likely use the SFX (small form factor) type power supplies (introduced in the micro-ATX specification), although if the case allows, a standard ATX power supply can also be used.

With the addition of flex-ATX, the family of ATX boards has now grown to include four definitions of size, as shown in Table 4.1:

Table 4.1 ATX Motherboard Form Factors

Form Factor	Max. Width	Max. Depth
ATX	12.0" (305mm)	9.6" (244mm)
Mini-ATX	11.2" (284mm)	8.2" (208mm)
Micro-ATX	9.6" (244mm)	9.6" (244mm)
Flex-ATX	9.0" (229mm)	7.5" (191mm)

Note that these dimensions are the maximum the board can be. It is always possible to make a board smaller as long as it conforms to the mounting hole and connector placement requirements detailed in the respective specifications. Each of these have the same basic screw hole and connector placement requirements, so if you have a case that will fit a full-sized ATX board, you could also mount a mini-, micro-, or flex-ATX board in that same case. Obviously if you have a smaller case designed for micro-ATX or flex-ATX, it will not be possible to put the larger mini-ATX or full sized ATX boards in that case.

NLX

NLX is a new low-profile form factor designed to replace the non-standard LPX design used in previous low-profile systems. First introduced in November of 1996 by Intel, NLX is proving to be the form factor of choice for Slimline corporate desktop systems now and in the future. NLX is similar in initial appearance to LPX, but with numerous improvements designed to allow full integration of the latest technologies. NLX is basically an improved version of the proprietary LPX design, and it is fully standardized, which means you should be able to replace one NLX board with another from a different manufacturer—something that was not possible with LPX.

Another limitation of LPX boards is the difficulty in handling the physical size of the newer Pentium II/III processors and their higher output thermal characteristics as well as newer bus structures such as AGP for video. The NLX form factor has been designed specifically to address these problems (see Figure 4.15).

Figure 4.15 NLX motherboard and riser combination.

The main characteristic of an NLX system is that the motherboard plugs into the riser, unlike LPX where the riser plugs into the motherboard. This means the motherboard can be removed from the system without disturbing the riser or any of the expansion cards plugged into it. In addition, the motherboard in an NLX system literally has no internal cables or connectors attached to it! All devices that normally plug into the motherboard, such as drive cables, the power supply, front panel light and switch connectors, etc., all plug into the riser instead (see Figure 4.16). By using the riser card as a connector concentration point, it is possible to remove the lid on an NLX system and literally slide the motherboard out the left side of the system without unplugging a single cable or connector on the inside. This allows for unbelievably quick motherboard changes; in fact, I have swapped motherboards in less than 30 seconds on NLX systems!

Figure 4.16 Orientation of the riser card in an NLX system.

In addition to being able to remove the motherboard so easily, you can also remove a power supply or any disk drive without removing any other boards from the system. Such a design is a boon for the corporate market, where ease and swiftness of servicing is a major feature. Not only can components be replaced with lightning speed, but because of the industry standard design, motherboards, power supplies, and other components will be interchangeable even among different systems.

Specific advantages of the NLX form factor include

- *Support for all desktop system processor technologies.* This is especially important in Pentium II/III systems, because the size of the Single Edge Contact cartridge this processor uses can run into physical fit problems on existing Baby-AT and LPX motherboards.
- *Flexibility in the face of rapidly changing processor technologies.* Backplane-like flexibility has been built into the form by allowing a new motherboard to be easily and quickly installed without tearing your entire system to pieces. But unlike traditional backplane systems, many industry leaders are putting their support behind NLX.
- *Support for newer technologies.* This includes Accelerated Graphics Port (AGP) high-performance graphic solutions, Universal Serial Bus (USB), and memory modules in DIMM or RIMM form.
- *Ease and speed of servicing and repair.* Compared to other industry standard interchangeable form factors, NLX systems are by far the easiest to work on, and allow component swaps or other servicing in the shortest amount of time.

Furthermore, with the importance of multimedia applications, connectivity support for such things as video playback, enhanced graphics, and extended audio have been built into the motherboard. This should represent a good cost savings over expensive daughterboard arrangements

that have been necessary for many advanced multimedia uses in the past. Although ATX also has this support, LPX and Baby-AT don't have the room for these additional connectors.

Figure 4.17 shows the basic NLX system layout, while the NLX motherboard dimensions are shown in Figure 4.18. Notice that, like ATX, the system is clear of the drive bays and other chassis-mounted components. Also, the motherboard and I/O cards (which, like the LPX form factor, are mounted parallel to the motherboard) can easily be slid in and out of the side of the chassis, leaving the riser card and other cards in place. The processor can be easily accessed and enjoys greater cooling than in a more closed-in layout.

Figure 4.17 NLX system chassis layout and cooling airflow.

The NLX motherboard is specified in three different lengths front to back of 13.6", 11.2" or 10" total (see Figure 4.18). With proper bracketry, the shorter boards can go into a case designed for a longer board.

As with most of the different form factors, you can identify NLX via the unique I/O shield or connector area at the back of the board (see Figure 4.19). I only need a quick look at the rear of any given system to determine what type of board is contained within. The following figure shows the unique stepped design of the NLX I/O connector area. This allows for a row of connectors all along the bottom, and has room for double-stacked connectors on one side.

Figure 4.18 NLX form factor. This shows a 13.6-inch long NLX board. The NLX specification also allows shorter 11.2-inch and 10-inch versions.

Figure 4.19 NLX motherboard I/O shield and connector area as seen from behind.

As you can see, the NLX form factor has been designed for maximum flexibility and space efficiency. Even extremely long I/O cards will fit easily, without getting in the way of other system components—a problem with Baby-AT form factor systems.

The specification and related information about the NLX form factor are available through the Platform Developer Web site located at <http://www.teleport.com/~ffsupport/>.

ATX, mini-ATX, micro-ATX, flex-ATX, and NLX form factors will be the predominant form factors used in virtually all future systems. Since these are well-defined standards that have achieved acceptance in the marketplace, I would avoid the older, obsolete standards such as Baby-AT. I recommend avoiding LPX or other proprietary systems if upgradability is a factor because it is not only difficult to locate a new motherboard that will fit, but LPX systems are also limited in

expansion slots and drive bays. Overall ATX is still the best choice for most new systems where expandability, upgradability, low cost, and ease of service are of prime importance.

WTX

WTX is a new board and system form factor developed for the mid-range workstation market. WTX goes beyond ATX and defines the size and shape of the board and the interface between the board and chassis, as well as required chassis features.

WTX was first released in September 1998 (1.0) and updated in February of 1999 (1.1). The specification and other information on WTX are available at the following Web site:

<http://www.wtx.org>.

The WTX form factor is designed to support

- Future Intel-based 32- and 64-bit processor technologies
- Dual processor motherboards
- Future memory technologies
- Future graphics technologies
- Flex Slot I/O (double-wide PCI) cards
- Deskside (tower) form factor
- Rack mount capability
- Easy accessibility to memory and expansion slots
- High-capacity power supplies

Figure 4.20 shows a typical WTX system with the cover removed. Note that easy access is provided to internal components via pull out drawers and swinging side panels.

WTX introduces a new slot called the Flex Slot, which is really a double-wide PCI slot designed to allow larger, more power hungry, multifunction cards to be utilized. The Flex Slot is primarily designed for a removable, customizable I/O card for WTX systems. By using the Flex Slot, the I/O signals are moved farther away from the processor, chipset, and memory in the system. This allows for improved Electromagnetic Interference (EMI) performance because I/O connectors and their associated cables are moved away from the strongest signal generators in the system. A Flex Slot I/O card can include features such as PCI, audio, LAN, SCSI, serial and parallel ports, keyboard and mouse connections, USB, 1394, and system management features such as fan speed control, all on a single card. Figure 4.21 shows an example Flex Slot I/O card for a WTX system.

Figure 4.20 Typical WTX system chassis showing internal layout and ease of access.

Figure 4.21 Flex Slot I/O card for a WTX system.

WTX motherboards can be a maximum width of 14 inches (356mm) and a maximum length of 16.75 inches (425 mm), which is significantly larger than ATX. There are no minimum motherboard dimensions, so board designers are free to design smaller boards as long as they meet the mounting criteria. Figure 4.22 shows WTX maximum board dimensions, sample connector locations, and mounting hole restrictions.

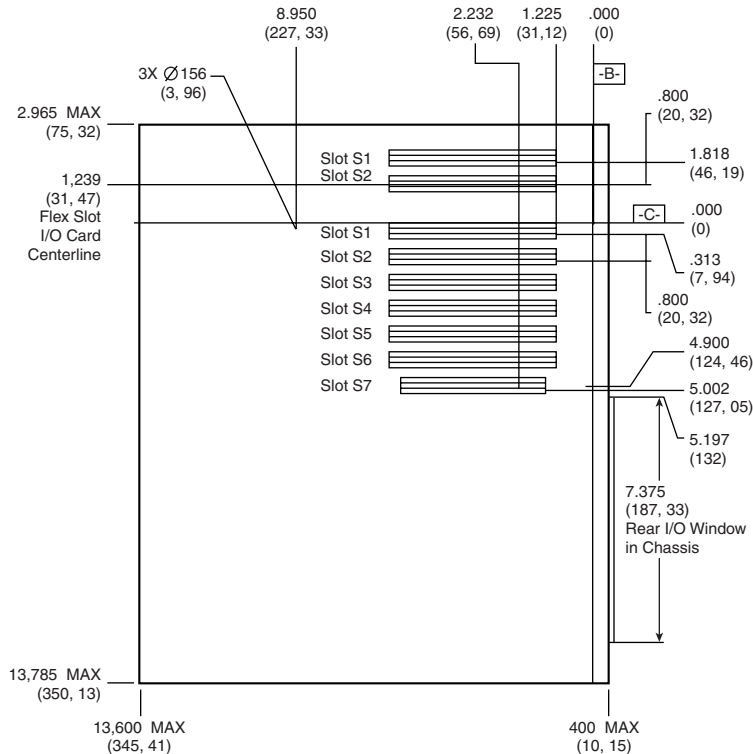

Figure 4.22 WTX motherboard dimensions and sample connector layout.

The WTX specification offers flexibility by leaving motherboard mounting features and locations undefined. Instead of defining exact screw positions, WTX motherboards must mount to a standard mounting adapter plate, which must be supplied with the board. The WTX chassis is designed to accept the mounting plate with attached motherboard and not just a bare board alone. Figure 4.23 shows the WTX motherboard mounting plate dimensions.

The WTX specification also defines keep-out zones or areas over the motherboard that must be free of any physical restrictions. This is to allow adequate clearance for tall or large items on the motherboard, and for proper cooling as well. Figure 4.24 shows the motherboard and plate as it would be installed in the system, along with the keep-out zones over the board.

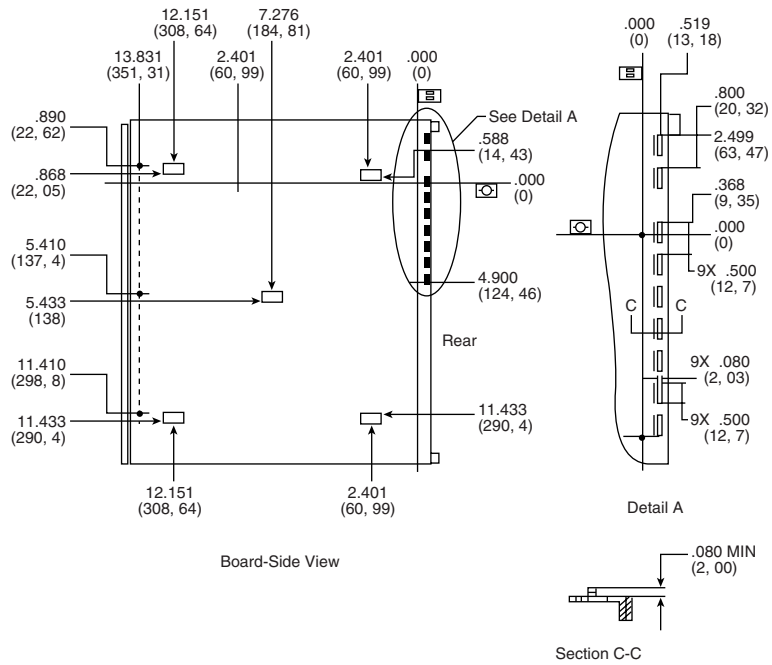

Figure 4.23 WTX motherboard mounting plate.

Figure 4.24 Typical WTX chassis showing board installation and keep-out zones.

To run a heavy-duty WTX system, new power supply designs are required. WTX specifically defines two power supply form factors and power levels in order to meet the power requirements of WTX systems. They are single fan 350w nominal and dual fan 850w nominal units respectively. The single fan power supply is intended for the lower power (around 350w) configurations of WTX systems. The dual fan power supply is for higher power configured workstations (up to around 850w). These will normally be supplied with the chassis, and are mounted on a swing out panel on one of the chassis sides.

With WTX we now have five industry standard form factors. Listed in order of cost/power from most to least they are as follows:

- WTX—For mid- to high-end workstations/servers
- ATX (and mini-ATX)—For power users, enthusiasts, low-end servers/workstations, higher-end home systems
- NLX—For corporate desktop, business workstations
- Micro-ATX—For midrange home systems, entertainment systems
- Flex-ATX—For low-end home systems, starter PCs, PC-based appliances

As you can see, WTX isn't a replacement for ATX, it is for much more expensive and much higher end type systems than ATX.

Proprietary Designs

Motherboards that are not one of the standard form factors such as Full-sized or Baby-AT, ATX, mini-ATX, micro-ATX, or NLX are deemed proprietary. Most people purchasing PCs should avoid proprietary designs because they do not allow for a future motherboard, power supply, or case upgrade, which limits future use and serviceability of the system. To me, proprietary systems are disposable PCs, because you can neither upgrade them, nor can you easily repair them. The problem is that the proprietary parts can only come from the original system manufacturer, and they usually cost many times more than non-proprietary parts. This means that after your proprietary system goes out of warranty, it is not only un-upgradable, but it is also essentially no longer worth repairing. If the motherboard or any component on it goes bad, you will be better off purchasing a completely new standard system than paying five times the normal price for a new proprietary motherboard. In addition, a new motherboard in a standard form factor system would be one or more generations newer and faster than the one you would be replacing. In a proprietary system, the replacement board would not only cost way too much, but it would be the same as the one that failed.

Note that it might be possible to perform limited upgrades to older systems with proprietary motherboards, in the form of custom (non-OEM) processor replacements with attached voltage regulators, usually called "overdrive" chips. Unfortunately these often overtax the board, power supply, and other components in the system, and because the board was not originally designed to work with them, they usually don't perform up to the standards of a less expensive new processor and motherboard combination. As such, I normally recommend upgrading the motherboard and processor together—something that can't be done with a proprietary system.

Most proprietary systems will still allow for disk drive, memory, or other simple upgrades, but even those can be limited because of board design and BIOS issues. The popular LPX motherboard design is at the heart of most proprietary systems. These systems are or were sold primarily in the retail store channel. This class of system has traditionally been dominated by Compaq and Packard Bell, and, as such, virtually all their systems have the problems inherent with their proprietary designs.

Some of these manufacturers seem to go out of their way to make their systems as physically incompatible as possible with any other system. Then, replacement parts, repairs, and upgrades are virtually impossible to find—except, of course, from the original system manufacturer and at a significantly higher price than the equivalent part would cost to fit a standard PC-compatible system.

For example, if the motherboard in my current ATX form factor system (and any system using a Baby-AT motherboard and case) dies, I can find any number of replacement boards that will bolt directly in—with my choice of processors and clock speeds—at great prices. If the motherboard dies in a newer Compaq, Packard Bell, Hewlett-Packard, or other proprietary form factor system, you'll pay for a replacement available only from the original manufacturer, and you have little or no opportunity to select a board with a faster or better processor than the one that failed. In other words, upgrading or repairing one of these systems via a motherboard replacement is difficult and usually not cost-effective.

Systems sold by the leading mail-order suppliers such as Dell, Gateway, Micron, and others are available in industry standard form factors such as ATX, micro-ATX, and NLX. This allows for easy upgrading and system expansion in the future. These standard factors allow you to replace your own motherboards, power supplies, and other components easily and select components from any number of suppliers other than where you originally bought the system.

Backplane Systems

One type of proprietary design is the backplane system. These systems do not have a motherboard in the true sense of the word. In a backplane system, the components normally found on a motherboard are located instead on an expansion adapter card plugged into a slot.

In these systems, the board with the slots is called a backplane, rather than a motherboard. Systems using this type of construction are called backplane systems.

Backplane systems come in two main types—passive and active. A passive backplane means the main backplane board does not contain any circuitry at all except for the bus connectors and maybe some buffer and driver circuits. All the circuitry found on a conventional motherboard is contained on one or more expansion cards installed in slots on the backplane. Some backplane systems use a passive design that incorporates the entire system circuitry into a single mothercard. The mothercard is essentially a complete motherboard that is designed to plug into a slot in the passive backplane. The passive backplane/mothercard concept allows the entire system to be easily upgraded by changing one or more cards. Because of the expense of the high-function mothercard, this type of system design is rarely found in PC systems. The passive backplane

design does enjoy popularity in industrial systems, which are often rack-mounted. Some high-end file servers also feature this design. Figure 4.25 shows Pentium II/III card-based systems for passive backplane systems. Figure 4.26 shows a rack-mount chassis with a passive backplane.

Figure 4.25 Pentium and Pentium II/III card-based motherboards (mothercards) for passive backplane systems.

Figure 4.26 A rack-mount chassis with passive backplane.

Passive backplane systems with mothercards (often called single-board computers) are by far the most popular backplane design. They are used in industrial or laboratory type systems, and are normally rack mountable. They usually have a large number of slots, extremely heavy-duty power supplies, and feature high-capacity, reverse flow cooling designed to pressurize the chassis with cool, filtered air.

An active backplane means the main backplane board contains bus control and usually other circuitry as well. Most active backplane systems contain all the circuitry found on a typical motherboard except for what is then called the *processor complex*. The processor complex is the name of the circuit board that contains the main system processor and any other circuitry directly related to it, such as clock control, cache, and so forth. The processor complex design allows the user to easily upgrade the system later to a new processor type by changing one card. In effect, it amounts to a modular motherboard with a replaceable processor section.

Many large PC manufacturers have built systems with an active backplane/processor complex. Both IBM and Compaq, for example, have used this type of design in some of their high-end (server class) systems. This allows an easier and generally more affordable upgrade than the passive backplane/mothercard design because the processor complex board is usually much cheaper than a mothercard. Unfortunately, because there are no standards for the processor complex interface to the system, these boards are proprietary and can only be purchased from the system manufacturer. This limited market and availability causes the prices of these boards to be higher than most complete motherboards from other manufacturers.

The motherboard system design and the backplane system design have advantages and disadvantages. Most original personal computers were designed as backplanes in the late 1970s. Apple and IBM shifted the market to the now traditional motherboard with a slot-type design because this type of system generally is cheaper to mass-produce than one with the backplane design. The theoretical advantage of a backplane system, however, is that you can upgrade it easily to a new processor and level of performance by changing a single card. For example, you can upgrade a system's processor just by changing the card. In a motherboard-design system, you often must change the motherboard, a seemingly more formidable task. Unfortunately, the reality of the situation is that a backplane design is often much more expensive to upgrade. For example, because the bus remains fixed on the backplane, the backplane design precludes more comprehensive upgrades that involve adding local bus slots.

Another nail in the coffin of backplane designs is the upgradable processor. Starting with the 486, Intel began standardizing the sockets or slots in which processors were to be installed, allowing a single motherboard to support a wider variety of processors and system speeds. Because board designs could be made more flexible, changing only the processor chip for a faster standard OEM type (not one of the kludgy "overdrive" chips) is the easiest and generally most cost-effective way to upgrade without changing the entire motherboard. To allow processor upgrades, Intel has standardized on a number of different types of CPU sockets and slots that allow for upgrading to any faster processors designed to fit the same common socket or slot.

Because of the limited availability of the processor-complex boards or mothercards, they usually end up being more expensive than a complete new motherboard that uses an industry-standard

form factor. The bottom line is that unless you have a requirement for a large capacity industrial or laboratory type system, especially one that would be rack mounted, you are better off sticking with standard ATX form factor PCs. They will certainly be far less expensive.

Motherboard Components

A modern motherboard has several components built in, including various sockets, slots, connectors, chips, and so on. This section examines the components found on a typical motherboard.

Most modern motherboards have at least the following major components on them:

- Processor socket/slot
- Chipset (North and South Bridges)
- Super I/O chip
- ROM BIOS (Flash ROM)
- SIMM/DIMM/RIMM sockets
- ISA/PCI/AGP bus slots
- CPU voltage regulator
- Battery

These components are discussed in the following sections.

Processor Sockets/Slots

The CPU is installed in a socket for all systems up to and including the Pentium Pro processor. The Pentium II processors and beyond use a slot where the processor card or cartridge plugs in.

Starting with the 486 processors, Intel designed the processor to be a user installable and replaceable part, and developed standards for CPU sockets that would allow different models of the same basic processor to plug in. These socket specifications were numbered and based on the socket or slot number you have on your motherboard. This means that you will know exactly what types of processors can be installed.

◀◀ See "Processor Sockets," 74.

Sockets for processors prior to the 486 were not numbered, and interchangeability was limited. Table 4.2 shows the relationship between the various processor sockets/slots and the chips designed to go into them.

Table 4.2 CPU Socket Specifications

Socket Number	Pins	Pin Layout	Voltage	Supported Processors
Socket 1	169	17×17 PGA	5v	486 SX/SX2, DX/DX2*, DX4 OverDrive
Socket 2	238	19×19 PGA	5v	486 SX/SX2, DX/DX2*, DX4 OverDrive, 486 Pentium OverDrive
Socket 3	237	19×19 PGA	5v/3.3v	486 SX/SX2, DX/DX2, DX4, 486 Pentium OverDrive, 5x86

Socket Number	Pins	Pin Layout	Voltage	Supported Processors
Socket 4	273	21×21 PGA	5v	Pentium 60/66, OverDrive
Socket 5	320	37×37 SPGA	3.3v/3.5v	Pentium 75-133, OverDrive
Socket 6**	235	19×19 PGA	3.3v	486 DX4, 486 Pentium OverDrive
Socket 7	321	37×37 SPGA	VRM	Pentium 75-266+, MMX, OverDrive, 6x86, K6
Socket 8	387	dual pattern SPGA	Auto VRM	Pentium Pro
Socket PGA370	370	37×37 SPGA	Auto VRM	PGA Celeron, future PIII
Slot 1	242	SEC/SEP Slot	Auto VRM	Pentium II, SEP Celeron, Pentium III
Slot 2/SC330	330	SEC Slot	Auto VRM	Pentium II Xeon, Pentium III Xeon

**Non-OverDrive DX4 also can be supported with the addition of an aftermarket 3.3v voltage regulator adapter.*

***Socket 6 was a proposed standard only and was never actually implemented in any systems.*

PGA = Pin Grid Array.

SPGA = Staggered Pin Grid Array.

VRM = Voltage Regulator Module.

SEC = Single Edge Contact cartridge.

SEP = Single-Edge Processor package (Pentium II without the plastic cartridge, for example, Celeron)

Chipsets

When the first PC motherboards were created by IBM, they used several discrete chips to complete the design. Besides the processor and optional math coprocessor, there were many other components required to complete the system. These other components included things such as the clock generator, bus controller, system timer, interrupt and DMA controllers, CMOS RAM and clock, and the keyboard controller. There were also a number of other simple logic chips used to complete the entire motherboard circuit, plus, of course, things such as the actual processor, math coprocessor (floating-point unit), memory, and other parts. Table 4.3 lists all the primary chip components used on the original PC/XT and AT motherboards.

Table 4.3 Primary Chip Components on Motherboards

Chip Function	PC/XT Version	AT Version
Processor	8088	80286
Math Coprocessor (Floating-Point Unit)	8087	80287
Clock Generator	8284	82284
Bus Controller	8288	82288
System Timer	8253	8254
Low-order Interrupt Controller	8259	8259
High-order Interrupt Controller	—	8259
Low-order DMA Controller	8237	8237
High-order DMA Controller	—	8237
CMOS RAM/Realtime Clock	—	MC146818
Keyboard Controller	8255	8042

In addition to the processor/coprocessor, a six-chip set was used to implement the primary motherboard circuit in the original PC and XT systems. IBM later upgraded this to a nine-chip design in the AT and later systems, mainly by adding additional Interrupt and DMA controller chips, and the non-volatile CMOS RAM/Real-time Clock chip. All these motherboard chip components came from Intel or an Intel-licensed manufacturer, except the CMOS/Clock chip, which came from Motorola. To build a clone or copy of one of these IBM systems back would require all these chips plus many smaller discrete logic chips to glue the design together, totaling to 100 or more individual chips. This kept the price of a motherboard high, and left little room on the board to integrate other functions.

In 1986, a company called Chips and Technologies introduced a revolutionary component called the 82C206—the main part of the first PC motherboard chipset. This was a single chip that integrated into it all the functions of the main motherboard chips in an AT-compatible system. This chip included the functions of the 82284 Clock Generator, 82288 Bus Controller, 8254 System Timer, dual 8259 Interrupt Controllers, dual 8237 DMA Controllers, and even the MC146818 CMOS/Clock chip. Besides the processor, virtually all the major chip components on a PC motherboard could now be replaced by a single chip. Four other chips augmented the 82C206 acting as buffers and memory controllers, thus completing virtually the entire motherboard circuit with five total chips. This first chipset was called the CS8220 chipset by Chips and Technologies. Needless to say, this was a revolutionary concept in PC motherboard manufacturing. Not only did it greatly reduce the cost of building a PC motherboard, but it also made it much easier to design a motherboard. The reduced component count meant the boards had more room for integrating other items formerly found on expansion cards. Later the four chips augmenting the 82C206 were replaced by a new set of only three chips, and the entire set was called the New Enhanced AT (NEAT) CS8221 chipset. This was later followed by the 82C836 Single Chip AT (SCAT) chipset, which finally condensed all the chips in the set down to a single chip.

The chipset idea was rapidly copied by other chip manufacturers. Companies such as Acer, Erso, Opti, Suntac, Symphony, UMC, and VLSI each gained an important share of this market. Unfortunately for many of them, the chipset market has been a volatile one, and many of them have long since gone out of business. In 1993, VLSI had become the dominant force in the chipset market and had the vast majority of the market share; by the next year, they, along with virtually everybody else in the chipset market, would be fighting to stay alive. This is because a new chipset manufacturer had come on the scene, and within a year or so of getting serious, they were totally dominating the chipset market. That company is Intel, and since 1994 they have had a virtual lock on the chipset market. If you have a motherboard built since 1994, chances are good that it has an Intel chipset on it along with an Intel processor. There are very few chipset competitors left, and the ones that are left are scratching for the lower end of the market. Today, that would include primarily ALi (Acer Laboratories, Inc.), VIA Technologies, and SiS (Silicon integrated Systems). It is interesting to note that Chips and Technologies survived by changing course to design and manufacture video chips, and found a niche in that market specifically for laptop and notebook video chipsets. They were bought out by Intel in 1998 as a way for Intel to get into the video chipset business.

Intel Chipsets

You cannot talk about chipsets today without discussing Intel. They currently own well over 90 percent of the chipset market, and virtually 100 percent of the higher end Pentium II/III chipset market. It is interesting to note that we probably have Compaq to thank for forcing Intel into the chipset business in the first place!

The thing that really started it all was the introduction of the EISA bus designed by Compaq in 1989. At that time, they had shared the bus with other manufacturers in an attempt to make it a market standard. However, they refused to share their EISA bus chipset—a set of custom chips needed to implement this bus on a motherboard.

Enter Intel, who decided to fill the chipset void for the rest of the PC manufacturers wanting to build EISA bus motherboards. As is well known today, the EISA bus failed to become a market success except for the niche server business, but Intel now had a taste of the chipset business and thus they apparently wouldn't forget. With the introduction of the 286 and 386 processors, Intel became impatient with how long it took the other chipset companies to create chipsets around their new processor designs; this delayed the introduction of motherboards that supported the new processors. For example, it took more than two years after the 286 processor was introduced for the first 286 motherboards to appear, and just over a year for the first 386 motherboards to appear after the 386 had been introduced. Intel couldn't sell their processors in volume until other manufacturers made motherboards that would support them, so they thought that by developing motherboard chipsets for a new processor in parallel with the new processor, they could jumpstart the motherboard business by providing ready-made chipsets for the motherboard manufacturers to use.

Intel tested this by introducing the 420 series chipsets along with their 486 processor in April of 1989. This allowed the motherboard companies to get busy right away, and it was only a few months before the first 486 motherboards appeared. Of course, the other chipset manufacturers weren't happy; now they had Intel as a competitor, and Intel would always have their new processor chipsets on the market first!

Intel then realized that they now made both processors *and* chipsets, which were 90 percent of the components on a motherboard. What better way to ensure that motherboards were available for their Pentium processor when it was introduced than by making their own motherboards as well, and having these boards ready on the new processor's introduction date. When the first Pentium processor debuted in 1993, Intel also debuted the 430LX chipset and a fully finished motherboard as well. Now not only were the chipset companies upset, but the motherboard companies weren't too happy either. Intel was not only the major supplier of parts needed to build finished boards (processors and chipsets), but Intel was now building and selling finished boards as well. By 1994, Intel had not only dominated the processor market, but they had cornered the chipset and motherboard markets as well.

Since then, Intel has remained on top in these markets, always introducing new chipsets and motherboards to go with their new processors. Their success in processors prompted them to take additional steps—making chipsets and then complete PC motherboards.

Now as Intel develops new processors, they develop chipsets and even complete motherboards simultaneously, which means they can be announced and shipped in unison. This eliminates the delay between introducing new processors and having motherboards and systems be capable of using them, which was common in the industry's early days. This delay is virtually eliminated today. It was amazing to me that on the day they introduced the first Pentium, Pentium II, and Pentium III processors, not only were there new chipsets available to support them, but complete motherboards were available as well. That very day, you could call Dell, Gateway, or Micron and order a complete "Intel" system using the new Intel processor, chipset, and motherboard. This has not made companies such as Compaq (who still like to make their own motherboards rather than purchase somebody else's off-the-shelf product) very happy, to say the least.

First, with the advent of the Pentium, Pentium Pro, Pentium II, and now the Pentium III processor, not only do more than 90 percent of the systems sold use Intel processors, but their motherboards also most likely have an Intel chipset on them. In fact, their entire motherboard was most likely made by Intel. In my seminars, I ask how many people in the class have Intel brand PCs. Of course, Intel does not sell or market a PC under their own name, so nobody thinks they have an "Intel brand" PC. But, if your motherboard was made by Intel, for all intents and purposes you sure seem to have an Intel brand PC, as far as I am concerned. Does it really matter whether Dell, Gateway, or Micron put that same Intel motherboard into a slightly different looking case with their name on it?

Intel Chipset Model Numbers

Intel started a pattern of numbering their chipsets as follows:

Chipset Number	Processor Family
420xx	P4 (486)
430xx	P5 (Pentium)
440xx	P6 (Pentium Pro/Pentium II/III)
450xx	P6 Server (Pentium Pro/Pentium II/III Xeon)

The chipset numbers listed here are an abbreviation of the actual chipset numbers stamped on the individual chips. For example, one of the current popular Pentium II/III chipsets is the Intel 440BX chipset, which really consists of two components, the 82443BX North Bridge and the 82371EX South Bridge. The North Bridge is so named because it is the connection between the high-speed processor bus (66 or 100MHz) and the slower AGP (66MHz) and PCI (33MHz) buses. The South Bridge is so named because it is the bridge between the PCI bus (33MHz) and the even slower ISA bus (8MHz). By reading the number and letter combinations on the larger chips on your motherboard, you can usually quickly identify the chipset your motherboard uses.

Most of Intel's chipsets (and those of Intel's competitors) are broken into a two-tiered architecture incorporating a North Bridge and South Bridge section. The North Bridge is the main portion of the chipset and incorporates the interface between the processor and the rest of the motherboard. The North Bridge components are what the chipset is named after, meaning that, for example, what we call the 440BX chipset is actually derived from the fact that the actual North

Bridge chip part number for that set is 82443BX. Figure 4.27 shows a sample motherboard (in this case an Intel SE440BX-2) with the locations of all chips and components.

Figure 4.27 Intel SE440BX-2 motherboard showing component locations. *Used by permission of Intel.*

The North Bridge contains the cache and main memory controllers and the interface between the high-speed (33MHz, 50MHz, 66MHz, or 100MHz) processor bus and the 33MHz PCI (Peripheral Component Interconnect) or 66MHz AGP (Accelerated Graphics Port) buses. Intel often refers to the North Bridge of their more recent chipsets as the PAC (PCI/AGP Controller). The North Bridge is essentially the main component of the motherboard and is the only motherboard circuit besides the processor that normally runs at full motherboard (processor bus) speed. Most modern chipsets use a single-chip North Bridge; however, some of the older ones actually consisted of up to three individual chips to make up the complete North Bridge circuit.

The South Bridge is the lower speed component in the chipset and has always been a single individual chip. The South Bridge is a somewhat interchangeable component in that different North Bridge chipsets often are designed to use the same South Bridge component. This modular design of the chipset allows for lower cost and greater flexibility for motherboard manufacturers. The South Bridge connects to the 33MHz PCI bus and contains the interface to the 8MHz ISA bus. It also normally contains the dual IDE hard disk controller interfaces, the USB (Universal Serial Bus) interface, and even the CMOS RAM and clock functions. The South Bridge contains all the components that make up the ISA bus, including the interrupt and DMA controllers.

Let's start by examining the Intel 486 motherboard chipsets and then work our way through the latest Pentium II sets.

Intel's Early 386/486 Chipsets

Intel's first real PC motherboard chipset was the 82350 chipset for the 386DX and 486 processors. This chipset was not very successful, mainly because the EISA bus was not very popular, and because there were many other manufacturers making standard 386 and 486 motherboard chipsets at the time. The market changed very quickly, and Intel dropped the EISA bus support and introduced follow-up 486 chipsets that were much more successful.

Table 4.4 shows the Intel 486 chipsets.

Table 4.4 Intel 486 Motherboard Chipsets

Chipset	420TX	420EX	420ZX
Codename	Saturn	Aries	Saturn II
Date Introduced	Nov. '92	March '94	March '94
Processor	5v 486	5v/3.3v 486	5v/3.3v 486
Bus Speed	up to 33 MHz	up to 50 MHz	up to 333 MHz
SMP (dual CPUs)	No	No	No
Memory Types	FPM	FPM	FPM
Parity/ECC	Parity	Parity	Parity
Max. Memory	128MMB	128MMB	160MMB
L2 Cache Type	Async	Async	Async
PCI Support	2.0	2.0	2.1
AGP Support	No	No	No

SMP = Symmetric Multiprocessing (Dual Processors)

FPM = Fast Page Mode

PCI = Peripheral Component Interconnect

AGP = Accelerated Graphics Port

Note: PCI 2.1 supports concurrent PCI operations.

Intel had pretty good success with their 486 chipsets. They had developed their current two-tiered approach to system design even back then. This design is such that all Intel 486, Pentium,

Pentium Pro, and Pentium II have been designed using two main components, which are commonly called the North Bridge and South Bridge.

Fifth-Generation (P5 Pentium Class) Chipsets

With the advent of the Pentium processor in March of 1993, Intel also introduced their first Pentium chipset, the 430LX chipset (code-named Mercury). This was the first Pentium chipset on the market and set the stage as Intel took this lead and ran with it. Other manufacturers took months to a year or more to get their Pentium chipsets out the door. Since the debut of their Pentium chipsets, Intel has dominated the chipset market with nobody even coming close. Table 4.5 shows the Intel Pentium motherboard chipsets.

Table 4.5 Intel Pentium Motherboard Chipsets (North Bridge)

Chipset	430LX	430NX	430FX	430MX	430HX	430VX	430TX
Codename	Mercury	Neptune	Triton	Mobile Triton	Triton II	Triton III	n/a
Date Introduced	Mar. '93	Mar. '94	Jan. '95	Oct. '95	Feb. '96	Feb. '96	Feb. '97
Bus Speed	66 MHz	66MHz	66MHz	66MHz	66MHz	66MHz	66MHz
CPUs Supported	P60/66	P75+	P75+	P75+	P75+	P75+	P75+
SMP (dual CPUs)	No	Yes	No	No	Yes	No	No
Memory Types	FPM	FPM	FPM/ EDO	FPM/ EDO	FPM/ EDO	FPM/ EDO/ SDRAM	FPM/ EDO/ SDRAM
Parity/ECC	Parity	Parity	Neither	Neither	Both	Neither	Neither
Max. Memory	192MB	512MB	128MB	128MB	512MB	128MB	256MB
Max. Cacheable	192MB	512MB	64MB	64MB	512MB	64MB	64MB
L2 Cache Type	Async	Async	Async/ Pburst	Async/ Pburst	Async/ Pburst	Async/ Pburst	Async/ Pburst
PCI Support	2.0	2.0	2.0	2.0	2.1	2.1	2.1
AGP Support	No	No	No	No	No	No	No
South Bridge	SIO	SIO	PIIX	MPIIX	PIIX3	PIIX3	PIIX4

SMP = Symmetric Multiprocessing (Dual Processors)

FPM = Fast Page Mode

EDO = Extended Data Out

BEDO = Burst EDO

SDRAM = Synchronous Dynamic RAM

Note

PCI 2.1 supports concurrent PCI operations.

Table 4.6 shows all the applicable Intel South Bridge chips, which are the second part of the modern Intel motherboard chipsets.

Table 4.6 Intel South Bridge Chips

Chip Name	SIO	PIIX	PIIX3	PIIX4	PIIX4E	ICH0	ICH
Part Number	82378IB /ZB	82371FB	82371SB	82371AB	82371EB	82801AB	82801AA
IDE Support	None	BMIDE	BMIDE	UDMA-33	UDMA-33	UDMA-33	UDMA-66
USB Support	None	None	Yes	Yes	Yes	Yes	Yes
CMOS/Clock	No	No	No	Yes	Yes	Yes	Yes
Power Management	SMM	SMM	SMM	SMM	SMM/ ACPI	SMM/ ACPI	SMM/ ACPI

SIO = System I/O

PIIX = PCI ISA IDE Xcelerator

ICH = I/O Controller Hub

USB = Universal Serial Bus

IDE = Integrated Drive Electronics (AT Attachment)

BMIDE = Bus Master IDE

UDMA = Ultra-DMA IDE

SMM = System Management Mode

ACPI = Advanced Configuration and Power Interface

The following sections detail all the Pentium motherboard chipsets and their specifications.

Intel 430LX (Mercury)

The 430LX was introduced in March of 1993, concurrent with the introduction of the first Pentium processors. This chipset was only used with the original Pentiums, which came in 60MHz and 66MHz versions. These were 5v chips and were used on motherboards with Socket 4 processor sockets.

◀◀ See "Processor Sockets," p. 79.

◀◀ See "First-Generation Pentium Processor," p. 133.

The 430LX chipset consisted of three total chips for the North Bridge portion. The main chip was the 82434LX system controller. This chip contained the processor-to-memory interface, cache controller, and PCI bus controller. There was also a pair of PCI bus interface accelerator chips, which were identical 82433LX chips.

The 430LX chipset was noted for the following:

- Single processor
- Support for up to 512KB of L2 cache
- Support for up to 192MB of standard DRAM

This chipset died off along with the 5v 60/66MHz Pentium processors.

Intel 430NX (Neptune)

Introduced in March of 1994, the 430NX was the first chipset designed to run the new 3.3v second generation Pentium processor. These were noted by having Socket 5 processor sockets, and an on-board 3.3v/3.5v voltage regulator for both the processor and chipset. This chipset was primarily designed for Pentiums with speeds from 75MHz to 133MHz, although mostly it was used

with 75MHz to 100MHz systems. Along with the lower voltage processor, this chipset ran faster, cooler, and more reliably than the first-generation Pentium processor and the corresponding 5v chipsets.

◀◀ See "CPU Operating Voltages," p. 91.

◀◀ See "Second-Generation Pentium Processor," p. 134.

The 430NX chipset consisted of three chips for the North Bridge component. The primary chip was the 82434NX, which included the cache and main memory (DRAM) controller and the control interface to the PCI bus. The actual PCI data was managed by a pair of 82433NX chips called local bus accelerators. Together, these two chips, plus the main 82434NX chip, constituted the North Bridge.

The South Bridge used with the 430NX chipset was the 82378ZB System I/O (SIO) chip. This component connected to the PCI bus and generated the lower speed ISA bus.

The 430NX chipset introduced the following improvements over the Mercury (430LX) chipset:

- Dual processor support
- Support for 512MB of system memory (up from 192MB for the LX Mercury chipset)

This chipset rapidly became the most popular chipset for the early 75MHz to 100MHz systems, overshadowing the older 60MHz and 66MHz systems that used the 430LX chipset.

Intel 430FX (Triton)

The 430FX (Triton) chipset rapidly became the most popular chipset ever, after it was introduced in January of 1995. This chipset is noted for being the first to support EDO (Extended Data Out) memory, which also became popular at the time. EDO was slightly faster than the standard FPM (Fast Page Mode) memory that had been used up until that time, but cost no more than the slower FPM. Unfortunately, while being known for faster memory support, the Triton chipset was also known as the first Pentium chipset without support for parity checking for memory. This was a major blow to PC reliability, although many did not know it at the time.

▶▶ See "EDO RAM," p. 427.

▶▶ See "Parity Checking," p. 459.

The Triton chipset lacked not only parity support from the previous 430NX chipset, but it also would only support a single CPU. The 430FX was designed as a low-end chipset, for home or non-mission-critical systems. As such, it did not replace the 430NX, which carried on in higher end network file servers and other more mission-critical systems.

The 430FX consisted of a three-chip North Bridge. The main chip was the 82437FX system controller that included the memory and cache controllers, CPU interface, and PCI bus controller, along with dual 82438FX data path chips for the PCI bus. The South Bridge was the first PIIX (PCI ISA IDE Xcelerator) chip that was the 82371FB. This chip acted not only as the bridge

between the 33MHz PCI bus and the slower 8MHz ISA bus, but also incorporated for the first time a dual-channel IDE interface. By moving the IDE interface off of the ISA bus and into the PIIX chip, it was now effectively connected to the PCI bus, allowing for much faster Bus Master IDE transfers. This was key in supporting the ATA-2 or Enhanced IDE interface for better hard disk performance.

The major points on the 430FX are

- Support for EDO memory
- Support for higher speed—pipelined burst cache
- PIIX South Bridge with high-speed Bus Master IDE
- Lack of support for parity-checked memory
- Only single CPU support
- Supported only 128MB of RAM, of which only 64MB could be cached

That last issue is one that many people are not aware of. The 430FX chipset can only cache up to 64MB of main memory. This means that if you install more than 64MB of RAM in your system, performance will suffer greatly. Now, many think this won't be that much of a problem—after all, they don't normally run enough software to load past the first 64MB anyway. That is another misunderstanding, because Windows 9x and NT/2000 (as well as all other protected mode operating systems including Linux, etc.) load from the top down. This means, for example, that if you install 96MB of RAM (one 64MB and one 32MB bank), virtually all your software, including the main operating system, will be loading into the non-cached region above 64MB. Only if you use more than 32MB would you begin to see an improvement in performance. Try disabling the L2 cache via your CMOS setup to see how slow your system will run without it. That is the performance you can expect if you install more than 64MB of RAM in a 430FX-based system.

This lack of cacheable memory, plus the lack of support for parity or ECC (error correcting code) memory, make this a non-recommended chipset in my book. Fortunately, this chipset became obsolete when the more powerful 430HX was introduced.

Intel 430HX (Triton II)

The Triton II 430HX chipset was created by Intel as a true replacement for the powerful 430NX chip. It added some of the high-speed memory features from the low-end 430FX, such as support for EDO memory and pipeline burst L2 cache. It also retained dual-processor support. In addition to supporting parity checking to detect memory errors, it also added support for ECC (error correcting code) memory to detect and correct single bit errors on-the-fly. And the great thing was that this was implemented using plain parity memory.

This was a chipset suitable for high-end or mission-critical system use such as file servers; it also worked well for lower end systems. Parity or ECC memory was not required—the chipset could easily be configured to use less expensive, nonparity, noncorrecting memory as well.

The HX chipset's primary advantages over the FX are

- Symmetric Multiprocessor (dual processor) support.
- Support for ECC (error correcting code) and parity memory.
- 512MB maximum RAM support (versus 128MB).
- L2 cache functions over 512MB RAM versus 64MB (providing optional cache Tag RAM is installed).
- Memory transfers in fewer cycles overall.
- PCI level 2.1 compliance that allows concurrent PCI operations.
- PIIX3 supports different IDE/ATA transfer speed settings on a single channel.
- PIIX3 South Bridge component supports USB.

The memory problems with caching in the 430FX were corrected in the 430HX. This chipset allowed for the possibility of caching the full 512MB of possible RAM as long as the correct amount of cache *tag* was installed. Tag is a small cache memory chip used to store the index to the data in the cache. Most 430HX systems shipped with a tag chip that could only manage 64MB of cached main memory, while you could optionally upgrade it to a larger capacity tag chip that would allow for caching the full 512MB of RAM.

The 430HX chipset was a true one-chip North Bridge. It was also one of the first chips out in a ball-grid array package, where the chip leads were configured as balls on the bottom of the chip. This allowed for a smaller chip package than the previous PQFP (Plastic Quad Flat Pack) packaging used on the older chips, and, because there was only one chip for the North Bridge, a very compact motherboard was possible. The South Bridge was the PIIX3 (82371SB) chip, which allowed for independent timing of the dual IDE channels. This meant that you could install two different speed devices on the same channel and configure their transfer speeds independently. Previous PIIX chips allowed both devices to work at the lowest common denominator speed supported by both. The PIIX3 also incorporated the USB for the first time on a PC motherboard. Unfortunately at the time, there were no devices available to attach to USB, nor was there any operating systems or driver support for the bus. USB ports were a curiosity at the time, and nobody had a use for them.

▶▶ See "USB (Universal Serial Bus)," p. 892.

The 430HX supports the newer PCI 2.1 standard, which allowed for concurrent PCI operations and greater performance. Combined with the support for EDO and pipelined burst cache, this was perhaps the best Pentium chipset for the power user's system. It offered not only excellent performance, but with ECC memory it offered a truly reliable and stable system design.

The 430HX was the only modern Intel Pentium-class chipset to offer parity and error-corrected memory support. This made it the recommended Intel chipset for mission-critical applications such as file servers, database servers, business systems, and so on. Of course, today few would recommend using any type of Pentium system as a file server in lieu of a more powerful, and yet not much more expensive, Pentium II/III system.

As this chipset and most of the Pentium processors are being phased out, you should look toward Pentium II systems for this kind of support.

Intel 430VX (Triton III)

The 430VX chipset never had an official code-name, although many in the industry began calling it the Triton III. The 430VX was designed to be a replacement for the low-end 430FX chipset. It was not a replacement for the higher powered 430HX chipset. As such, the VX has only one significant technical advantage over the HX, but in almost all other respects is more like the 430FX than the HX.

The VX has the following features:

- Support for 66MHz SDRAM (synchronous DRAM)
- No parity or ECC memory support
- Single processor only
- Supports only 128MB RAM
- Supports only 64MB of cached RAM

Although the support for SDRAM is a nice bonus, the actual speed derived from such memory is limited. This is because with a good L2 cache, there will only be a cache miss about 5 percent of the time the system is reading or writing memory, which means that the cache performance is actually more important than main memory performance. This is why most 430HX systems are faster than 430VX systems even though the VX can use faster SDRAM memory. Also, note that because the VX was designed as a low-end chipset for low-cost retail systems, most of them would never see any SDRAM memory anyway.

Like with the 430FX, the VX has the limitation of being capable to cache only 64MB of main memory. With the memory price crash of 1996 bringing memory prices down to where more than 64MB is actually affordable for most people, and with Windows software using more and more memory, this is really becoming a limitation.

The 430VX chipset was rapidly made obsolete in the market by the 430TX chipset that followed.

Intel 430TX

The 430TX chipset never had a code-name that I am aware of; however, some persisted in calling it the Triton IV. The 430TX was Intel's last Pentium chipset. It was designed not only to be used in desktop systems, but to replace the 430MX mobile Pentium chipset for laptop and notebook systems.

The 430TX has some refinements over the 430VX, but, unfortunately, it still lacks support for parity or ECC memory, and retains the 64MB cacheable RAM limitation of the older FX and VX chipsets. The 430TX was not designed to replace the high-end 430HX chipset, which still remained the chipset of choice for mission-critical systems. This is probably because of Intel's de-emphasizing of the Pentium; they are trying to wean us from Pentium processors and force the market—especially for higher end mission-critical systems—to the more powerful Pentium II/III.

The TX chipset features include the following:

- 66MHz SDRAM support
- Cacheable memory still limited to 64MB
- Support for Ultra-ATA, or Ultra-DMA 33 (UDMA) IDE transfers
- Lower power consumption for mobile use
- No parity or ECC memory support
- Single processor only

▶▶ See “ATA/ATAPI-4,” p. 526

Because the Pentium processor has been relegated to low-end system use only, the fact that it lacks parity or ECC memory support, as well as the lack of support for cacheable memory over 64MB, has not been much of a problem for the market for which this chipset is intended. You should not use it for business-class systems, especially those that are mission-critical.

Those seeking a true high-performance chipset and a system that is robust—and which has support for mission-critical features such as ECC memory or for caching more than 64MB of memory—should be looking at Pentium II systems and not the lowly Pentium. Intel has recently stopped all further Pentium processor manufacturing and is only continuing to sell what they have in inventory.

Third-Party (Non-Intel) P5 Pentium Class Chipsets

VIA Technologies

VIA Technologies, Inc. was founded in 1987, and has become a major designer of PC motherboard chipsets. VIA employs state-of-the-art manufacturing capability through foundry relationships with leading silicon manufacturers, such as Toshiba and Taiwan Semiconductor Manufacturing Corporation.

Apollo VP-1

The VT82C580VP Apollo VP-1 is a four-chip set released in October of 1995 and used in older Socket 5 and Socket 7 systems. The Apollo VP-1 is an equivalent alternative to the Intel 430VX chipset, and features support for SDRAM, EDO, or Fast Page Mode memory as well as pipeline-burst SRAM cache. The VP-1 consists of the VT82C585VP 208-pin PQFP (Plastic Quad Flat Pack), two VT82C587VP 100-pin PQFP chips acting as the North Bridge, and the VT82C586 208-pin PQFP South Bridge chip.

Apollo VP2

The two-chip Apollo VP2 chipset was released in May of 1996. The VP2 is a high-performance Socket 7 chipset including several features over the previous VP-1 chipset. The VP2 adds support for ECC (error correcting code) memory over the VPX. The VP2 has also been licensed by AMD as their AMD 640 chipset. Motherboards using the Apollo VP2 can support P5 class processors, including the Intel Pentium and Pentium MMX, AMD K5 and K6, and Cyrix/IBM 6x86 and 6x86MX (MII) processors.

The VP2 chipset consists of the VT82C595 328 pin BGA (Ball Grid Array) package North Bridge chip, which supports up to 2MB of L2 cache and up to 512MB DRAM. Additional performance-related features include a fast DRAM controller with support for SDRAM, EDO, BEDO, and FPM DRAM types in mixed combinations with 32/64-bit data bus widths and row and column addressing, a deeper buffer with enhanced performance, and an intelligent PCI bus controller with Concurrent PCI master/CPU/IDE (PCI 2.1) operations. For data integrity and server use, the VP2/97 incorporates support for ECC or parity memory.

The Apollo VP2 features the VIA VT82C586B PCI-IDE South Bridge controller chip, which complies with the Microsoft PC97 industry specification by supporting ACPI/OnNow, Ultra DMA/33, and USB technologies.

Apollo VPX

The VT82C580VPX Apollo VPX is a four-chip set for Socket 7 motherboards released in December of 1996. The Apollo VPX is functionally equivalent to the Intel 430TX chipset, but also has specific performance enhancements relative to the 430TX. The VPX was designed as a replacement for the VP-1 chipset, and is an upgrade of that set designed to add support for the newer AMD and Cyrix P5 processors.

The Apollo VPX consists of the VT82C585VPX North Bridge and VT82C586B South Bridge chips. There are also two 208-pin PQFP frame buffers that go with the North Bridge memory interface. The Apollo VPX/97 features the VIA VT82C586B PCI-IDE South Bridge controller chip that complies with the Microsoft PC97 industry standard by supporting ACPI/OnNow, Ultra-DMA/33, and USB technologies. VIA also offers a non-PC97 version of the Apollo VPX that includes the older VT82C586A South Bridge and which was used in more entry-level PC designs.

Motherboards using the Apollo VPX can support P5 class processors, including the Intel Pentium and Pentium MMX, AMD K5 and K6, and Cyrix/IBM 6x86 and 6x86MX (MII) processors. To enable proper implementation of the Cyrix/IBM 6x86 200+ processor, the chipset features an asynchronous CPU bus that operates at either 66 or 75MHz speeds. The Apollo VPX is an upgrade over the Apollo VP-1 with the additional feature of Concurrent PCI master/CPU/IDE operations (PCI 2.1). The VPX also supports up to 2MB of L2 cache and up to 512MB DRAM.

Apollo VP3

The Apollo VP3 is one of the first P5 class chipsets to implement the Intel AGP (Advanced Graphics Port) specification. Intel offers that interface with their Pentium II (P6) class chipsets. This allows a higher performance Socket 7 motherboard to be built that can accept the faster AGP video cards. The Socket 7 interface allows P5 class processors such as the Intel Pentium and Pentium MMX, AMD K5 and K6, and Cyrix/IBM 6x86 and 6x86MX (MII) to be utilized.

The Apollo VP3 chipset consists of the VT82C597 North Bridge system controller (472-pin BGA) and the VT82C586B South Bridge (208-pin PQFP). The VT82C597 North Bridge provides superior performance between the CPU, optional synchronous cache, DRAM, AGP bus, and the PCI bus with pipelined, burst, and concurrent operation. The VT82C597 complies with the Accelerated Graphics Port Specification 1.0 and features a 66MHz master system bus.

Apollo MVP3

The Apollo MVP3 adds to the VP3 chip by supporting the new Super-7 100MHz Socket-7 specification. This allows the newer high-speed P5 processors such as the AMD K6 and Cyrix/IBM MII processors to be supported. The Apollo MVP3 chipset is a two-chip chipset that consists of the VT82C598AT North Bridge system controller and the VT82C586B South Bridge. The VT82C598AT chip is a 476-pin BGA (Ball Grid Array) package and the VT82C586B chip is a 208-pin PQFP (Plastic Quad Flat Pack) package.

The VT82C598AT North Bridge chip includes the CPU-to-PCI bridge, the L2 cache and buffer controller, the DRAM controller, the AGP interface, and the PCI IDE controller. The VT82C598AT North Bridge provides superior performance between the CPU, optional synchronous cache, DRAM, AGP bus, and the PCI bus with pipelined, burst, and concurrent operation. The DRAM controller supports standard Fast Page Mode (FPM), EDO, SDRAM, and DDR (Double Data Rate) SDRAM. The VT82C598AT complies with the Accelerated Graphics Port Specification 1.0 and features support for 66/75/83/100MHz CPU bus frequencies and the 66MHz AGP bus frequency.

The VT82C586B South Bridge includes the PCI-to-ISA bridge, ACPI support, SMBus, the USB host/hub interface, the Ultra-33 IDE Master controller, PS/2 Keyboard/Mouse controller, and the I/O controller. The chip also contains the keyboard and PS/2 mouse controller.

This chipset is closest to the Intel 430TX in that it supports Socket 7 chips (Pentium and P5-compatible processors), SDRAM DIMM memory, and is physically a two-chip set. It differs mainly in that it allows operation at speeds up to 100MHz and supports AGP—features only available with the Pentium II boards and chipsets from Intel. This is an attempt to make the Socket 7 motherboards and processors more competitive with the lower-end Pentium II chips such as the Celeron. The South Bridge is compatible with the newer Intel PIIX4e in that it includes UDMA IDE, USB, CMOS RAM, plus ACPI 1.0 power management.

One big benefit over the Intel 430TX is support for ECC (error correcting code) memory or parity checking can be selected on a bank-by-bank basis, which allows mixing of parity and ECC modules. The 430TX from Intel doesn't support any ECC or parity functions at all. Memory timing for FPM is X-3-3-3, whereas EDO is X-2-2-2, and SDRAM is X-1-1-1, which is similar to the Intel 430TX.

Another benefit over the 430TX is in memory cacheability. The 430TX allows caching up to only 64MB of main memory, a significant limitation in higher end systems. The maximum cacheable range is determined by a combination of cache memory size and the number of cache tag bits used. The most common L2 cache sizes will be 512KB or 1MB of L2 cache on the motherboard, allowing either 128MB or 256MB of main memory to be cached. The maximum configuration of 2MB of L2 cache will allow up to 512MB of main memory to be cacheable. Intel solves this in the Pentium II by including sufficient cache tag RAM in the L2 cache built in to the Pentium II processors to allow either 512MB of main memory or 4GB of main memory to be cached.

The MVP3 seems to be the chipset of choice in the higher end Socket 7 motherboards from DFI, FIC, Tyan, Acer, and others.

Acer Laboratories, Inc (Ali)

Acer Laboratories, Inc. was originally founded in 1987 as an independent research and development center for the Acer Group. In 1993, ALi separated financially and legally from Acer Inc. and became a member company of the Acer Group. ALi has rapidly claimed a prominent position among PC chipset manufacturers.

Aladdin IV

The Aladdin IV from Acer Labs is a two-chip set for P5 class processors consisting of the M1531 North Bridge and either an M1533 or M1543 South Bridge chip. The Aladdin IV supports all Intel, AMD, Cyrix/IBM and other P5-class CPUs including the Intel Pentium and Pentium MMX, AMD K5 and K6, and the Cyrix/IBM 6x86 and 6x86MX (MII) processors. The Aladdin IV is equivalent to the Intel 430TX chipset, with the addition of error-correcting memory support and higher-speed 75MHz and 83.3MHz operation. Also, when using the M1543 South Bridge, an additional Super I/O chip is not necessary as those functions are included in the M1543 South Bridge.

The M1531 North Bridge is a 328-pin BGA (Ball Grid Array) chip that supports CPU bus speeds of 83.3 MHz, 75 MHz, 66 MHz, 60 MHz, and 50MHz. The M1531 also supports Pipelined-Burst SRAM cache in sizes of up to 1MB, allowing either 64MB (with 8-bit Tag SRAM) or up to 512MB (with 11-bit Tag SRAM) of cacheable main memory. FPM, EDO, or SDRAM main memory modules are supported for a total capacity of 1GB in up to four total banks. Memory timing is 6-3-3-3 for back-to-back FPM reads, 5-2-2-2 for back-to-back EDO reads, and 6-1-1-1 for back-to-back SDRAM reads. For reliability and integrity in mission-critical or server applications, ECC (Error Correcting Code) or parity is supported. PCI spec. 2.1 is also supported, allowing concurrent PCI operations.

The M1533 South Bridge integrates ACPI support, two-channel Ultra-DMA 33 IDE master controller, two-port USB controller, and a standard Keyboard/Mouse controller. A more full-function M1543 South Bridge is also available that has everything in the M1533 South Bridge plus all the functions of a normally separate Super I/O controller. The M1543 integrates ACPI support, two-channel Ultra-DMA 33 IDE controller, two-port USB controller, and a standard keyboard/mouse controller. Also included is an integrated Super I/O including a 2.88MB floppy disk controller, two high-performance serial ports, and a multi-mode parallel port. The serial ports incorporate 16550-compatible UARTs (Universal Asynchronous Receiver Transmitters) with 16-byte FIFO (First In First Out) buffers and Serial Infra Red (SIR) capability. The multimode Parallel Port includes support for Standard Parallel Port (SPP) mode, PS/2 bidirectional mode, Enhanced Parallel Port (EPP) mode, and the Microsoft and Hewlett Packard Extended Capabilities Port (ECP) mode.

Aladdin V

The Acer Labs (ALi) Aladdin V Chipset is a two-chip set that consists of the M1541 North Bridge chip and the M1543 South Bridge/Super I/O controller combo chip. The M1541 North Bridge is a 456-pin BGA package chip while the M1543 South Bridge is a 328-pin BGA package chip. The M1541 chipset is similar to the previous M1532 chipset with the addition of higher speed (up to 100MHz) operation and AGP (Accelerated Graphics Port) support.

The M1541 North Bridge includes the CPU-to-PCI bridge, the L2 cache and buffer controller, the DRAM controller, the AGP interface, and the PCI controller. The M1541 supports the Super-7 high-speed 100MHz Socket 7 processor interface used by some of the newer AMD and Cyrix/IBM P5 processors. It will also run the processor bus at 83.3MHz, 75MHz, 66MHz, 60MHz, and 50MHz for backward compatibility. When running the CPU bus at 75MHz, the PCI bus only runs at 30MHz; however, when the CPU bus is running at 83.3MHz or 100MHz, the PCI bus will run at full 33MHz PCI standard speed.

The M1541 also integrates enough cache Tag RAM (16K×10) internally to support 512KB of L2 cache, simplifying the L2 cache design and further reducing the number of chips on the motherboard. Cacheable memory is up to 512MB of RAM when using 512KB L2 cache and 1GB of RAM when using 1MB of L2 cache. FPM, EDO, or SDRAM memory is supported, in up to four banks and up to 1GB total RAM. ECC/Parity is also supported for mission-critical or fileserver applications to improve reliability. Memory timing is 6-3-3-3-3-3-3 for back-to-back FPM reads, 5-2-2-2-2-2-2 for back-to-back EDO reads, and 6-1-1-1-2-1-1-1 for back-to-back SDRAM reads. For more information on memory timing, see chapter 6.

Finally, Accelerated Graphics Port (AGP) Interface specification V1.0 is supported, along with 1x and 2x modes, allowing the latest graphics cards to be utilized.

The M1543 South Bridge and Super I/O combo chip includes ACPI support, the USB host/hub interface, dual channel Ultra-DMA/33 IDE host interface, keyboard and mouse controller, and the Super I/O controller. The built-in Super I/O consists of an integrated floppy disk controller, two serial ports with infrared support, and a multimode parallel port.

Silicon integrated Systems (SiS)

Silicon integrated Systems (SiS) was formerly known as Symphony Labs and is one of the three largest non-Intel PC motherboard chipset manufacturers.

5581 and 5582

The SiS5581 and 5582 chips are both 553-pin BGA package single-chip sets incorporating both North and South Bridge functions. The SiS5582 is targeted for AT/ATX form factor motherboards while the SiS5581 is intended to be used on LPX/NLX form factor boards. In all other ways, the two North Bridge chips are identical. The SiS 5581/5582 is a single-chip set designed to be a high-performance, low-cost alternative that is functionally equivalent to Intel's 430TX chipset. By having everything in a single chip, a low-cost motherboard can be produced.

The 5581/5582 consists of both North and South Bridge functions, including PCI to ISA bridge function, PCI IDE function, Universal Serial Bus host/hub function, Integrated RTC, and Integrated Keyboard Controller. These chips support a CPU bus speed of 50, 55, 60, 66, and 75MHz.

A maximum of 512KB of L2 cache is supported, with a maximum cacheable range of 128MB of main memory. The maximum cacheable range is determined by a combination of cache memory size, and the number of Tag bits used. The most common cache size that will allow caching of up

to 128MB of RAM will be 512KB, although up to 384MB of RAM can technically be installed in up to three total banks. Because this is designed for low-cost systems, ECC (Error Correcting Code) or parity functions are not supported. Main memory timing is x-3-3-3 for FPM, while EDO timing is x-2-2-2, and SDRAM timing is x-1-1-1.

The 5581/5582 chipset also includes Advanced Configuration and Power Interface (ACPI) power management, a dual channel Ultra-DMA/33 IDE interface, USB controller, and even the CMOS RAM and Real Time Clock (RTC). PCI v2.1 is supported that allows concurrent PCI operation; however, AGP is not supported in this chipset.

5591 and 5592

The SiS 5591/5592 is a three-chip set consisting of either a 5591 or 5592 North Bridge chip along with a SiS5595 South Bridge. The 5591/5592 North Bridge chips are both 3.3v 553-pin BGA package chips, while the 5595 South Bridge chip is a 5v 208-pin PQFP (Plastic Quad Flat Pack) package chip. The SiS5591 North Bridge is targeted for ATX form factor motherboards while the SiS5592 version is intended to be used on the NLX form factor. In all other ways, the two North Bridge chips are identical.

The 5591/5592 North Bridge chips include the Host-to-PCI bridge, the L2 cache controller, the DRAM controller, the Accelerated Graphics Port interface, and the PCI IDE controller. The SiS5595 South Bridge includes the PCI-to-ISA bridge, the ACPI/APM power management unit, the Universal Serial Bus host/hub interface, and the ISA bus interface that contains the ISA bus controller, the DMA controllers, the interrupt controllers, and the Timers. It also integrates the Keyboard controller and the Real Time Clock (RTC).

The 5591/5592 North Bridge chips support CPU bus speeds of up to 75MHz. They also support up to 1MB of L2 cache allowing up to 256MB of main memory to be cacheable. The maximum cacheable main memory amount is determined by a combination of cache memory size and the number of Tag bits used. Most common cache sizes will be 512KB and 1MB. The 512KB cache with 7 Tag bits will allow only 64M of memory to be cached, while 8 Tag bits will allow caching of up to 128MB. With 1MB of cache onboard, the cacheable range is doubled to a maximum of 256MB.

A maximum of 256MB of total RAM is allowed in up to three banks. Both ECC and parity are supported for mission-critical or file server applications. Main memory timing for FPM memory is x-3-3-3, EDO timing is x-2-2-2, and SDRAM is x-1-1-1.

PCI specification 2.1 is supported at up to 33MHz, and AGP specification 1.0 is supported in both 1x and 2x modes. The separate 5595 South Bridge includes a dual-channel Ultra-DMA/33 interface and support for USB.

Sixth-Generation (P6 Pentium Pro/Pentium II/III Class) Chipsets

Although Intel clearly dominated the Pentium chipset world, they are virtually the only game in town for the Pentium Pro and Pentium II/III chipsets. The biggest reason for this is that since the

Pentium first came out in 1993, Intel has been introducing new chipsets (and even complete ready-to-go motherboards) simultaneously with their new processors. This makes it hard for anybody else to catch up. Another problem for other chipset manufacturers is that Intel has been reluctant to license the Slot 1 and Socket 370 interface used by the Celeron and Pentium II/III processors, while the Socket 7 interface used by the Pentium has been freely available for license. Still, some licenses have been granted, and you should see other chipmakers developing Socket 370 or Slot 1 processors in the future. For now, Intel has most of the Celeron/Pentium II/III market to themselves.

Several of the third-party chipset manufacturers such as VIA Technologies, Acer Laboratories, Inc (ALi), and Silicon integrated Systems (SiS) have recently introduced chipsets for Slot 1 or Socket 370 motherboards.

Note that because the Pentium Pro, Celeron, and Pentium II/III are essentially the same processor with different cache designs, the same chipset can be used for Socket 8 (Pentium Pro), Socket 370 (Celeron), and Slot 1 (Celeron/Pentium II/III) designs. Of course, the newer P6 class chipsets are optimized for the Slot 1/Socket 370 architecture and nobody is doing any new Socket 8 designs. This is also true for the Pentium Pro, which is essentially obsolete compared to the Celeron/Pentium II/III and is currently being used only in limited file server applications.

Although there are a few newcomers to the P6 chipset market, virtually all Pentium Pro, Celeron, and Pentium II/III motherboards use Intel chipsets; their market share here is for all practical purposes near 100 percent.

The sixth-generation P6 (Pentium Pro/Celeron/Pentium II/III) motherboard chipsets continue with the North Bridge/South Bridge design first debuted in the Pentium processor chipsets. In fact, the South Bridge portion of the chipset is the same as that used in many of the Pentium chipsets.

Table 4.7 shows the chipsets used on Pentium Pro motherboards.

Table 4.7 Pentium Pro Motherboard Chipsets (North Bridge)

Chipset	450KX	450GX	440FX
Codename	Orion	Orion Server	Natoma
Workstation Date Introduced	Nov. 1995	Nov. 1995	May 1996
Bus Speed	66 MHz	66 MHz	66 MHz
SMP (dual CPUs)	Yes	Yes (4 CPUs)	Yes
Memory Types	FPM	FPM	FPM/EDO/BEDO
Parity/ECC	Both	Both	Both
Maximum Memory	8GB	1GB	1GB
L2 Cache Type	In CPU	In CPU	In CPU
Maximum Cacheable	1GB	1GB	1GB
PCI Support	2.0	2.0	2.1

(continues)

Table 4.7 Continued

Chipset	450KX	450GX	440FX
AGP Support	No	No	No
AGP Speed	n/a	n/a	n/a
South Bridge	various	various	PIIX3

SMP = Symmetric Multiprocessing (Dual Processors)

FPM = Fast Page Mode

EDO = Extended Data Out

BEDO = Burst EDO

SDRAM = Synchronous Dynamic RAM

Pburst = Pipeline Burst (Synchronous)

PCI = Peripheral Component Interconnect

AGP = Accelerated Graphics Port

SIO = System I/O

PIIX = PCI ISA IDE Xcelerator

Note

PCI 2.1 supports concurrent PCI operations.

For the Celeron and Pentium II/III motherboards, Intel offers the chipsets in Table 4.8.

Table 4.8 Celeron and Pentium II/III Motherboard Chipsets (North Bridge)

Chipset	440FX	440LX	440EX	440BX
Codename	Natoma	none	none	none
Date Introduced	May 1996	Aug. 1997	April 1998	April 1999
Part Numbers	82441FX 82442FX	82443LX	82443EX	82443BX
Bus Speed	66 MHz	66 MHz	66 MHz	66/100 MHz

PCI Support	2.1	2.1	2.1	2.1
AGP Support	No	AGP-2x	AGP-2x	AGP-2x
South Bridge	82371SB (PIIX3)	82371AB (PIIX4)	82371EB (PIIX4E)	82371EB (PIIX4E)

Chipset	440GX	450NX	440ZX	810
Codename	none	none	none	Whitney
Date Introduced	June 1998	June '98	November '98	April '99
Part Numbers	82443GX	82451NX 82452NX 82453NX 82454NX	82443ZX	82810/ 82810- DC100 82802AB/AC
Bus Speed	100 MHz	100 MHz	66/100 MHz*	66/100 MHz

Chipset	440GX	450NX	440ZX	810
Optimum Processor	Pentium II/III, Xeon	Pentium II/III, Xeon	Celeron, Pentium II/III	Celeron, Pentium II/III
SMP (dual CPUs)	Yes	Yes, up to 4	No	No
Memory Types	SDRAM	FPM/EDO	SDRAM	SDRAM
Parity/ECC	Both	Both	Neither	Neither
Maximum Memory	2GB	8 GB	256 MB	256 MB
Memory Banks	4	4	2	2
PCI Support	2.1	2.1	2.1	2.2
AGP Support	AGP-2x	No	AGP-2x	Direct AGP
South Bridge	82371EB (PIIX4E)	82371EB (PIIX4E)	82371EB (PIIX4E)	82801AA/ AB (ICH/ICH0)

* Note the 440ZX is available in a cheaper 440ZX-66 version, which will only run 66MHz

SMP = Symmetric Multiprocessing (Dual Processors)

FPM = Fast Page Mode

EDO = Extended Data Out

BEDO = Burst EDO

SDRAM = Synchronous Dynamic RAM

Pburst = Pipeline Burst (Synchronous)

PCI = Peripheral Component Interconnect

AGP = Accelerated Graphics Port

SIO = System I/O

PIIX = PCI ISA IDE Xcelerator

ICH = I/O Controller Hub

Note

Pentium Pro, Celeron, and Pentium II/III CPUs have their secondary cache integrated into the CPU package. Therefore, cache characteristics for these machines are not dependent on the chipset but are quite dependent on the processor instead.

Most Intel chipsets are designed as a two-part system, using a North Bridge and a South Bridge component. Often the same South Bridge component can be used with several different North Bridge chipsets. Table 4.9 shows a list of all the current Intel South Bridge components and their capabilities.

Table 4.9 Intel South Bridge Chips

Chip Name	SIO	PIIX	PIIX3	PIIX4	PIIX4E	ICH0	ICH
Part Number	82378IB /ZB	82371FB	82371SB	82371AB	82371EB	82801AB	82801AA
IDE Support	None	BMIDE	BMIDE	UDMA-33	UDMA-33	UDMA-33	UDMA-66
USB Support	None	None	Yes	Yes	Yes	Yes	Yes
CMOS/Clock	No	No	No	Yes	Yes	Yes	Yes
Power Management	SMM	SMM	SMM	SMM	SMM/ ACPI	SMM/ ACPI	SMM/ ACPI

SIO = System I/O

PIIX = PCI ISA IDE Xcelerator

ICH = I/O Controller Hub

USB = Universal Serial Bus

IDE = Integrated Drive Electronics (AT Attachment)

BMIDE = Bus Master IDE

UDMA = Ultra-DMA IDE

SMM = System Management Mode

ACPI = Advanced Configuration and Power Interface

The following sections examine the P6 chipsets for both the Pentium Pro and Pentium II processors.

Intel 450KX/GX (Orion Workstation/Server)

The first chipsets to support the Pentium Pro were the 450KX and GX, both code-named Orion. The 450KX was designed for networked or standalone workstations; the more powerful 450GX was designed for file servers. The GX server chipset was particularly suited to the server role, as it supports up to four Pentium Pro processors for Symmetric Multiprocessing (SMP) servers, up to 8GB of four-way interleaved memory with ECC or parity, and two bridged PCI buses. The 450KX is the workstation or standalone user version of Orion and as such it supports fewer processors (one or two) and less memory (1GB) than the GX. The 450GX and 450KX both have full support for ECC memory—a requirement for server and workstation use.

The 450GX and 450KX North Bridge is comprised of four individual chip components—an 82454KX/GX PCI Bridge, an 82452KX/GX Data Path (DP), an 82453KX/GX Data Controller (DC), and an 82451KX/GX Memory Interface Controller (MIC). Options for QFP (Quad Flat Pack) or BGA (Ball Grid Array) packaging were available on the PCI Bridge and the DP. BGA uses less space on a board.

The 450's high reliability is obtained through ECC from the Pentium Pro processor data bus to memory. Reliability is also enhanced by parity protection on the processor bus, control bus, and on all PCI signals. In addition, single-bit error correction is provided, thereby avoiding server downtime because of spurious memory errors caused by cosmic rays.

►► See "Parity and ECC," p. 457.

Until the introduction of the following 440FX chipset, these were used almost exclusively in file servers. After the debut of the 440FX, the expensive Orion chips all but disappeared due to their complexity and high cost.

Intel 440FX (Natoma)

The first popular mainstream P6 (Pentium Pro or Pentium II) motherboard chipset was the 440FX, which was code-named Natoma. The 440FX was designed by Intel to be a lower cost and somewhat higher performance replacement for the 450KX workstation chipset. It offered better memory performance through support of EDO memory, which the prior 450KX lacked.

The 440FX uses half the number of components than the previous Intel chipset. It offers additional features such as support for the PCI 2.1 (Concurrent PCI) standard, Universal Serial Bus (USB) support, and reliability through error checking and correction (ECC).

The Concurrent PCI processing architecture maximizes system performance with simultaneous activity on the CPU, PCI, and ISA buses. Concurrent PCI provides increased bandwidth to better support 2D/3D graphics, video and audio, and processing for host-based applications. ECC memory support delivers improved reliability to business system users.

The main features of this chipset include

- Support for up to 1GB of EDO memory
- Full 1GB cacheability (based on the processor because the L2 cache and tag are in the CPU)
- Support for USB
- Support for BusMaster IDE
- Full parity/ECC support

The 440FX consists of a two-chip North Bridge. The main component is the 82441FX PCI Bridge and Memory controller, along with the 82442FX Data Bus accelerator for the PCI bus. This chipset uses the PIIX3 82371SB South Bridge chip that supports high-speed busmaster DMA IDE interfaces and USB, and it acts as the bridge between the PCI and ISA buses.

Note that this was the first P6 chipset to support EDO memory, but it lacked support for the faster SDRAM. Also, the PIIX3 used with this chipset does not support the faster Ultra DMA IDE hard drives.

The 440FX was the chipset used on the first Pentium II motherboards, which have the same basic architecture as the Pentium Pro. The Pentium II was released several months before the chipset that was supposedly designed for it was ready, and so early PII motherboards used the older 440FX chipset. This chipset was never designed with the Pentium II in mind, whereas the newer 440LX was optimized specifically to take advantage of the Pentium II architecture. For that reason, I normally recommended that people stay away from the original 440FX-based PII motherboards and wait for Pentium II systems that used the forthcoming 440LX chipset. When the new chipset was introduced, the 440FX was quickly superseded by the improved 440LX design.

Intel 440LX

The 440LX quickly took over in the marketplace after it debuted in August of 1997. This was the first chipset to really take full advantage of the Pentium II processor. Compared to the 440FX, the 440LX chipset offers several improvements:

- Support for the new Advanced Graphics Port (AGP) video card bus
- Support for 66MHz SDRAM memory
- Support for the Ultra DMA IDE interface
- Support for Universal Serial Bus (USB)

The 440LX rapidly became the most popular chip for all new Pentium II systems from the end of 1997 through the beginning of 1998.

Intel 440EX

The 440EX is designed to be a low-cost lower performance alternative to the 440LX chipset. It was introduced in April 1998 along with the Intel Celeron low-end Pentium II processor. The 440EX lacks several features in the more powerful 440LX, including dual processor and ECC or

parity memory support. This chipset is basically designed for low-end 66MHz bus-based systems that use the new Intel Celeron low-end Pentium II processor. Note that boards with the 440EX will fully support a full-blown Pentium II but lack some of the features of the more powerful 440LX or 440BX chipsets.

The main things to note about the 440EX are listed here:

- Designed with a feature set tuned for the low-end PC market
- Primarily for the Intel Celeron processor
- Supports AGP
- Does not support ECC or parity memory
- Single processor support only

Although it is based on the core technology of the Intel 440LX, the 440EX is basically considered a lower-feature, lower-reliability version of that chipset designed for non-mission-critical systems.

The 440EX consists of a 82443EX PCI AGP Controller (PAC) North Bridge component and the new 82371EB (PIIX4E) South Bridge chip. Although this chipset is fine for most low-end use, I would normally recommend the faster, more powerful, and more reliable (with ECC memory) 440BX instead.

Intel 440BX

The Intel 440BX chipset was introduced in April of 1998 and was the first chipset to run the processor host bus (and basically the motherboard) at 100MHz. The 440BX was designed specifically to support the faster Pentium II/III processors at 350MHz, 400MHz, 450MHz, or 500MHz. A mobile version of this chipset also is the first Pentium II/III chipset for notebook or laptop systems.

The main change from the previous 440LX to the BX is that the 440BX chipset improves performance by increasing the bandwidth of the system bus from 66MHz to 100MHz. The chipset can run at either 66- or 100MHz, allowing one basic motherboard design to support all Pentium II/III processor speeds from 233MHz to 500MHz and beyond.

Intel 440BX highlights

- Support for 100MHz SDRAM (PC100)
- Support for both 100MHz or 66MHz system and memory bus designs
- Support for up to 1GB of memory in up to four banks (four DIMMs)
- Support for ECC (Error Correcting Code) memory
- Support for ACPI (Advanced Configuration and Power Interface specification)
- The first chipset to support the Mobile Intel Pentium II processor

▶▶ See "Mobile Pentium II," p. 1218.

The Intel 440BX consists of a single North Bridge chip called the 82443BX Host Bridge/Controller, which is paired with a new 82371EB PCI-ISA/IDE Xcelerator (PIIX4E) South Bridge chip. The new South Bridge adds support for the ACPI specification version 1.0. Figure 4.28 shows a typical system block diagram using the 440BX.

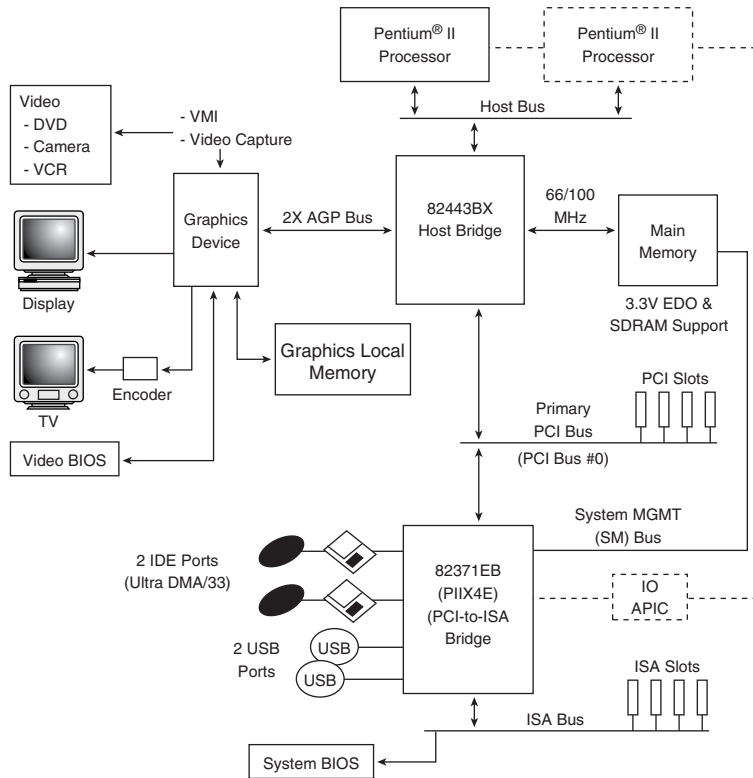

Figure 4.28 System block diagram using the Intel 440BX chipset.

The 440BX is currently the most popular high-end chipset in the Intel arsenal for standard desktop users. It offers superior performance and high reliability through the use of ECC (Error Correcting Code), SDRAM (Synchronous DRAM), and DIMMs (Dual Inline Memory Modules).

Intel 440ZX and 440ZX-66

The 440ZX is designed to be a low-cost version of the 440BX. The 440ZX brings 66 or 100MHz performance to entry-level Celeron and low-end Pentium II/III systems. The 440ZX is pin-compatible with the more expensive 440BX, meaning existing 440BX motherboards can be easily redesigned to use this lower cost chipset.

Note that there are two versions of the 440ZX, the standard one, will run at 100MHz or 66MHz, and the 440ZX-66, which will only run at the slower 66MHz.

The features of the 440ZX include the following:

- Optimized for the micro-ATX form factor
- Support for Celeron and Pentium II/III processors at up to 100MHz bus speeds
- The main differences from the 440BX include
 - No parity or ECC memory support
 - Only two banks of memory (two DIMMs) supported
 - Maximum memory only 256MB
 - Only runs up to 66MHz (440ZX-66)

The 440ZX is not a replacement for the 440BX; instead, it is designed to be used in less expensive systems where the greater memory capabilities, performance, and data integrity functions (ECC memory) of the 440BX are not needed.

Intel 440GX

The Intel 440GX AGPset is the first chipset optimized for high-volume midrange workstations and lower cost servers. The 440GX is essentially a version of the 440BX that has been upgraded to support the Slot 2 (also called SC330) processor slot for the Pentium II/III Xeon processor. The 440GX can still be used in Slot 1 designs as well. It also supports up to 2GB of memory, twice that of the 440BX. Other than these items, the 440GX is essentially the same as the 440BX. Because the 440GX is core-compatible with the 440BX, motherboard manufacturers will be able to quickly and easily modify their existing Slot 1 440BX board designs into Slot 1 or 2 440GX designs.

The main features of the 440GX include

- Support for Slot 1 and Slot 2
- Support for 100MHz system bus
- Support for up to 2GB of SDRAM memory

This chipset allows for lower cost, high-performance workstations and servers using the Slot 2 based Xeon processors.

Intel 450NX

The 450NX chipset is designed for multiprocessor systems and standard high-volume servers based on the Pentium II/III Xeon processor. The Intel 450NX chipset consists of four components: the 82454NX PCI Expander Bridge (PXB), 82451NX Memory and I/O Bridge Controller (MIOC), 82452NX RAS/CAS Generator (RCG), and 82453NX Data Path Multiplexer (MUX).

The 450NX supports up to four Pentium II/III Xeon processors at 100MHz. Two dedicated PCI Expander Bridges (PXBs) can be connected via the Expander Bus. Each PXB provides two independent 32-bit, 33MHz PCI buses, with an option to link the two buses into a single 64-bit, 33MHz bus.

Figure 4.29 shows a typical high-end server block diagram using the 450NX chipset.

Figure 4.29 High-end server block diagram using the Intel 440NX chipset.

The 450NX supports one or two memory cards. Each card incorporates an RCG chip and two MUX chips, in addition to the memory DIMMs. Up to 8GB of memory is supported in total.

The primary features of the 450NX include the following:

- Slot 2 (SC330) processor bus interface at 100MHz
- Supports up to four-way processing
- Support for two dedicated PCI expander bridges (PXBs)
- Up to four 32-bit PCI buses or two 64-bit PCI buses

The 450NX chipset does not support AGP, because high-end video is not an issue in network file servers.

Intel 810

Introduced in April of 1999, the Intel 810 chipset (code-named Whitney) represents a major change in chipset design from the standard North and South Bridges that have been used since the 486 days. The 810 chipset allows for improvements in system performance, all for less cost and system complexity.

The major features of the 810 chipset include

- 440BX chipset technology foundation
- 66/100MHz System Bus capability
- Integrated Intel 3D graphics with Direct AGP for 2D and 3D graphics
- Efficient use of system memory for graphics performance
- Optional 4MB of dedicated display cache video memory
- Digital Video Out port compatible with DVI specification for flat panel displays
- Software MPEG-2 DVD playback with Hardware Motion Compensation
- Accelerated Hub Architecture for increased 66MHz I/O performance
- Supports UDMA-66 for high performance IDE drives
- Integrated Audio-Codec 97 (AC97) controller
- Supports low-power sleep modes
- Random Number Generator (RNG) for stronger security products
- Integrated USB controller
- Elimination of ISA Bus

The 810 chipset (see Figure 4.30) consists of three major components:

- *82810 Graphics Memory Controller Hub (GMCH)*. 421 Ball Grid Array (BGA) package
- *82801 Integrated Controller Hub (ICH)*. 241 Ball Grid Array (BGA) package
- *82802 Firmware Hub (FWH)*. In either 32-pin Plastic Leaded Chip Carrier (PLCC) or 40-pin Thin Small Outline Package (TSOP) packages

Figure 4.30 Intel 810 chipset showing the 82810 (GMCH), 82801 (ICH), and 82802 (FWH) chips. Photograph used by permission of Intel Corporation.

Compared to the previous North/South Bridge designs, there are some fairly significant changes in the 810 chipset. The previous system designs had the North Bridge acting as the memory controller, talking to the South Bridge chip via the PCI bus. This new design has the Graphics Memory Controller Hub (GMCH) taking the place of the North Bridge, which talks to the I/O

Controller Hub (ICH) via a 66MHz dedicated interface called the Accelerated Hub Architecture (AHA) bus. In particular, implementing a direct connection between the North and South Bridges in this manner was key in implementing the new UDMA-66 high-speed IDE interface for hard disks, DVD drives, and other IDE devices.

Figure 4.31 shows a system block diagram for the 810 chipset.

Overall there is still a three-tier system approach as with the previous North/South Bridge and super I/O chip circuits used in previous motherboard designs. The big difference is that the lowest speed in this new design is the 33MHz PCI bus. The old 8MHz ISA bus is finally put out to pasture, as there is no direct provision for ISA in this chipset. It is possible to integrate an ISA bridge chip in an 810 motherboard, so you might yet see some of these boards with ISA slots, but it is doubtful due to the extra cost and little benefit this would provide.

With the 810 chipset, ISA is finally dead.

Figure 4.31 Intel 810 Chipset system block diagram.

The 82810 Graphics Memory Controller Hub (GMCH) uses an internal Direct AGP (integrated AGP) interface to create 2D and 3D effects and images. The video capability integrated into the 82810 chip features Hardware Motion Compensation to improve software DVD video quality and both analog and direct digital video out ports, which enable connections to either traditional TVs (via an external converter module) or the new direct digital flat panel displays. The GMCH chip also incorporates the System Manageability Bus, which allows networking equipment to monitor the 810 chipset platform. Using ACPI specifications, the system manageability function enables low-power sleep mode and conserves energy when the system is idle.

Note that there are two versions of the GMCH, known as the 82810 and 82810-DC100. The latter DC100 (Display Cache 100MHz) version has the option for up to 4MB of 100MHz SDRAM to be directly connected as a dedicated display cache. The regular 82810 GMCH chip lacks this provision.

The 82801 I/O Controller Hub (ICH) employs Accelerated Hub Architecture for a direct connection from the GMCH chip. This is twice as fast (266MB/sec) as the previous North/South Bridge connections that used the PCI bus. Plus, the AHA bus is dedicated, meaning that no other devices will be on it. The AHA bus also incorporates optimized arbitration rules allowing more functions to run concurrently, enabling better video and audio performance.

The ICH also integrates dual IDE controllers, which run up to either 33MB/s (UDMA-33 or Ultra-ATA/33) or 66MB/s (UDMA-66 or Ultra-ATA/66). Note that there are two versions of the ICH chip. The 82801AA (ICH) incorporates the 66MB/s capable IDE and supports up to six PCI slots, while the 82801AB (ICH0) only supports 33MB/sec maximum and supports up to four PCI slots.

The ICH also integrates an interface to an Audio-Codec 97 (AC97) controller, dual USB ports, and the PCI bus with up to four or six slots. The Integrated Audio-Codec 97 controller enables software audio and modem by using the processor to run sound and modem software. By reusing existing system resources, this lowers the system cost by eliminating components.

The 82802 Firmware Hub (FWH) incorporates the system BIOS and video BIOS, eliminating a redundant nonvolatile memory component. The BIOS within the FWH is flash type memory, so it can be field updated at any time. In addition, the 82802 contains a hardware Random Number Generator (RNG). The RNG provides truly random numbers to enable fundamental security building blocks supporting stronger encryption, digital signing, and security protocols. There are two versions of the FWH, called the 82802AB and 82802AC respectively. The AB version incorporates 512KB (4Mbit) of flash BIOS memory, and the AC version incorporates a full 1MB (8Mbit) of BIOS ROM.

With the Intel 810 chipset, Intel has done something that many in the industry were afraid of—they have integrated the video and graphics controller directly into the motherboard chipset. This means that systems using the 810 chipset won't have an AGP slot, and won't be able to use conventional AGP video cards. From a performance standpoint, this is not really a problem. The video they have integrated is an outstanding performer, and it has direct access to the rest of the chipset at a data rate even faster than standard AGP. The direct AGP interface built-in to the 810 chipset runs at 100MHz, rather than the 66MHz of standard AGP. Intel calls the integrated

interface Direct AGP, and it describes the direct connection between the memory and processor controllers with the video controller all within the same chip.

This probably dictates the future of mainstream PCs, which means the video card, as we know it, will be reserved only for higher end systems. With the 810 chipset, Intel has let it be known in a big way that they have entered the PC video business. If I were a video chip or board manufacturer, I would be carefully studying my options in other areas for the future!

In fact, the theme with the 810 chipset is one of integration. The integrated video means no video cards are required; the integrated AC97 interface means that conventional modems and sound cards are not required. Plus, there is an integrated CMOS/Clock chip (in the ICH), and even the BIOS is integrated in the FWH chip. All in all the 810 should be taken as a sign for things to come in the PC industry, which means more integration, better overall performance, and less cost.

Third-Party (non-Intel) P6 Class Chipsets

Acer Laboratories, Inc. (ALi)

Aladdin Pro II

The Acer Labs (ALi) Aladdin Pro II M1621 is a two-chip set for P6 (Pentium Pro and Pentium II) processors consisting of two BGA package chips, the 456-pin BGA package M1621 North Bridge, and either the M1533 or M1543 South Bridge. This is one of the first Slot 1 P6 processor chipsets from a company other than Intel.

The M1621 North Bridge includes an AGP, memory and I/O controller, and a data path with multiport buffers for data acceleration. It can support multiple Pentium II processors with bus speeds of 60, 66, and 100MHz. This chipset is equivalent to the 440BX chipset from Intel.

The integrated memory controller supports FPM, EDO, and SDRAM with a total capacity of up to 1GB (SDRAM) or 2GB (EDO). ECC (Error Correcting Code) memory is supported, allowing use in mission-critical or fileserver applications. Memory timing is x-1-1-1-1-1-1-1 in back-to-back SDRAM reads, or x-2-2-2-2-2-2-2 in back-to-back EDO reads.

The M1621 supports AGP v1.0, in both 1x and 2x modes, and is fully compliant with PCI Rev. 2.1, allowing for concurrent PCI operations. The M1621 can be used with either the M1533 South Bridge or M1543 South Bridge/Super I/O combo chips.

The M1533 South Bridge includes the following features:

- PCI-to-ISA Bridge
- Built-in keyboard/mouse controller
- Enhanced Power Management, featuring ACPI (Advanced Configuration and Power Interface)
- Two-port USB interface
- Dual channel Ultra-DMA/33 IDE host adapter
- 328-pin BGA package

M1543 includes all features in the 1533 plus fully integrated Super I/O, including a Floppy Disk Controller, two high-speed serial ports, and one multimode parallel port.

VIA Technologies

Apollo P6/97

The VT82C680 Apollo P6 is a high-performance, cost-effective, and energy-efficient chipset for the implementation of PCI/ISA desktop and notebook personal computer systems based on 64-bit Intel P6 processors. This was one of the first non-Intel P6 chipsets of any kind available and is functionally equivalent to the Intel 440FX chipset. The Apollo P6 chipset supports dual processor configurations with up to 66MHz external CPU bus speed. The DRAM and PCI bus are also independently powered so that each of the buses can be run at 3.3v or 5v. The ISA bus always runs at 5v. The Apollo P6 supports up to 1GB of DRAM. This chipset never really achieved much popularity in the market.

Apollo Pro

The Apollo Pro is a high-performance chipset for Slot 1 mobile and desktop PC systems. The Apollo Pro includes support for advanced system power management capability for both desktop and mobile PC applications, PC100 SDRAM, AGP 2x mode, and multiple CPU/DRAM timing configurations. The Apollo Pro chipset is comparable in features to the 440BX and PIIX4e chipset from Intel, and represents one of the first non-Intel chipsets to support the Socket 1 architecture.

The VIA Apollo Pro consists of two devices—the VT82C691 North Bridge chip and the VT82C596, a BGA-packaged South Bridge with a full set of mobile, power-management features. For cost-effective desktop designs, the VT82C691 can also be configured with the VT82C586B South Bridge.

The VT82C691 Apollo Pro North Bridge supports all Slot-1 (Intel Pentium II) and Socket 8 (Intel Pentium Pro) processors. The Apollo Pro also supports the 66MHz and the newer 100 MHz CPU external bus speed required by the 350MHz and faster Pentium II processors. AGP v1.0 and PCI 2.1 are also supported, as are FPM, EDO, and SDRAM. Different DRAM types may be used in mixed combinations in up to eight banks and up to 1GB of DRAM. EDO memory timing is 5-2-2-2-2-2-2 for back-to-back accesses, and SDRAM timing is 6-1-1-1-2-1-1-1 for back-to-back accesses.

The VT82C596 South Bridge supports both ACPI (Advanced Configuration and Power Interface) and APM (Advanced Power Management), and includes an integrated USB Controller and dual UltraDMA-66 EIDE ports.

Silicon integrated Systems (SiS)

SiS5600/5595

The 5600/5595 chipset was introduced in June 1998, and is designed for low-cost Celeron CPUs with a 66MHz or 100MHz host bus. SiS intends to use this low-cost chipset to help push the Pentium II PC technology toward the sub-\$1,000 PC market.

Super I/O Chips

The third major chip seen on most PC motherboards is called the Super I/O chip. This is a chip that normally integrates devices formerly found on separate expansion cards in older systems.

Most Super I/O chips contain, at a minimum, the following components:

- Floppy controller
- Dual serial port controllers
- Parallel port controller

The floppy controllers on most Super I/O chips will handle two drives, but some of them can only handle one. Older systems often required a separate floppy controller card.

The dual serial port is another item that was formerly on one or more cards. Most of the better Super I/O chips implement a buffered serial port design known as a UART (Universal Asynchronous Receiver Transmitter), one for each port. Most mimic the standalone NS16550A high-speed UART, which was created by National Semiconductor. By putting the function of two of these chips into the Super I/O chip, we essentially have these ports built-in to the motherboard.

Virtually all Super I/O chips also include a high-speed multimode parallel port. The better ones allow three modes, called standard (bidirectional), Enhanced Parallel Port (EPP), and the Enhanced Capabilities Port (ECP) modes. The ECP mode is the fastest and most powerful, but selecting it also means your port will use an ISA bus 8-bit DMA channel, usually DMA channel 3. As long as you account for this and don't set anything else to that channel (such as a sound card, and so on), the ECP mode parallel port should work fine. Some of the newer printers and scanners that connect to the system via the parallel port will use ECP mode, which was initially invented by Hewlett-Packard.

The Super I/O chip may contain other components, as well. For example, currently the most popular Pentium II motherboard on the market—the Intel SE440BX ATX motherboard—uses an SMC (Standard Microsystems Corp.) FDC37C777 Super I/O chip. This chip incorporates the following functions:

- Single floppy drive interface
- Two high-speed serial ports
- One ECP/EPP multimode parallel port
- 8042-style keyboard and mouse controller

Only the keyboard and mouse controller are surprising here; all the other components are in most Super I/O chips. The integrated keyboard and mouse controller saves the need to have this chip as a separate part on the board.

One thing I've noticed over the years is that the role of the Super I/O chip has decreased more and more in the newer motherboards. This is primarily due to Intel moving Super I/O functions such as IDE directly into the chipset South Bridge component, where these devices can attach to

the PCI bus rather than the ISA bus. One of the shortcomings of the Super I/O chip is that it is interfaced to the system via the ISA bus, and shares all the speed and performance limitations of that 8MHz bus. Moving the IDE over to the PCI bus allowed higher speed IDE drives to be developed that could transfer at the faster 33MHz PCI bus speed.

As Intel combines more and more functions into their main chipset, and as USB-based peripherals replace standard serial, parallel, and floppy controller-based devices, you will probably see the Super I/O chip fade away on some future motherboard designs. At least one of the third-party chipsets has already combined the South Bridge and Super I/O chip into a single component, saving space and reducing parts count on the motherboard.

Motherboard CMOS RAM Addresses

In the original AT system, a Motorola 146818 chip was used as the RTC (Real-time Clock) and CMOS (Complementary Metal-Oxide Semiconductor)RAM chip. This is a special chip that had a simple digital clock, which used 10 bytes of RAM, and an additional 54 more bytes of leftover RAM in which you could store anything you wanted. The designers of the IBM AT used these extra 54 bytes to store the system configuration.

Modern PC systems don't use the Motorola chip; instead, they incorporate the functions of this chip into the motherboard chipset (South Bridge), Super I/O chip, or they use a special battery and NVRAM (Non-Volatile RAM) module from companies such as Dallas or Benchmarq.

Table 4.10 shows the standard format of the information stored in the 64-byte standard CMOS RAM module. This information controls the configuration of the system and is read and written by the system Setup program.

Table 4.10 AT CMOS RAM Addresses

Offset Hex	Offset Dec	Field Size	Function
00h	0	1 byte	Current second in binary coded decimal (BCD)

Note that many newer systems have more than 64 bytes of CMOS RAM; in fact, in some systems they might have 2KB or 4KB. The extra room is used to store the Plug-and-Play information detailing the configuration of adapter cards and other options in the system. As such, there is no 100 percent standard for how CMOS information is stored in all systems. Table 4.10 only shows how the original systems did it; newer BIOS versions and motherboard designs can do things differently. You should consult the BIOS manufacturer for more information if you want the full details of how CMOS is stored, because the CMOS configuration and Setup program is normally a part of the BIOS. This is another example of how close the relationship is between the BIOS and the motherboard hardware.

There are backup programs and utilities in the public domain for CMOS RAM information, which can be useful for saving and later restoring a configuration. Unfortunately, these programs would be BIOS specific and would only function on a BIOS they are designed for. As such, I don't normally rely on these programs because they are too motherboard and BIOS specific and will not work on all my systems seamlessly.

Table 4.11 shows the values that can be stored by your system BIOS in a special CMOS byte called the diagnostics status byte. By examining this location with a diagnostics program, you can determine whether your system has set trouble codes, which indicate that a problem previously has occurred.

Table 4.11 CMOS RAM Diagnostic Status Byte Codes

Bit Number 7 6 5 4 3 2 1 0	Hex	Function
1	80	Real-time clock (RTC) chip lost power
. 1	40	CMOS RAM checksum is bad
. . 1	20	Invalid configuration information found at POST
. . . 1	10	Memory size compare error at POST
. . . . 1	08	Fixed disk or adapter failed initialization
. 1	04	Real-time clock (RTC) time found invalid
. 1	02	Adapters do not match configuration
. 1	01	Time-out reading an adapter ID
. 1	00	No errors found (Normal)

If the Diagnostic status byte is any value other than zero, you will normally get a CMOS configuration error on startup. These types of errors can be cleared by rerunning the Setup program.

Motherboard Interface Connectors

There are a variety of different connectors on a modern motherboard. Figure 4.32 shows the location of these connectors on a typical motherboard (using the Intel SE440BX model as the example). Several of these connectors such as power supply connectors, serial and parallel ports, and keyboard/mouse connectors are covered in other chapters. Tables 4.12–4.16 contain the pinouts of most of the other different interface and I/O connectors you will find.

Caution

Do not place a jumper on this connector; serious board damage will result if the 12v is shorted to ground.

Note that some boards have a board mounted piezo speaker. It is enabled by placing a jumper over pins 3 and 4, which routes the speaker output to the board-mounted speaker. Removing the jumper allows a conventional speaker to be plugged in.

Some other connectors that you might find on some newer motherboards are listed in Tables 4.17–4.22.

System Bus Functions and Features

At the heart of every motherboard are the buses that make it up. A *bus* is a common pathway across which data can travel within a computer. This pathway is used for communication and can be established between two or more computer elements.

The PC has a hierarchy of different buses. Most modern PCs have at least three different buses; some have four or more. They are hierarchical because each slower bus is connected to the faster one above it. Each device in the system is connected to one of the buses, and some devices (primarily the chipset) act as bridges between the various buses.

The main buses in a modern system are as follows:

- *The Processor Bus.* This is the highest-speed bus in the system and is at the core of the chipset and motherboard. This bus is used primarily by the processor to pass information to and from cache or main memory and the North Bridge of the chipset. The processor bus in Pentium II systems runs at either 66 or 100MHz and has the full 64-bit data path width of the processor.
- *The AGP (Accelerated Graphics Port) Bus.* This is a high-speed 66MHz, 32-bit bus specifically for a video card. It is connected to the North Bridge of the chipset and is manifested as a single AGP slot in systems that support it.
- *The PCI (Peripheral Component Interconnect) Bus.* This is a 33Mhz, 32-bit bus found in virtually all newer 486 systems and Pentium and higher processor systems. This bus is generated by the chipset North Bridge, which acts as the PCI controller. This bus is manifested in the system as a collection of 32-bit slots, normally about four on most motherboards. High-speed peripherals such as SCSI adapters, network cards, video cards, and more can be plugged in to PCI bus slots. The chipset South Bridge is plugged in to the PCI bus, and from there generates the IDE and USB ports.
- *The ISA (Industry Standard Architecture) Bus.* This is an 8MHz, 16-bit bus that remains in systems today after first appearing in the original PC in 8-bit, 5MHz form, and in the 1984 IBM AT in full 16-bit form. It is a very slow-speed bus, but is still ideal for certain slow-speed or older peripherals. The PC industry has been loath to give up this bus, despite pressure from Microsoft and Intel to do away with it in future PC designs. Most people have used it in recent times for plug-in modems, sound cards, and various other low-speed peripherals. The ISA bus is generated by the South Bridge part of the motherboard chipset, which acts as the ISA bus controller and the interface between the ISA bus and the faster PCI bus above it. The motherboard's Super I/O chip is normally connected to this bus.

The system chipset is the conductor that controls the orchestra of system components, allowing each to have their turn on their respective buses.

Bus Type	Width (bits)	Speed (MHz)	Bandwidth (MB/sec)
8-bit ISA	8	4.77	2.39
16-bit ISA	16	8.33	8.33
EISA*	32	8.33	33.3
VLB*	32	33.33	133.33
PCI	32	33.33	133.33
PCI-2x**	32	66.66	266.66
PCI 64-bit**	64	33.33	266.66
PCI-2x 64-bit**	64	66.66	533.33
AGP	32	66.66	266.66
AGP-2x	32	66.66	533.33
AGP-4x*	32	66.66	1,066.66

* EISA and VLB are no longer used in current motherboard designs.

** Note that these bus types are proposed and have not yet been implemented in PC systems.

The PCI bus has two proposed extensions. One is to go from 32 bits to 64 bits. The other is to double the clock speed of the bus to 66MHz. So far, neither of these has been implemented in PC systems, and it doesn't seem likely they will in the near future. More likely we will see improvements in other areas such as AGP, which has already moved to 2x mode and will move to a 4x mode in the future.

Interestingly enough, these faster modes will be achieved at the same clock rate; the only difference is that 2 or 4 bits will be transferred for every hertz (cycle) rather than the 1 bit per cycle standard today. This will allow the AGP bus to keep pace with future video needs, all the way to over 1,066MB/sec!

The following sections discuss the processor and other subset buses in the system, and the main I/O buses mentioned in the previous table.

The Processor Bus

The processor bus is the communication pathway between the CPU and motherboard chipset, more specifically the North Bridge. This bus runs at the full motherboard speed—normally 66MHz, 75MHz, or 100MHz—and is used to transfer data between the CPU and the chipset North Bridge. It also transfers data between the CPU and an external memory cache on Pentium (P5 class) systems. Figure 4.19 shows how this bus fits into a typical Pentium (P5 class) PC system.

Later in this chapter, Figure 4.34 shows where and how the other main buses, such as the PCI and IDE buses, fit into the system. As you can see, there is clearly a three-tier architecture with the fastest CPU bus on top, the PCI bus next, and the ISA bus at the bottom. Different components in the system are connected to one of these three main buses.

Pentium (P5) class systems have an external cache for the CPU; these caches are connected to the processor bus that runs at the motherboard speed (normally 66MHz). Thus, as the Pentium processors have been getting faster and faster, the L2 cache has unfortunately remained at the relatively slow motherboard speed. This was solved in the Pentium Pro and Pentium II systems. They have moved the L2 cache off of the motherboard and directly onto the CPU. By incorporating the L2 cache in the CPU, they can run it at a speed closer to the true CPU speed. In the Pentium Pro, the L2 cache actually does run at full CPU speed, but in the Pentium II it runs at one half of the processor speed. This is still much faster than the motherboard-bound cache on the Socket 7 P5 class systems. The built-in L2 CPU cache is one of the main reasons the Socket 8 and Slot 1 architecture is superior to the Socket 7 designs.

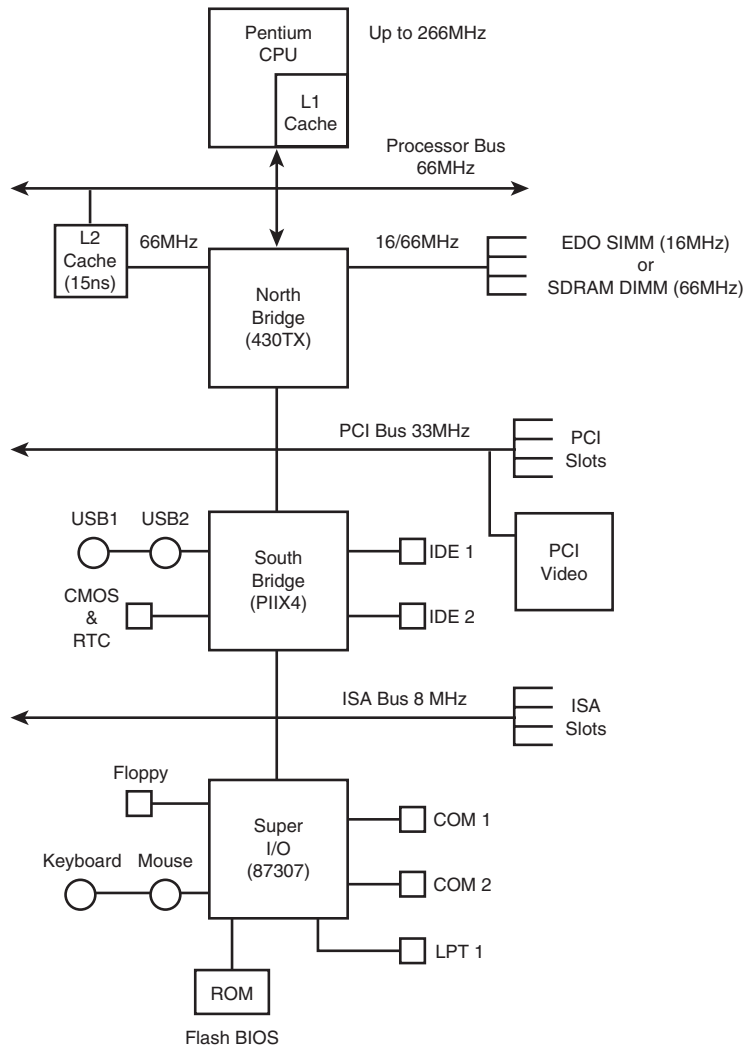

Figure 4.34 Typical Pentium (P5 Class) system architecture showing the different bus levels in the system.

Note that recently there is a new version of the Socket 7 architecture called *Super-7*. It is designed primarily by AMD and Cyrix for their new Socket 7 P5 class processors that run at motherboard speeds up to 100MHz. This is definitely better than 66MHz, but still not quite up to the Slot-1 architecture where the L2 cache automatically scales up in speed along with the processor. By moving the L2 cache off the motherboard, the Slot 1 designs offer greater performance.

Figure 4.35 shows the typical Pentium III system design. You can see the two main changes: One is that the L2 cache now runs at half processor core speed rather than motherboard speed. Also note that the motherboard speed has been increased to 100MHz, which dramatically improves main memory performance combined with 100MHz SDRAM memory. The other main change is the addition of a new single slot bus called AGP (Accelerated Graphics Port). This allows the video card to be on its own dedicated high-speed bus, which runs at twice the speed of PCI. Actually, the speed is misleading, as AGP has 2x and 4x modes that allow a further doubling or quadrupling of the speed over the base of 66MHz. This results in incredible video bandwidth, which is necessary for full-motion video capture and display.

Because the purpose of the processor bus is to get information to and from the CPU at the fastest possible speed, this bus operates at a much faster rate than any other bus in your system; no bottleneck exists here. The bus consists of electrical circuits for data, addresses (the address bus, which is discussed in the following section), and control purposes. In a Pentium-based system, the processor bus has 64 data lines, 32 address lines, and associated control lines. The Pentium Pro and Pentium II have 36 address lines, but otherwise are the same as the Pentium and Pentium MMX.

The processor bus operates at the same base clock rate as the CPU does externally. This can be misleading because most CPUs these days run internally at a higher clock rate than they do externally. For example, a Pentium 266 system has a Pentium CPU running at 266MHz internally, but only 66.6MHz externally, while a Pentium II 450 runs at 450MHz internally but only 100MHz externally. A Pentium 133, 166, 200, and even a Pentium 233 also run the processor external bus at 66.6MHz. In most newer systems, the actual processor speed is some multiple (1.5x, 2x, 2.5x, 3x, and so on) of the processor bus.

◀◀ See "Processor Speed Ratings," p. 42.

The processor bus is tied to the external processor pin connections and can transfer one bit of data per data line every one or two clock cycles. Thus, a Pentium, Pentium Pro, or Pentium II can transfer 64 bits of data at a time.

To determine the transfer rate for the processor bus, you multiply the data width (64 bits for a Pentium, Pentium Pro, or Pentium II) by the clock speed of the bus (the same as the base or unmultiplied clock speed of the CPU). If you are using a Pentium, Pentium MMX, Pentium Pro, or Pentium II chip that runs at a 66MHz motherboard speed, and it can transfer a bit of data each clock cycle on each data line, you have a maximum instantaneous transfer rate of roughly 528MB/sec. You get this result by using the following formula:

$$66\text{MHz} \times 64 \text{ bits} = 4,224\text{Mbit/sec}$$

$$4,224\text{Mbit/sec} \div 8 = 528\text{MB/sec}$$

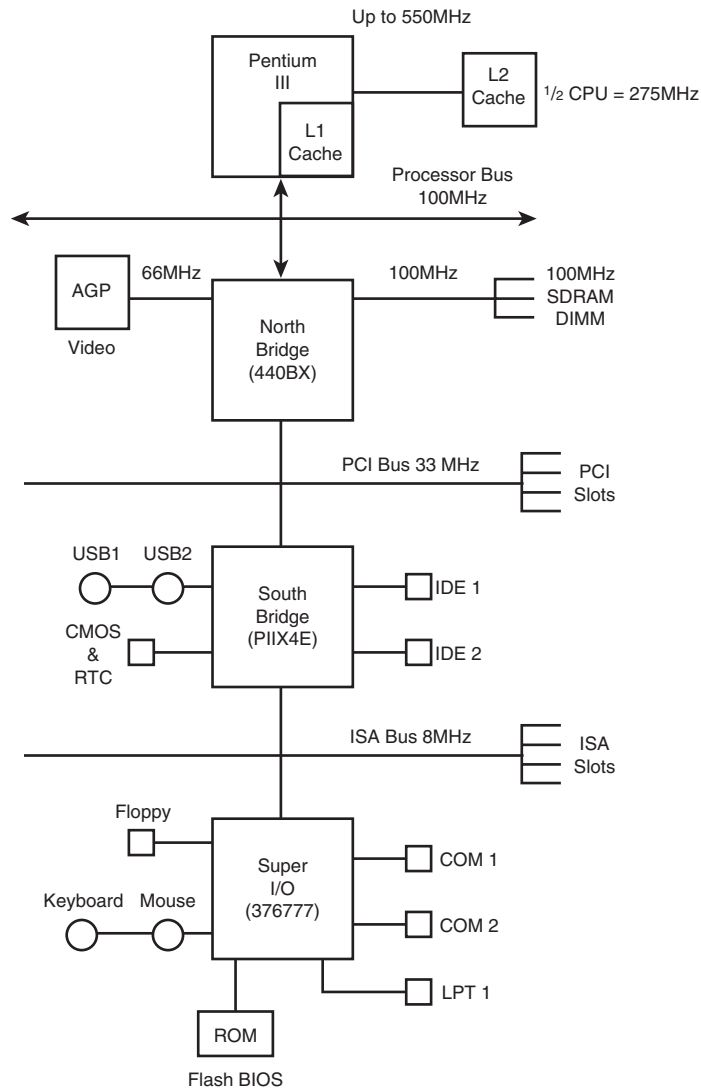

Figure 4.35 Typical Pentium III system architecture showing the different bus levels in the system.

This transfer rate, often called the *bandwidth of the bus*, represents a maximum. Like all maximums, this rate does not represent the normal operating bandwidth; you should expect much lower average throughput. Other limiting factors such as chipset design, memory design and speed, and so on conspire to lower the effective average throughput.

The Memory Bus

The memory bus is used to transfer information between the CPU and main memory—the RAM in your system. This bus is connected to the motherboard chipset North Bridge chip. Depending on the type of memory your chipset (and therefore motherboard) is designed to handle, the North Bridge will run the memory bus at different speeds. Systems that use FPM (Fast Page Mode) or EDO (Extended Data Out) memory with a 60ns access time run the memory bus at only 16MHz. That is because 16MHz results in about 60ns cycling speed. Newer chipsets and motherboards that support SDRAM can run the memory bus at 66MHz (15ns) or up to 100MHz (10ns). This obviously results in faster memory performance and virtually negates the need for having cache memory on the motherboard. That is why the Pentium II processor was designed to include a higher speed L2 cache built in, as the SDRAM memory on the motherboard already runs at the same speed as the motherboard cache found in older Pentium systems. Figure 4.32 and Figure 4.33 show how the memory bus fits into your PC.

Note

Notice that the main memory bus is always the same width as the processor bus. This will define the size of what is called a “bank” of memory. Memory banks and their width relative to processor buses are discussed in the “Memory Banks” section in Chapter 6.

The Need for Expansion Slots

The I/O bus or expansion slots are what enables your CPU to communicate with peripheral devices. The bus and its associated expansion slots are needed because basic systems cannot possibly satisfy all the needs of all the people who buy them. The I/O bus enables you to add devices to your computer to expand its capabilities. The most basic computer components, such as sound cards and video cards, can be plugged into expansion slots; you also can plug in more specialized devices, such as network interface cards, SCSI host adapters, and others.

Note

In most modern PC systems, a variety of basic peripheral devices are built into the motherboard. Most systems today have at least dual (primary and secondary) IDE interfaces, dual USB (Universal Serial Bus) ports, a floppy controller, two serial ports, a parallel port, keyboard, and mouse controller built directly into the motherboard. These devices are normally distributed between the motherboard chipset South Bridge and the Super I/O chip. (Super I/O chips are discussed earlier in this chapter.)

Many will even add more items such as a built-in sound card, video adapter, SCSI host adapter, or network interface also built into the motherboard. Those items are not built into the motherboard chipset or Super I/O chip, but would be configured as additional chips installed on the board. Nevertheless, these built-in controllers and ports still use the I/O bus to communicate with the CPU. In essence, even though they are built in, they act as if there are cards plugged into the system’s bus slots, including using system resources in the same manner.

Types of I/O Buses

Since the introduction of the first PC, many I/O buses have been introduced. The reason is simple: Faster I/O speeds are necessary for better system performance. This need for higher performance involves three main areas:

- Faster CPUs
- Increasing software demands
- Greater multimedia requirements

Each of these areas requires the I/O bus to be as fast as possible. Surprisingly, virtually all PC systems shipped today still incorporate the same basic bus architecture as the 1984 vintage IBM PC/AT. However, most of these systems now also include a second high-speed local I/O bus such as VL-Bus or PCI, which offer much greater performance for adapters that need it. Many of the newest systems also include a third high-speed bus called AGP for improved video performance beyond what PCI offers.

One of the primary reasons why new I/O-bus structures have been slow in coming is compatibility—that old catch-22 that anchors much of the PC industry to the past. One of the hallmarks of the PC's success is its standardization. This standardization spawned thousands of third-party I/O cards, each originally built for the early bus specifications of the PC. If a new high-performance bus system was introduced, it often had to be compatible with the older bus systems so that the older I/O cards would not be obsolete. Therefore, bus technologies seem to evolve rather than make quantum leaps forward.

You can identify different types of I/O buses by their architecture. The main types of I/O architecture are

- ISA
- Micro Channel Architecture (MCA)
- EISA
- VESA Local Bus (VL-Bus)
- PCI Local Bus
- AGP
- PC-Card (formerly PCMCIA)
- FireWire (IEEE-1394)
- Universal Serial Bus (USB)

▶▶ See "PC Cards" pg. 1236.

▶▶ See "IEEE 1394 (Also called i.link or FireWire)" pg. 896.

▶▶ See "USB (Universal Serial Bus)" pg. 892.

The differences among these buses consist primarily of the amount of data that they can transfer at one time and the speed at which they can do it. Each bus architecture is implemented by a

chipset that is connected to the processor bus. Typically, this chipset also controls the memory bus (refer to Figure 4.18 earlier in this chapter). The following sections describe the different types of PC buses.

The ISA Bus

ISA, which is an acronym for *Industry Standard Architecture*, is the bus architecture that was introduced as an 8-bit bus with the original IBM PC in 1981; it was later expanded to 16 bits with the IBM PC/AT in 1984. ISA is the basis of the modern personal computer and the primary architecture used in the vast majority of PC systems on the market today. It may seem amazing that such a presumably antiquated architecture is used in today's high-performance systems, but this is true for reasons of reliability, affordability, and compatibility, plus this old bus is still faster than many of the peripherals that we connect to it!

Two versions of the ISA bus exist, based on the number of data bits that can be transferred on the bus at a time. The older version is an 8-bit bus; the newer version is a 16-bit bus. The original 8-bit version ran at 4.77MHz in the PC and XT. The 16-bit version used in the AT ran at 6MHz, and then 8MHz. Later, the industry as a whole agreed on an 8.33MHz maximum standard speed for 8/16-bit versions of the ISA bus for backward compatibility. Some systems have the capability to run the ISA bus faster than this, but some adapter cards will not function properly at higher speeds. ISA data transfers require anywhere from two to eight cycles. Therefore, the theoretical maximum data rate of the ISA bus is about 8MB/sec, as the following formula shows:

$$\begin{aligned}8\text{MHz}\times 16\text{ bits} &= 128\text{Mbit/sec} \\128\text{Mbit/sec}\div 2\text{ cycles} &= 64\text{Mbit/sec} \\64\text{Mbit/sec}\div 8 &= 8\text{MB/sec}\end{aligned}$$

The bandwidth of the 8-bit bus would be half this figure (4MB/sec). Remember, however, that these figures are theoretical maximums; because of I/O bus protocols, the effective bandwidth is much lower—typically by almost half. Even so, at 8MB/sec, the ISA bus is still faster than many of the peripherals we connect to it.

The 8-Bit ISA Bus

This bus architecture is used in the original IBM PC computers. Although virtually nonexistent in new systems today, this architecture still exists in hundreds of thousands of PC systems in the field.

Physically, the 8-bit ISA expansion slot resembles the tongue-and-groove system that furniture makers once used to hold two pieces of wood together. It is specifically called a *card/edge connector*. An adapter card with 62 contacts on its bottom edge plugs into a slot on the motherboard that has 62 matching contacts. Electronically, this slot provides eight data lines and 20 addressing lines, enabling the slot to handle 1MB of memory.

Figure 4.36 describes the pinouts for the 8-bit ISA bus.

Figure 4.37 shows how these pins are oriented in the expansion slot.

Figure 4.36 Pinouts for the 8-bit ISA bus.

Figure 4.37 The 8-bit ISA bus connector.

Although the design of the bus is simple, IBM waited until 1987 to publish full specifications for the timings of the data and address lines, so in the early days of PC compatibles, manufacturers had to do their best to figure out how to make adapter boards. This problem was solved, however, as PC-compatible personal computers became more widely accepted as the industry standard and manufacturers had more time and incentive to build adapter boards that worked correctly with the bus.

The dimensions of 8-bit ISA adapter cards are as follows:

- 4.2 inches (106.68mm) high
- 13.13 inches (333.5mm) long
- 0.5 inch (12.7mm) wide

The 16-Bit ISA Bus

IBM threw a bombshell on the PC world when it introduced the AT with the 286 processor in 1984. This processor had a 16-bit data bus, which meant that communications between the processor and the motherboard as well as memory would now be 16 bits wide instead of only 8. Although this processor could have been installed on a motherboard with only an 8-bit I/O bus, that would have meant a huge sacrifice in the performance of any adapter cards or other devices installed on the bus.

The introduction of the 286 chip posed a problem for IBM in relation to its next generation of PCs: Should the company create a new I/O bus and associated expansion slots to try to come up with a system that could support both 8- and 16-bit cards? IBM opted for the latter solution, and the PC/AT was introduced with a set of expansion slots with 16-bit extension connectors. You can plug an 8-bit card into the forward part of the slot or a 16-bit card into both parts of the slot.

Note

The expansion slots for the 16-bit ISA bus also introduced access keys to the PC environment. An *access key* is a cutout or notch in an adapter card that fits over a corresponding tab in the connector into which the adapter card is inserted. Access keys typically are used to keep adapter cards from being inserted into a connector improperly.

The extension connector in each 16-bit expansion slot adds 36 connector pins to carry the extra signals necessary to implement the wider data path. In addition, two of the pins in the 8-bit portion of the connector were changed. These two minor changes do not alter the function of 8-bit cards.

Figure 4.38 describes the pinouts for the full 16-bit ISA expansion slot.

Figure 4.39 shows the orientation and relation of 8-bit and 16-bit ISA bus slots.

The extended 16-bit slots physically interfere with some 8-bit adapter cards that have a *skirt*—an extended area of the card that drops down toward the motherboard just after the connector. To handle these cards, IBM left two expansion ports in the PC/AT without the 16-bit extensions. These slots, which are identical to the expansion slots in earlier systems, can handle any skirted PC or XT expansion card. This is not a problem today, as no skirted 8-bit cards have been manufactured for years.

Note

Sixteen-bit ISA expansion slots were introduced in 1984. Since then, virtually every manufacturer of 8-bit expansion cards has designed them without drop-down skirts so that they fit properly in 16-bit slots. Most new systems do not have any 8-bit only slots, because a properly designed 8-bit card will work in any 16-bit slot.

Note that some poorly designed motherboards or adapter cards may have fitment problems. It is not uncommon to find that a full-length card will not work in a particular slot due to interference with the processor heat sink, SIMM or DIMM memory, voltage regulators, or other components on the board. Systems using the LPX motherboard and even the Baby-AT motherboard form factors are especially prone to these types of problems. This is another reason I recommend ATX form factor systems—things fit so much better.

Figure 4.39 The 8-bit and 16-bit ISA bus connectors.

Two heights actually are available for cards that are commonly used in AT systems: 4.8 inches and 4.2 inches (the height of older PC-XT cards). The shorter cards became an issue when IBM introduced the XT Model 286. Because this model has an AT motherboard in an XT case, it needs AT-type boards with the 4.2-inch maximum height. Most board makers trimmed the height of their boards; many manufacturers now make only 4.2-inch tall (or less) boards so that they will work in systems with either profile.

32-Bit Buses

After 32-bit CPUs became available, it was some time before 32-bit bus standards became available. Before MCA and EISA specs were released, some vendors began creating their own proprietary 32-bit buses, which were extensions of the ISA bus. Although the proprietary buses were few and far between, they do still exist.

The expanded portions of the bus typically are used for proprietary memory expansion or video cards. Because the systems are proprietary (meaning that they are nonstandard), pinouts and specifications are not available.

The Micro Channel Bus

The introduction of 32-bit chips meant that the ISA bus could not handle the power of another new generation of CPUs. The 386DX chips can transfer 32 bits of data at a time, but the ISA bus can handle a maximum 16 bits. Rather than extend the ISA bus again, IBM decided to build a new bus; the result was the MCA bus. *MCA* (an acronym for *Micro Channel Architecture*) is completely different from the ISA bus and is technically superior in every way.

IBM not only wanted to replace the old ISA standard, but also to receive royalties on it; the company required vendors that licensed the new MCA bus to pay IBM royalties for using the ISA bus in all previous systems. This requirement led to the development of the competing EISA bus (see the next section on the EISA bus) and hindered acceptance of the MCA bus. Another reason why MCA has not been adopted universally for systems with 32-bit slots is that adapter cards designed for ISA systems do not work in MCA systems.

Note

The MCA bus is not compatible with the older ISA bus, so cards designed for the ISA bus do not work in an MCA system.

MCA runs asynchronously with the main processor, meaning that fewer possibilities exist for timing problems among adapter cards plugged into the bus.

MCA systems produced a new level of ease of use, as anyone who has set up one of these systems can tell you. An MCA system has no jumpers and switches—neither on the motherboard nor on any expansion adapter. You don't need an electrical engineering degree to plug a card into a PC. What you do need is the Reference disk, which goes with the particular system, and the Options disks, which go with each of the cards installed in the system. Once a card is installed, you can load the Options disks files onto the Reference disk; after that, you don't need the Options disks anymore. The Reference disk contains the special BIOS and system setup program needed for an MCA system, and the system cannot be configured without it. IBM maintains a library of all of their Reference and Options disks at <ftp://ftp.pc.ibm.com/pub/pccbbs>. Check this site if you need any of these files.

The MCA bus also supports bus mastering. Through implementing bus mastering, the MCA bus provides significant performance improvements over the older ISA buses. (Bus mastering is also implemented in the EISA bus. General information related to bus mastering is discussed in the

“Bus Mastering” section later in this chapter.) In the MCA bus mastering implementation, any bus mastering devices can request unobstructed use of the bus in order to communicate with another device on the bus. The request is made through a device known as the *Central Arbitration Control Point (CACP)*. This device arbitrates the competition for the bus, making sure all devices have access and that no single device monopolizes the bus.

Each device is given a priority code to ensure that order is preserved within the system. The main CPU is given the lowest priority code. Memory refresh has the highest priority, followed by the DMA channels, and then the bus masters installed in the I/O slots. One exception to this is when an NMI (non-maskable interrupt) occurs. In this instance, control returns to the CPU immediately.

The MCA specification provides for four adapter sizes, which are described in Table 4.24.

Table 4.24 Physical Sizes of MCA Adapter Cards

Adapter Type	Height (in Inches)	Length (in Inches)
Type 3	3.475	12.3
Type 3 half	3.475	6.35
Type 5	4.825	13.1
Type 9	9.0	13.1

Four types of slots are involved in the MCA design:

- 16-bit
- 16-bit with video extensions
- 16-bit with memory-matched extensions
- 32-bit

IBM still has all the technical reference manuals for MCA available; however, development has stopped for MCA devices because other faster and more feature-rich buses are available today.

The EISA Bus

EISA is an acronym for *Extended Industry Standard Architecture*. This standard was announced in September 1988 as a response to IBM’s introduction of the MCA bus—more specifically, to the way that IBM wanted to handle licensing of the MCA bus. Vendors did not feel obligated to pay retroactive royalties on the ISA bus, so they turned their backs on IBM and created their own buses.

The EISA standard was developed primarily by Compaq, and was intended as being their way of taking over future development of the PC bus away from IBM. Compaq knew that nobody would clone their bus if they were the only company that had it, so they essentially gave the design away to other leading manufacturers. They formed the EISA committee, a non-profit organization designed specifically to control development of the EISA bus. Very few EISA adapters were ever developed. Those that were developed centered mainly around disk array controllers and server type network cards.

The EISA bus provides 32-bit slots for use with 386DX or higher systems. The EISA slot enables manufacturers to design adapter cards that have many of the capabilities of MCA adapters, but the bus also supports adapter cards created for the older ISA standard. EISA provides markedly faster hard drive throughput when used with devices such as SCSI bus-mastering hard drive controllers. Compared with 16-bit ISA system architecture, EISA permits greater system expansion with fewer adapter conflicts.

The EISA bus adds 90 new connections (55 new signals) without increasing the physical connector size of the 16-bit ISA bus. At first glance, the 32-bit EISA slot looks a lot like the 16-bit ISA slot. The EISA adapter, however, has two rows of connectors. The first row is the same kind used in 16-bit ISA cards; the other, thinner row extends from the 16-bit connectors. This means that ISA cards can still be used in EISA bus slots. Although this compatibility was not enough to ensure the popularity of EISA buses, it is a feature that was carried over into the newer VL-Bus standard. The physical specifications of an EISA card are as follows:

- 5 inches (127mm) high
- 13.13 inches (333.5mm) long
- 0.5 inches (12.7mm) wide

The EISA bus can handle up to 32 bits of data at an 8.33MHz cycle rate. Most data transfers require a minimum of two cycles, although faster cycle rates are possible if an adapter card provides tight timing specifications. The maximum bandwidth on the bus is 33MB/sec, as the following formula shows:

- $8.33\text{MHz} \times 32 \text{ bits} = 266.56\text{Mbit/sec}$
- $266.56\text{Mbit/sec} \div 8 = 33.32\text{MB/sec}$

Data transfers through an 8- or 16-bit expansion card across the bus would be reduced appropriately. Remember, however, that these figures represent theoretical maximums. Wait states, interrupts, and other protocol factors can reduce the effective bandwidth—typically, by half.

Figure 4.40 describes the pinouts for the EISA bus.

Figure 4.41 shows the locations of the pins.

Figure 4.41 The card connector for the EISA bus.

Automated Setup

EISA systems also use an automated setup to deal with adapter-board interrupts and addressing issues. These issues often cause problems when several different adapter boards are installed in an ISA system. EISA setup software recognizes potential conflicts and automatically configures the system to avoid them. EISA does, however, enable you to do your own troubleshooting, as well as to configure the boards through jumpers and switches. This concept was not new to EISA; IBM's MCA bus also supported configuration via software. Another new feature of EISA systems is *IRQ sharing*, meaning that multiple bus cards can share a single interrupt. This feature has also been implemented in PCI bus cards.

Similar to the MCA bus and the Reference disk required there, systems with an EISA bus require an EISA Configuration disk, along with options disks containing files specific to each EISA adapter installed. You can get the EISA Configuration disk from the manufacturer of your system or motherboard and the Options disks from the manufacturer of the specific boards you are using. Just as with MCA based systems, without these disks and files, you cannot properly configure an EISA system.

Note

Although automated setup traditionally has not been available in ISA systems, it is now available with Plug-and-Play (PnP) systems and components. PnP systems are discussed toward the end of this chapter in the section titled "Plug-and-Play Systems."

Local Buses

The I/O buses discussed so far (ISA, MCA, and EISA) have one thing in common: relatively slow speed. The three newer bus types that we will look at in the following few sections all use the *local bus* concept explained in this section to address the speed issue. The three main local buses found in PC systems are

- VL-Bus (VESA Local Bus)
- PCI (Peripheral Component Interconnect)
- AGP (Accelerated Graphics Port)

The speed limitation of ISA, MCA, and EISA is a carryover from the days of the original PC, when the I/O bus operated at the same speed as the processor bus. As the speed of the processor bus increased, the I/O bus realized only nominal speed improvements, primarily from an increase in the bandwidth of the bus. The I/O bus had to remain at a slower speed, because the huge installed base of adapter cards could operate only at slower speeds.

Figure 4.42 shows a conceptual block diagram of the buses in a computer system.

The thought of a computer system running slower than it could is very bothersome to some computer users. Even so, the slow speed of the I/O bus is nothing more than a nuisance in most cases. You don't need blazing speed to communicate with a keyboard or mouse—you gain nothing in performance. The real problem occurs in subsystems in which you need the speed, such as video and disk controllers.

Figure 4.42 Bus layout in a traditional PC.

The speed problem became acute when graphical user interfaces (such as Windows) became prevalent. These systems required the processing of so much video data that the I/O bus became a literal bottleneck for the entire computer system. In other words, it did little good to have a processor that was capable of 66MHz to 450MHz or faster if you could put data through the I/O bus at a rate of only 8MHz.

An obvious solution to this problem is to move some of the slotted I/O to an area where it could access the faster speeds of the processor bus—much the same way as the external cache. Figure 4.43 shows this arrangement.

This arrangement became known as *local bus*, because external devices (adapter cards) now could access the part of the bus that was local to the CPU—the processor bus. Physically, the slots provided to tap this new configuration would need to be different from existing bus slots to prevent adapter cards designed for slower buses from being plugged into the higher bus speeds, which this design made accessible.

It is interesting to note that the very first 8-bit and 16-bit ISA buses were a form of local bus architecture. These systems had the processor bus as the main bus, and everything ran at full processor speeds. When ISA systems ran faster than 8MHz, the main ISA bus had to be decoupled from the processor bus because expansion cards, memory, and so on could not keep up. In 1992, an extension to the ISA bus called the *VESA local bus* (VL-Bus) started showing up on PC systems, indicating a return to local bus architecture. Since then, the *Peripheral Component Interconnect* (PCI) local bus has supplanted VL-Bus and the Accelerated Graphics Port (AGP) bus has been introduced to complement PCI.

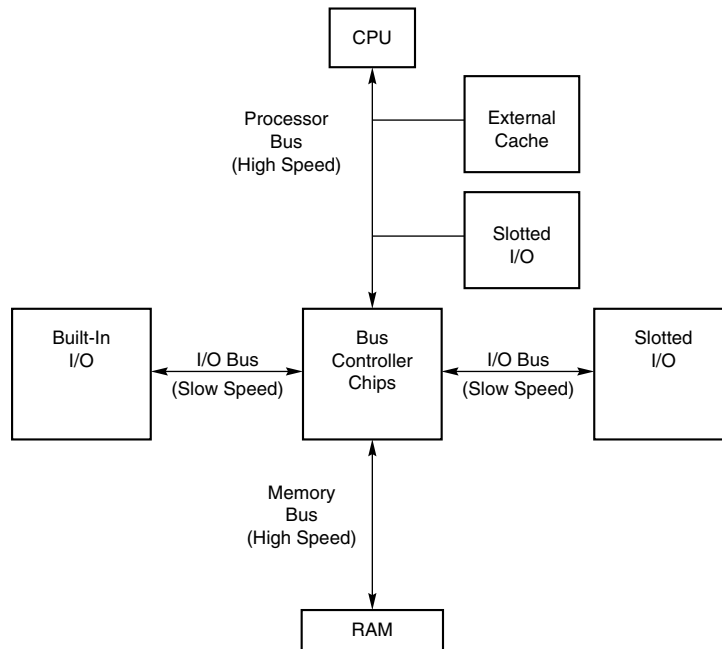

Figure 4.43 How a local bus works.

Note

A system does not have to have a local bus expansion slot to incorporate local bus technology; instead, the local bus device can be built directly into the motherboard. (In such a case, the local bus-slotted I/O shown in Figure 4.41 would in fact be built-in I/O.) This built-in approach to local bus is the way the first local bus systems were designed.

Local bus solutions do not replace earlier standards, such as ISA; they are designed into the system as a bus that is closer to the processor in the system architecture. Older buses such as ISA have been kept around for backward compatibility with slower types of adapters that don't need any faster connection to the system (such as modems). Therefore, a typical system will have AGP, PCI and ISA slots. Older cards still are compatible with the system, but high-speed adapter cards can take advantage of the AGP and PCI local bus slots as well.

The performance of graphical user interfaces such as Windows and OS/2 have been tremendously improved by moving the video cards off of the slow ISA bus and onto faster PCI and now AGP local buses.

VESA Local Bus

The VESA local bus was the most popular local bus design from its debut in August 1992 through 1994. It was created by the VESA committee, a non-profit organization founded by NEC to further develop video display and bus standards. In a similar fashion to how EISA evolved, NEC had

done most of the work on the VL-Bus (as it would be called), and after founding the non-profit VESA committee, they turned over future development to VESA. At first, the local bus slot seemed primarily designed to be used for video cards. Improving video performance was a top priority at NEC to help sell their high-end displays as well as their own PC systems. By 1991, video performance had become a real bottleneck in most PC systems.

The Video Electronics Standards Association (VESA) developed a standardized local bus specification known as *VESA local bus (VL-Bus)*. As in earlier local bus implementations, the VL-Bus slot offers direct access to system memory at the speed of the processor itself. The VL-Bus can move data 32 bits at a time, enabling data to flow between the CPU and a compatible video subsystem or hard drive at the full 32-bit data width of the 486 chip. The maximum rated throughput of the VL-Bus is 128MB to 132MB/sec. In other words, local bus went a long way toward removing the major bottlenecks that existed in earlier bus configurations.

Additionally, VL-Bus offers manufacturers of hard-drive interface cards an opportunity to overcome another traditional bottleneck: the rate at which data can flow between the hard drive and the CPU. The average 16-bit IDE drive and interface can achieve throughput of up to 5MB/sec, whereas VL-Bus hard drive adapters for IDE drives are touted as providing throughput of as much as 8MB/sec. In real-world situations, the true throughput of VL-Bus hard drive adapters is somewhat less than 8MB/sec, but VL-Bus still provides a substantial boost in hard-drive performance.

Despite all the benefits of the VL-Bus (and, by extension, of all local buses), this technology has a few drawbacks, which are described in the following list:

- *Dependence on a 486 CPU.* The VL-Bus inherently is tied to the 486 processor bus. This bus is quite different from that used by Pentium and later processors. A VL-Bus that operates at the full rated speed of a Pentium has not been developed, although stopgap measures (such as stepping down speed or developing bus bridges) are available. Unfortunately, these result in poor performance. Some systems have been developed with both VL-Bus and PCI slots, but because of design compromises, performance often suffers.
- *Speed limitations.* The VL-Bus specification provides for speeds of up to 66MHz on the bus, but the electrical characteristics of the VL-Bus connector limit an adapter card to no more than 40–50MHz. In practice, running the VL-Bus at speeds over 33MHz cause many problems, so 33MHz has become the acceptable speed limit. Systems that use faster processor bus speeds must buffer and step down the clock on the VL-Bus or add wait states. Note that if the main CPU uses a clock modifier (such as the kind that doubles clock speeds), the VL-Bus uses the unmodified CPU clock speed as its bus speed.
- *Electrical limitations.* The processor bus has very tight timing rules that may vary from CPU to CPU. These timing rules were designed for limited loading on the bus, meaning that the only elements originally intended to be connected to the local bus are elements such as the external cache and the bus controller chips. As you add more circuitry, you increase the electrical load. If the local bus is not implemented correctly, the additional load can lead to problems such as loss of data integrity and timing problems between the CPU and the VL-Bus cards.
- *Card limitations.* Depending on the electrical loading of a system, the number of VL-Bus cards is limited. Although the VL-Bus specification provides for as many as three cards, this can be achieved only at clock rates of up to 40MHz with an otherwise low system-board load. As the system-board load and clock rate increases, the number of cards supported decreases. Only one VL-Bus card can be supported at 50MHz with a high system-board load. In practice, these limits could not usually be reached without problems.

The VL-Bus did not seem to be a well-engineered concept. The design was simple indeed—just take the pins from the 486 processor and run them out to a card connector socket. In other words, the VL-Bus is essentially the raw 486 processor bus. This allowed a very inexpensive design, because no additional chipsets or interface chips were required. A motherboard designer could add VL-Bus slots to their 486 motherboards very easily and at a very low cost. This is why these slots appeared on virtually all 486 system designs overnight.

Unfortunately, the 486 processor bus was not designed to have multiple devices (called *loads*) plugged into it at one time. Problems arose with timing glitches caused by the capacitance introduced into the circuit by different cards. Since the VL-Bus ran at the same speed as the processor bus, different processor speeds meant different bus speeds and full compatibility was difficult to achieve. Although the VL-Bus could be adapted to other processors, including the 386 or even the Pentium, it was designed for the 486, and worked best as a 486 solution only. Despite the low cost, after a new bus called *PCI (Peripheral Component Interconnect)* appeared, VL-Bus fell into disfavor very quickly. It never did catch on with Pentium systems, and there is little or no further development of the VL-Bus in the PC industry. I would not recommend purchasing VL-Bus cards or systems today.

For a used system, or as an inexpensive upgrade for an older system, VL-Bus might be appropriate and can provide an acceptable solution for high-speed computing.

Physically, the VL-Bus slot is an extension of the slots used for whatever type of base system you have. If you have an ISA system, the VL-Bus is positioned as an extension of your existing 16-bit ISA slots. Likewise, if you have an EISA system or MCA system, the VL-Bus slots are extensions of those existing slots. Figure 4.44 shows how the VL-Bus slots could be situated in an ISA system. The VESA extension has 112 contacts and uses the same physical connector as the MCA bus.

The VL-Bus adds a total 116 pin locations to the bus connectors that your system already has. Table 4.25 lists the pinouts for only the VL-Bus connector portion of the total connector. (For pins for which two purposes are listed, the second purpose applies when the card is in 64-bit transfer mode.)

Figure 4.44 An example of VL-Bus slots in an ISA system.

Figure 4.45 The card connector for the VL-Bus.

The PCI Bus

In early 1992, Intel spearheaded the creation of another industry group. It was formed with the same goals as the VESA group in relation to the PC bus. Recognizing the need to overcome weaknesses in the ISA and EISA buses, the PCI Special Interest Group was formed.

The Peripheral Component Interconnect (PCI) bus specification was released in June 1992 as version 1.0; it was later updated in April 1993 as version 2.0, and in early 1995 the latest revision 2.1 appeared. PCI redesigned the traditional PC bus by inserting another bus between the CPU and the native I/O bus by means of bridges. Rather than tap directly into the processor bus, with its delicate electrical timing (as was done in the VL-Bus), a new set of controller chips was developed to extend the bus, as shown in Figure 4.46.

Figure 4.46 Conceptual diagram of the PCI bus.

The PCI bus often is called a *mezzanine bus* because it adds another layer to the traditional bus configuration. PCI bypasses the standard I/O bus; it uses the system bus to increase the bus clock speed and take full advantage of the CPU's data path. Systems that integrate the PCI bus became available in mid 1993 and have since become the mainstay high-end systems.

Information is transferred across the PCI bus at 33MHz, at the full data width of the CPU. When the bus is used in conjunction with a 32-bit CPU, the bandwidth is 132MB per second, as the following formula shows:

$$33\text{MHz} \times 32 \text{ bits} = 1,056\text{Mbit/sec}$$

$$1,056\text{Mbit/sec} \div 8 = 132\text{MB/sec}$$

When the bus is used in future 64-bit implementations, the bandwidth doubles, meaning that you can transfer data at speeds up to 264MB/sec. Real-life data transfer speeds necessarily will be lower, but still much faster than anything else that is currently available. Part of the reason for this faster real-life throughput is the fact that the PCI bus can operate concurrently with the processor bus; it does not supplant it. The CPU can be processing data in an external cache while the PCI bus is busy transferring information between other parts of the system—a major design benefit of the PCI bus.

A PCI adapter card uses its own unique connector. This connector can be identified within a computer system because it typically is offset from the normal ISA, MCA, or EISA connectors. See Figure 4.47 for an example. The size of a PCI card can be the same as that of the cards used in the system's normal I/O bus.

Figure 4.47 Possible configuration of PCI slots in relation to ISA or EISA slots.

The PCI specification identifies three board configurations, each designed for a specific type of system with specific power requirements. The 5v specification is for stationary computer systems, the 3.3v specification is for portable machines, and the universal specification is for motherboards and cards that work in either type of system.

Table 4.26 shows the 5v PCI pinouts, and Figure 4.48 shows the pin locations. Table 4.27 shows the 3.3v PCI pinouts; the pin locations are indicated in Figure 4.49. Finally, Table 4.28 shows the pinouts, and Figure 4.50 shows the pin locations for a universal PCI slot and card. Notice that each figure shows both the 32-bit and 64-bit variations on the respective specifications.

Note

If the PCI card supports only 32 data bits, it needs only pins B1/A1 through B62/A62. Pins B63/A63 through B94/A94 are used only if the card supports 64 data bits.

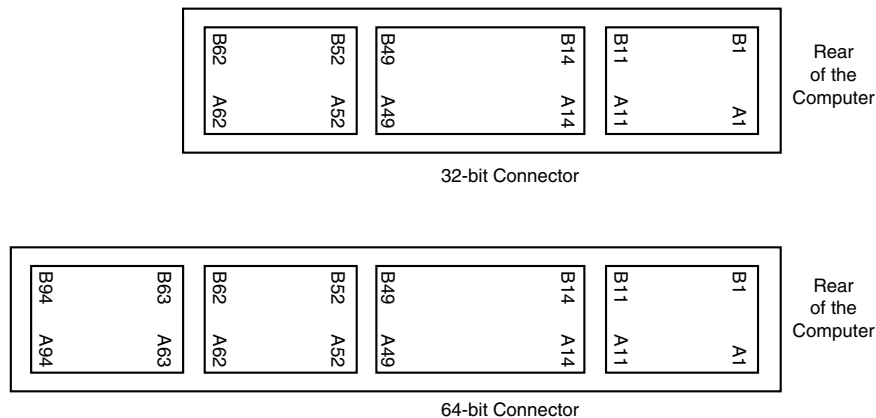

Figure 4.50 The universal PCI slot and card configuration.

Notice that the universal PCI board specifications effectively combine the 5v and 3.3v specifications. For pins for which the voltage is different, the universal specification labels the pin simply V I/O. This type of pin represents a special power pin for defining and driving the PCI signaling rail.

Another important feature of PCI is the fact that it was the model for the Intel PnP specification. This means that PCI cards do not have jumpers and switches, and are instead configured through software. True PnP systems are capable of automatically configuring the adapters, while non-PnP systems with ISA slots have to configure the adapters through a program that is usually a part of the system CMOS configuration. Starting in late 1995, most PC-compatible systems have included a PnP BIOS that allows the automatic PnP configuration.

Accelerated Graphics Port (AGP)

The Accelerated Graphics Port (AGP) was created by Intel as a new bus specifically designed for high performance graphics and video support. AGP is based on PCI, but contains a number of additions and enhancements, and is physically, electrically, and logically independent of PCI. For example the AGP connector is similar to PCI, although it has additional signals and is positioned differently in the system. Unlike PCI, which is a true bus with multiple connectors (slots), AGP is more of a point-to-point high performance connection designed specifically for a video card in a system, as only one AGP slot is allowed for a single video card.

The AGP specification 1.0 was originally released by Intel in July of 1996, and defined a 66MHz clock rate with 1x or 2x signaling using 3.3 volts. AGP version 2.0 was released in May 1998, and added 4x signaling as well as a lower 1.5v operating capability. There is also a new AGP Pro specification that defines a slightly longer slot with additional power pins at each end to drive bigger and faster AGP cards which consume more than 25 watts of power, up to a maximum of 110 watts. AGP Pro cards would likely be used for high-end graphics workstations. AGP Pro slots are backward compatible, meaning standard AGP card will plug in.

AGP is a high-speed connection, and runs at a base frequency of 66MHz (actually 66.66MHz), which is double that of standard PCI. In the basic AGP mode called 1x, a single transfer is done every cycle. Since the AGP bus is 32 bits (4 bytes) wide, at 66 million times per second it would be capable of transferring data at a rate of about 266MB/sec (million bytes per second)! The original AGP specification also defines a 2x mode, where two transfers are done every cycle, resulting in 533 MB/sec. Using an analogy where every cycle is equivalent to the back and forth swing of a pendulum, the 1x mode is thought of as transferring information at the start of each swing. In 2x mode, an additional transfer would occur every time the pendulum completed half a swing, thereby doubling performance while technically maintaining the same clock rate, or in this case, the same number of swings per second. Most modern AGP cards work in the 2x mode.

The newer AGP 2.0 specification adds the capability for 4x transfers, which transfers data four times per cycle and equals a data transfer rate of 1,066 MB/sec. The Table 4.29 shows the differences in clock rates and data transfer speeds for the various AGP modes.

Table 4.29 Clock Rates Versus Data Transfer Speeds

AGP Mode	Base Clock Rate	Effective Clock Rate	Data Transfer Rate
1x	66MHz	66MHz	266MB/sec
2x	66MHz	133MHz	533MB/sec
4x	66MHz	266MHz	1,066MB/sec

Because AGP is independent of PCI, using an AGP video card will free up the PCI bus for more traditional input and output, such as for IDE/ATA or SCSI controllers, USB controllers, sound cards, etc.

Besides faster video performance, one of the main reasons Intel designed AGP was to allow the video card to have a high-speed connection directly to the system RAM. This will allow an AGP video card to have direct access to the system RAM, reducing the need for more and more video memory. This is especially important because memory hungry 3D video becomes more and more prevalent on PCs.

AGP will allow the speed of the video card to pace the requirements for high-speed 3D graphics rendering as well as full motion video on the PC in the future.

System Resources

System resources are the communications channels, addresses, and other signals used by hardware devices to communicate on the bus. At their lowest level, these resources typically include the following:

- Memory addresses
- IRQ (interrupt request) channels
- DMA (direct memory access) channels
- I/O port addresses

I have listed these roughly in the order you would experience problems with them. Memory conflicts are perhaps the most troublesome of these, certainly the most difficult to fully explain and overcome. These are discussed in Chapter 6, “Memory,” which focuses on the others listed here in the order you will likely have problems with them.

IRQs cause more problems than DMA because they are in much higher demand; therefore, virtually all cards will use IRQ channels. There are fewer problems with DMA channels because few cards use them, and there are usually more than enough channels to go around. I/O ports are used by all hardware devices on the bus, but there are technically 64KB of them, which means plenty to go around. With all these resources, you have to make sure that a unique card or hardware function uses each resource; in most cases they cannot or should not be shared.

These resources are required and used by many different components of your system. Adapter cards need these resources to communicate with your system and accomplish their purposes. Not all adapter cards have the same resource requirements. A serial communications port, for example, needs an IRQ channel and I/O port address, whereas a soundboard needs these resources and normally at least one DMA channel as well. Most network cards use a 16KB block of memory addresses, an IRQ channel, and an I/O port address.

As your system increases in complexity, the chance for resource conflicts increases dramatically. Modern systems with sound cards and network cards can really push the envelope and become a configuration nightmare for the uninitiated. So that you can resolve conflicts, most adapter cards allow you to modify resource assignments by using the Plug-and-Play software that comes with the card or the device manager in Windows 95 and later. Even if the automatic configuration gets confused (which happens more often than it should), fortunately, in almost all cases there is a logical way to configure the system—once you know the rules.

Interrupts (IRQs)

Interrupt request channels (IRQs), or hardware interrupts, are used by various hardware devices to signal the motherboard that a request must be fulfilled. This procedure is the same as a student raising his hand to indicate that he needs attention.

These interrupt channels are represented by wires on the motherboard and in the slot connectors. When a particular interrupt is invoked, a special routine takes over the system, which first saves all the CPU register contents in a stack, and then directs the system to the interrupt vector table. This vector table contains a list of memory addresses that correspond to the interrupt channels. Depending on which interrupt was invoked, the program corresponding to that channel is run.

The pointers in the vector table point to the address of whatever software driver is used to service the card that generated the interrupt. For a network card, for example, the vector may point to the address of the network drivers that have been loaded to operate the card; for a hard disk controller, the vector may point to the BIOS code that operates the controller.

After the particular software routine finishes performing whatever function the card needed, the interrupt-control software returns the stack contents to the CPU registers, and the system then resumes whatever it was doing before the interrupt occurred.

Through the use of interrupts, your system can respond to external events in a timely fashion. Each time a serial port presents a byte to your system, an interrupt is generated to ensure that the system reads that byte before another comes in. Keep in mind that in some cases a port device—in particular, a modem with a 16550 or higher UART chip—may incorporate a byte buffer that allows multiple characters to be stored before an interrupt is generated.

Hardware interrupts are generally prioritized by their numbers; with some exceptions, the highest-priority interrupts have the lowest numbers. Higher-priority interrupts take precedence over lower-priority interrupts by interrupting them. As a result, several interrupts can occur in your system concurrently, each interrupt nesting within another.

If you overload the system—in this case, by running out of stack resources (too many interrupts were generated too quickly)—an internal stack overflow error occurs and your system halts. The message usually appears as `Internal stack overflow - system halted` at a DOS prompt. If you experience this type of system error and run DOS, you can compensate for it by using the `STACKS` parameter in your `CONFIG.SYS` file to increase the available stack resources. Most people will not see this error in Windows 95 or Windows NT.

The ISA bus uses edge-triggered *interrupt sensing*, in which an interrupt is sensed by a signal sent on a particular wire located in the slot connector. A different wire corresponds to each possible hardware interrupt. Because the motherboard cannot recognize which slot contains the card that used an interrupt line and therefore generated the interrupt, confusion would result if more than one card were set to use a particular interrupt. Each interrupt, therefore, usually is designated for a single hardware device. Most of the time, interrupts cannot be shared.

A device can be designed to share interrupts, and a few devices allow this; but, most cannot because of the way interrupts are signaled in the ISA bus. The PCI bus allows interrupt sharing, in fact, virtually all PCI cards are set to PCI interrupt A, and share that interrupt on the PCI bus. The real problem is that there are technically two sets of hardware interrupts in the system, PCI interrupts and ISA interrupts. For PCI cards to work in a PC, the PCI interrupts must be mapped to ISA interrupts, which are normally non-shareable. This means in many cases you would have to assign a non-conflicting interrupt for each card.

The solution to the interrupt sharing problem for PCI cards is something called *PCI IRQ Steering*, which is supported in newer operating systems and BIOS. PCI IRQ Steering allows a plug-and-play operating system such as Windows to dynamically map or steer PCI cards (which all use PCI INTA#) to ISA interrupts, and allows several PCI cards to be mapped to the same ISA interrupt. More information on PCI IRQ Steering is found in the section on PCI interrupts later in this chapter.

Hardware interrupts are sometimes referred to as *maskable interrupts*, which means that the interrupts can be masked or turned off for a short time while the CPU is used for other critical operations. It is up to the system BIOS and programs to manage interrupts properly and efficiently for the best system performance.

Because interrupts usually cannot be shared in an ISA bus system, you often run into conflicts and can even run out of interrupts when you are adding boards to a system. If two boards use the

same IRQ to signal the system, the resulting conflict prevents either board from operating properly. The following sections discuss the IRQs that any standard devices use, as well as what may be free in your system.

8-Bit ISA Bus Interrupts

The PC and XT (the systems based on the 8-bit 8086 CPU) provide for eight different external hardware interrupts. Table 4.30 shows the typical uses for these interrupts, which are numbered 0–7.

Table 4.30 8-Bit ISA Bus Default Interrupt Assignments

IRQ	Function	Bus Slot
0	System Timer	No
1	Keyboard Controller	No
2	Available	Yes (8-bit)
3	Serial Port 2 (COM2:)	Yes (8-bit)
4	Serial Port 1 (COM1:)	Yes (8-bit)
5	Hard Disk Controller	Yes (8-bit)
6	Floppy Disk Controller	Yes (8-bit)
7	Parallel Port 1 (LPT1:)	Yes (8-bit)

If you have a system that has one of the original 8-bit ISA buses, you will find that the IRQ resources provided by the system present a severe limitation. Installing several devices that need the services of system IRQs in a PC/XT-type system can be a study in frustration, because the only way to resolve the interrupt-shortage problem is to remove the adapter board that you need the least.

16-Bit ISA, EISA, and MCA Bus Interrupts

The introduction of the AT, based on the 286 processor, was accompanied by an increase in the number of external hardware interrupts that the bus would support. The number of interrupts was doubled to 16 by using two Intel 8259 interrupt controllers, piping the interrupts generated by the second one through the unused IRQ 2 in the first controller. This arrangement effectively means that only 15 IRQ assignments are available, and IRQ 2 effectively became inaccessible.

By routing all the interrupts from the second IRQ controller through IRQ 2 on the first, all these new interrupts are assigned a nested priority level between IRQ 1 and IRQ 3. Thus, IRQ 15 ends up having a higher priority than IRQ 3. Figure 4.51 shows how the two 8259 chips were wired to create the cascade through IRQ 2 on the first chip.

To prevent problems with boards set to use IRQ 2, the AT system designers routed one of the new interrupts (IRQ 9) to fill the slot position left open after removing IRQ 2. This means that any card you install in a modern system that claims to use IRQ 2 is really using IRQ 9 instead. Some cards now label this selection as IRQ 2/9, while others may only call it IRQ 2 or IRQ 9. No matter what the labeling says, you must never set two cards to use that interrupt!

Figure 4.51 Interrupt controller cascade wiring.

Table 4.31 shows the typical uses for interrupts in the 16-bit ISA, EISA, and MCA buses, and lists them in priority order from highest to lowest.

Table 4.31 16/32-Bit ISA/PCI Default Interrupt Assignments

IRQ	Standard Function	Bus Slot	Card Type	Recommended Use
0	System Timer	No	-	-
1	Keyboard Controller	No	-	-
2	2nd IRQ Controller Cascade	No	-	-
8	Real-time Clock	No	-	-
9	Available (appears as IRQ 2)	Yes	8/16-bit	Network Interface Card
10	Available	Yes	16-bit	USB
11	Available	Yes	16-bit	SCSI Host Adapter
12	Motherboard Mouse Port Available	Yes	16-bit	Motherboard Mouse Port
13	Math Coprocessor	No	-	-
14	Primary IDE	Yes	16-bit	Primary IDE (Hard disks)
15	Secondary IDE/Available	Yes	16-bit	Secondary IDE (CDROM/Tape)
3	Serial Port 2 (COM2:)	Yes	8/16-bit	COM2:/Internal Modem
4	Serial Port 1 (COM1:)	Yes	8/16-bit	COM1:
5	Sound/Parallel Port 2 (LPT2:)	Yes	8/16-bit	Sound Card
6	Floppy Disk Controller	Yes	8/16-bit	Floppy Controller
7	Parallel Port 1 (LPT1:)	Yes	8/16-bit	LPT1:

Notice that interrupts 0, 1, 2, 8, and 13 are not on the bus connectors and are not accessible to adapter cards. Interrupts 8, 10, 11, 12, 13, 14, and 15 are from the second interrupt controller and are accessible only by boards that use the 16-bit extension connector, because this is where these wires are located. IRQ 9 is rewired to the 8-bit slot connector in place of IRQ 2, which means that IRQ 9 replaces IRQ 2 and, therefore, is available to 8-bit cards, which treat it as though it were IRQ 2.

Note

Although the 16-bit ISA bus has twice as many interrupts as systems that have the 8-bit ISA bus, you still might run out of available interrupts, because only 16-bit adapters can use most of the newly available interrupts. Thirty-two-bit PCI adapters can be mapped to any ISA IRQs.

The extra IRQ lines in a 16-bit ISA system are of little help unless the adapter boards that you plan to use enable you to configure them for one of the unused IRQs. Some devices are hard-wired so that they can use only a particular IRQ. If you have a device that already uses that IRQ, you must resolve the conflict before installing the second adapter. If neither adapter enables you to reconfigure its IRQ use, chances are that you cannot use the two devices in the same system.

PCI Interrupts

The PCI bus supports hardware interrupts (IRQs) that can be used by PCI devices to signal to the bus that they need attention. There are four PCI interrupts called INTA#, INTB#, INTC#, and INTD#. These INTx# interrupts are *level-sensitive*, which means that the electrical signaling allows for them to be shared among PCI cards. In fact, all single device or single function PCI chips or cards that use only one interrupt must use INTA#. This is one of the rules in the PCI specification. If there are additional devices within a chip or on-board a card, the additional devices can use INTB# through INTD#. Since there are very few multifunction PCI chips or boards, this means that practically all the devices on a given PCI bus will be sharing INTA#.

In order for the PCI bus to function in a PC, the PCI interrupts must be mapped to ISA interrupts. Since ISA interrupts cannot be shared, in most cases each PCI card that is using INTA# on the PCI bus must be mapped to a different non-sharable ISA interrupt. For example, you could have a system with four PCI slots, and four PCI cards installed each using PCI interrupt INTA#. These cards would be each mapped to a different available ISA interrupt request (IRQ), such as IRQ9, IRQ10, IRQ11, and IRQ5 in most cases.

Finding unique IRQs for each device on both the ISA and PCI buses has always been a problem; there simply aren't enough free ones to go around. Setting two ISA devices to the same IRQ has never been possible, but on most newer systems it may be possible to share IRQs between multiple PCI devices. Newer system BIOS as well as plug-and-play operating systems such as Windows 95B (OSR 2) or later, Windows 98, and Windows 2000 all support a function known as PCI IRQ (interrupt request) Steering. For this to work, both your system BIOS and operating system must support IRQ Steering. Older system BIOS and Windows 95 or 95a do not have support for PCI IRQ Steering.

Normally, the BIOS assigns unique IRQs to PCI devices. If your system supports PCI IRQ Steering, and it is enabled, Windows assigns IRQs to PCI devices. Even when IRQ Steering is enabled, the BIOS still initially assigns IRQs to PCI devices. Although Windows has the capability to change these settings, it generally does not do so automatically, except where necessary to eliminate conflicts. If there are insufficient free IRQs to go around, IRQ Steering allows Windows to assign multiple PCI devices to a single IRQ, thus enabling all the devices in the system to function properly. Without IRQ Steering, Windows will begin to disable devices once it runs out of free IRQs to assign.

To determine if your system is using IRQ Steering, you can follow these steps:

1. Click Start, Settings, Control Panel, and then double-click System.
2. Click the Device Manager tab.
3. Double-click the System Devices branch.
4. Double-click PCI Bus, and then click the IRQ Steering tab. There will be a check; it will display IRQ Steering as either Enabled or Disabled. If enabled, it will also specify where the IRQ table has been read from.

IRQ Steering is controlled by one of four different routing tables that Windows attempts to read. Windows searches for the tables in order and uses the first one it finds. You cannot control the order in which Windows searches for these tables, but by selecting or deselecting the “Get IRQ table using...” check boxes, you can control which table Windows will find first by disabling the search for specific tables. Windows searches for the following tables:

- ACPI BIOS table
- MS Specification table
- Protected Mode PCIBIOS 2.1 table
- Real Mode PCIBIOS 2.1 table

Windows first tries to use the ACPI BIOS table to program IRQ Steering, followed by the MS Specification table, the Protected Mode PCIBIOS 2.1 table, and the Real Mode PCIBIOS 2.1 table. Windows 95 OSR2 and later versions only offer a choice for selecting the PCIBIOS 2.1 tables via a single check box, which is by default disabled. Under Windows 98, all IRQ table choices are selected by default, except the third one, which is the Protected Mode PCIBIOS 2.1 table.

If you are having a problem with a PCI device related to IRQ settings under Windows 95, try selecting the PCIBIOS 2.1 table and restarting. Under Windows 98, try clearing the ACPI BIOS table selection and restarting. If the problem persists, try selecting the Protected Mode PCIBIOS 2.1 table and restarting. You should only select “Get IRQ table from Protected Mode PCIBIOS 2.1 call” if a PCI device is not working properly.

If IRQ Steering is shown as disabled in Device Manager, make sure the “Use IRQ Steering” check box is selected. After selecting this and restarting, if IRQ Steering is still showing as disabled, the IRQ routing table that must be provided by the BIOS to the operating system may be missing or

contain errors. Check your BIOS setup to be sure PCI IRQ Steering is enabled. If there is still no success, you might have to select the “Get IRQ table from Protected Mode PCIBIOS 2.1 call” check box, or your BIOS does not support PCI bus IRQ Steering. Contact the manufacturer of your motherboard or BIOS to see if your board or BIOS supports IRQ Steering.

On systems that have support for IRQ Steering, an “IRQ Holder for PCI Steering” might be displayed when you view the System Devices branch of Device Manager. This indicates that an IRQ has been mapped to PCI and is unavailable for ISA devices, even if no PCI devices are currently using the IRQ. To view IRQs that are programmed for PCI-mode, follow these steps:

1. Click Start, Settings, Control Panel, and then double-click System.
2. Click the Device Manager tab.
3. Double-click the System Devices branch.
4. Double-click the IRQ Holder for PCI Steering you want to view, and then click the Resources tab.

I have found this interrupt steering or mapping to be the source of a great deal of confusion. Even though PCI interrupts (INTx#) can be (and are by default) shared, each card or device that might be sharing a PCI interrupt must be mapped or steered to a unique ISA IRQ, which in turn cannot normally be shared. It is only possible to have several PCI devices mapped to the same ISA IRQ if

- No ISA devices are using the IRQ.
- The BIOS and operating system support PCI IRQ Steering.
- PCI IRQ Steering is enabled.

Without PCI IRQ Steering support, the sharing capabilities of the PCI interrupts are of little benefit, because all PCI to ISA IRQ assignments must then be unique. Without PCI IRQ Steering, you can easily run out of available ISA interrupts. If IRQ Steering is supported and enabled, multiple PCI devices will be capable of sharing a single IRQ, allowing for more system expansion without running out of available IRQs. Better support for IRQ Steering is one of the best reasons for upgrading to Windows 98, especially if you are using the original OSR1 release of 95.

Another source of confusion is that the interrupt listing shown in the Windows Device Manager may show the PCI to ISA interrupt mapping as multiple entries for a given ISA interrupt. One entry would be for the device actually mapped to the interrupt, for example a built-in USB controller, while the other entry for the same IRQ will say *IRQ Holder for PCI Steering*. This latter entry, even though claiming to use the same IRQ, does not indicate a resource conflict; instead it represents the chipset circuitry putting a reservation on that interrupt for mapping purposes. This is part of the plug-and-play capabilities of PCI and the modern motherboard chipsets.

Note that it is possible to have internal devices on the PCI bus even though all the PCI slots are free. For example, most systems today have two IDE controllers and a USB controller as devices on the PCI bus. Normally, the PCI IDE controllers are mapped to ISA interrupts 14 (primary IDE) and 15 (secondary IDE), while the USB controller can be mapped to the normally available ISA interrupts 9, 10, 11, or 5.

▶▶ See “USB (Universal Serial Bus)” p. 892.

The PCI bus allows two types of devices to exist, called *bus masters* (initiators) or *slaves* (targets). A bus master is a device that can take control of the bus and initiate a transfer. The target device is the intended destination of the transfer. Most PCI devices can act as both masters and targets, and to be compliant with the PC 97 and newer system design guides, all PCI slots must support bus master cards.

The PCI bus is an arbitrated bus. This means that a central arbiter (part of the PCI bus controller in the motherboard chipset) governs all bus transfers, giving fair and controlled access to all the devices on the bus. Before a master can use the bus, it must first request control from the central arbiter, and then it is only granted control for a specified maximum number of cycles. This arbitration allows equal and fair access to all the bus master devices, prevents a single device from hogging the bus, and also prevents deadlocks because of simultaneous multiple device access. In this manner, the PCI bus acts much like a local area network (LAN), albeit one that is contained entirely within the system and runs at a much higher speed than conventional external networks between PCs.

IRQ Conflicts

Perhaps the most common IRQ conflict is the one between the integrated COM2: port found in most modern motherboards and an internal (card-based) modem. The problem stems from the fact that true PC card-based modems (not the so-called WinModems, which are software based) incorporate a serial port as part of the card's circuitry. This serial port is set as COM2: by default. Your PC sees this as having two COM2: ports, each using the same IRQ and I/O port address resources.

The solution to this problem is easy: Enter the system BIOS Setup and disable the built-in COM2: port in the system. While you are there, you might think about disabling the COM1: port also, because it is unlikely that you are using it. Disabling unused COMx: ports is one of the best ways to free up a couple of IRQs for other devices to use.

Another common IRQ conflict involves serial (COM) ports. You may have noticed in the preceding two sections that two IRQs are set aside for two COM ports. IRQ 3 is used for COM2:, and IRQ 4 is used for COM1:. The problem occurs when you have more than two serial ports in a system. When people add COM3: and COM4: ports, they often don't set them to non-conflicting interrupts, and the result is a conflict and the ports don't work.

Contributing to the problem are poorly designed COM port boards that do not allow IRQ settings other than 3 or 4. What happens is that they end up setting COM3: to IRQ 4 (sharing it with COM1:), and COM4: to IRQ 3 (sharing it with COM2:). This is not acceptable, as it will prevent you from using the two COM ports on any one of the interrupt channels simultaneously. This was somewhat acceptable under plain DOS, because single-tasking (running only one program at a time) was the order of the day, but is totally unacceptable with Windows and OS/2. If you must share IRQs, you can usually get away with sharing devices on the same IRQ as long as they use different COM ports. For instance, a scanner and an internal modem could share an IRQ, although if the two devices are used simultaneously, a conflict will result.

The best solution is to purchase a multiport serial I/O card that will allow non-conflicting interrupt settings, or an intelligent card with its own processor that can handle the multiple ports on-board and only use one interrupt in the system.

▶▶ See “Serial Ports” p. 872.

If a device listed in the table is not present, such as the motherboard mouse port (IRQ 12) or parallel port 2 (IRQ 5), you can consider those interrupts as available. For example, a second parallel port is a rarity, and most systems will have a sound card installed and set for IRQ 5. Also, on most systems IRQ 15 is assigned to a secondary IDE controller. If you do not have a second IDE hard drive, you could disable the secondary IDE controller to free up that IRQ for another device.

Note that an easy way to check your interrupt settings is to use the Device Manager in Windows 95/98, NT, or Windows 2000. By double-clicking on the Computer Properties icon in the Device Manager, you can get concise lists of all used system resources. Microsoft has also included a program called HWDIAG on Windows 95B and newer versions, which does an excellent job of reporting system resource usage.

DMA Channels

DMA (Direct Memory Access) channels are used by high-speed communications devices that must send and receive information at high speed. A serial or parallel port does not use a DMA channel, but a sound card or SCSI adapter often does. DMA channels sometimes can be shared if the devices are not the type that would need them simultaneously. For example, you can have a network adapter and a tape backup adapter sharing DMA channel 1, but you cannot back up while the network is running. To back up during network operation, you must ensure that each adapter uses a unique DMA channel.

8-Bit ISA Bus DMA Channels

In the 8-bit ISA bus, four DMA channels support high-speed data transfers between I/O devices and memory. Three of the channels are available to the expansion slots. Table 4.32 shows the typical uses of these DMA channels.

Table 4.32 8-Bit ISA Default DMA-Channel Assignments

DMA	Standard Function	Bus Slot
0	Dynamic RAM Refresh	No
1	Available	Yes (8-bit)
2	Floppy disk controller	Yes (8-bit)
3	Hard disk controller	Yes (8-bit)

Because most systems typically have both a floppy and hard disk drive, only one DMA channel is available in 8-bit ISA systems.

16-Bit ISA DMA Channels

Since the introduction of the 286 CPU, the ISA bus has supported eight DMA channels, with seven channels available to the expansion slots. Like the expanded IRQ lines described earlier in this chapter, the added DMA channels were created by cascading a second DMA controller to the first one. DMA channel 4 is used to cascade channels 0–3 to the microprocessor. Channels 0–3 are available for 8-bit transfers, and channels 5–7 are for 16-bit transfers only. Table 4.33 shows the typical uses for the DMA channels.

Table 4.33 16/32-Bit ISA/PCI Default DMA-Channel Assignments

DMA	Standard Function	Bus Slot	Card Type	Transfer	Recommended Use
0	Available	Yes	16-bit	8-bit	Integrated Sound
1	Available	Yes	8/16-bit	8-bit	8-bit Sound
2	Floppy Disk Controller	Yes	8/16-bit	8-bit	Floppy Controller
3	Available	Yes	8/16-bit	8-bit	LPT1: in ECP Mode
4	1st DMA Controller Cascade	No	-	16-bit	
5	Available	Yes	16-bit	16-bit	16-bit Sound
6	Available	Yes	16-bit	16-bit	ISA SCSI Adapter
7	Available	Yes	16-bit	16-bit	Available

Note that PCI adapters don't use these ISA DMA channels these are only for ISA cards.

The only standard DMA channel used in all systems is DMA 2, which is universally used by the floppy controller. DMA 4 is not usable and does not appear in the bus slots. DMA channels 1 and 5 are most commonly used by ISA sound cards such as the Sound Blaster 16. These cards use both an 8- and a 16-bit DMA channel for high-speed transfers.

Note

Although DMA channel 0 appears in a 16-bit slot connector extension and therefore can only be used by a 16-bit card, it only does 8-bit transfers! Because of this, you will generally not see DMA 0 as a choice on 16-bit cards. Most 16-bit cards (such as SCSI host adapters) that use DMA channels have their choices limited to DMA 5–7.

EISA

Realizing the shortcomings inherent in the way DMA channels are implemented in the ISA bus, the creators of the EISA specification created a specific DMA controller for their new bus. They increased the number of address lines to include the entire address bus, thus allowing transfers anywhere within the address space of the system. Each DMA channel can be set to run 8-, 16-, or 32-bit transfers. In addition, each DMA channel can be separately programmed to run any of four types of bus cycles when transferring data:

- *Compatible*. This transfer method is included to match the same DMA timing as used in the ISA bus. This is done for compatibility reasons; all ISA cards can operate in an EISA system in this transfer mode.

- *Type A.* This transfer type compresses the DMA timing by 25 percent over the Compatible method. It was designed to run with most (but not all) ISA cards and still yield a speed increase.
- *Type B.* This transfer type compresses timing by 50 percent over the Compatible method. Using this method, most EISA cards function properly, but only a few ISA cards will be problem-free.
- *Type C.* This transfer method compresses timing by 87.5 percent over the Compatible method; it is the fastest DMA transfer method available under the EISA specification. No ISA cards will work using this transfer method.

EISA DMA also allows for special reading and writing operations referred to as *scatter write* and *gather read*. Scattered writes are done by reading a contiguous block of data and writing it to more than one area of memory at the same time. Gathered reads involve reading from more than one place in memory and writing to a device. These functions are often referred to as *buffered chaining*, and they increase the throughput of DMA operations.

MCA

It might be assumed that because MCA is a complete rebuilding of the PC bus structure that DMA in an MCA environment would be better constructed. This is not so. Quite the contrary, DMA in MCA systems were for the most part all designed around one DMA controller with the following issues:

- It can only connect to two 8-bit data paths. This can only transfer one or two bytes per bus cycle.
- It is only connected to AO:A23 on the address bus. This means it can only make use of the lower 16MB of memory.
- Runs at 10MHz.

The incapability of the DMA controller to address more than two bytes per transfer severely cripples this otherwise powerful bus.

I/O Port Addresses

Your computer's I/O ports enable communications between devices and software in your system. They are equivalent to two-way radio channels. If you want to talk to your serial port, you need to know what I/O port (radio channel) it is listening on. Similarly, if you want to receive data from the serial port, you need to listen on the same channel it is transmitting on.

Unlike IRQs and DMA channels, we have an abundance of I/O ports in our systems. There are 65,535 ports to be exact—numbered from 0000h to FFFFh—and this is an artifact of the Intel processor design more than anything else. Even though most devices use up to eight ports for themselves, with that many to spare, we aren't going to run out anytime soon. The biggest problem you have to worry about is setting two devices to use the same port.

Most modern plug-and-play systems will resolve any port conflicts and select alternative ports for one of the conflicting devices.

One confusing issue is that I/O ports are designated by hexadecimal addresses similar to memory addresses. They are not memory; they are ports. The difference is that when you send data to memory address 1000h, it gets stored in your SIMM or DIMM memory. If you send data to I/O port address 1000h, it gets sent out on the bus on that “channel” and anybody listening in would then “hear” it. If nobody was listening to that port address, the data would reach the end of the bus and be absorbed by the bus terminating resistors.

Driver programs are primarily what interact with devices at the different port addresses. The driver must know which ports the device is using to work with it, and vice versa. That is not usually a problem because the driver and device both come from the same company.

Motherboard and chipset devices are normally set to use I/O port addresses from 0h to FFh, and all other devices use from 100h to FFFFh. Table 4.34 shows the commonly used motherboard and chipset based I/O port usage:

Table 4.34 Motherboard and Chipset-based Device Port Addresses

Address (hex)	Size	Description
0000 - 000F	16 bytes	Chipset - 8237 DMA 1
0020 - 0021	2 bytes	Chipset - 8259 interrupt controller 1
002E - 002F	2 bytes	Super I/O controller Configuration registers
0040 - 0043	4 bytes	Chipset - Counter/Timer 1
0048 - 004B	4 bytes	Chipset - Counter/Timer 2
0060	1 byte	Keyboard/Mouse controller byte - reset IRQ
0061	1 byte	Chipset - NMI, speaker control
0064	1 byte	Keyboard/Mouse Controller, CMD/STAT Byte
0070, bit 7	1 bit	Chipset - Enable NMI
0070, bits 6:0	7 bits	MC146818 - Real-time clock, Address
0071	1 byte	MC146818 - Real-time clock, Data
0078	1 byte	Reserved - Board configuration
0079	1 byte	Reserved - Board configuration
0080 - 008F	16 bytes	Chipset - DMA page registers
00A0 - 00A1	2 bytes	Chipset - 8259 interrupt controller 2
00B2	1 byte	APM control port
00B3	1 byte	APM status port
00C0 - 00DE	31 bytes	Chipset - 8237 DMA 2
00F0	1 byte	Math Coprocessor Reset Numeric Error

To find out exactly what port addresses are being used on your motherboard, consult the board documentation or look these settings up in the Windows Device Manager.

Bus-based devices normally use the addresses from 100h on up. Table 4.35 lists the commonly used bus-based device addresses and some common adapter cards and their settings:

Table 4.35 Bus-based Device Port Addresses

Address (hex)	Size	Description
0130 - 0133	4 bytes	Adaptec SCSI adapter (alternate)
0134 - 0137	4 bytes	Adaptec SCSI adapter (alternate)
0168 - 016F	8 bytes	Fourth IDE interface
0170 - 0177	8 bytes	Secondary IDE interface
01E8 - 01EF	8 bytes	Third IDE interface
01F0 - 01F7	8 bytes	Primary IDE / AT (16-bit) Hard Disk Controller
0200 - 0207	8 bytes	Gameport or Joystick adapter
0210 - 0217	8 bytes	IBM XT expansion chassis
0220 - 0233	20 bytes	Creative Labs Sound Blaster 16 audio (default)
0230 - 0233	4 bytes	Adaptec SCSI adapter (alternate)
0234 - 0237	4 bytes	Adaptec SCSI adapter (alternate)
0238 - 023B	4 bytes	MS bus mouse (alternate)
023C - 023F	4 bytes	MS bus mouse (default)
0240 - 024F	16 bytes	SMC Ethernet adapter (default)
0240 - 0253	20 bytes	Creative Labs Sound Blaster 16 audio (alternate)
0258 - 025F	8 bytes	Intel above board
0260 - 026F	16 bytes	SMC Ethernet adapter (alternate)
0260 - 0273	20 bytes	Creative Labs Sound Blaster 16 audio (alternate)
0270 - 0273	4 bytes	Plug-and-Play I/O read ports
0278 - 027F	8 bytes	Parallel Port 2 (LPT2)
0280 - 028F	16 bytes	SMC Ethernet adapter (alternate)
0280 - 0293	20 bytes	Creative Labs Sound Blaster 16 audio (alternate)
02A0 - 02AF	16 bytes	SMC Ethernet adapter (alternate)
02C0 - 02CF	16 bytes	SMC Ethernet adapter (alternate)
02E0 - 02EF	16 bytes	SMC Ethernet adapter (alternate)
02E8 - 02EF	8 bytes	Serial Port 4 (COM4)
02EC - 02EF	4 bytes	Video, 8514 or ATI standard ports
02F8 - 02FF	8 bytes	Serial Port 2 (COM2)
0300 - 0301	2 bytes	MPU-401 MIDI Port (secondary)
0300 - 030F	16 bytes	SMC Ethernet adapter (alternate)
0320 - 0323	4 bytes	XT (8-bit) hard disk controller
0320 - 032F	16 bytes	SMC Ethernet adapter (alternate)
0330 - 0331	2 bytes	MPU-401 MIDI port (default)
0330 - 0333	4 bytes	Adaptec SCSI adapter (default)
0334 - 0337	4 bytes	Adaptec SCSI adapter (alternate)
0340 - 034F	16 bytes	SMC Ethernet adapter (alternate)
0360 - 036F	16 bytes	SMC Ethernet adapter (alternate)
0366	1 byte	Fourth IDE command port
0367, bits 6:0	7 bits	Fourth IDE status port

Address (hex)	Size	Description
0370 - 0375	6 bytes	Secondary floppy controller
0376	1 byte	Secondary IDE command port
0377, bit 7	1 bit	Secondary floppy controller Disk Change
0377, bits 6:0	7 bits	Secondary IDE status port
0378 - 037F	8 bytes	Parallel Port 1 (LPT1)
0380 - 038F	16 bytes	SMC Ethernet adapter (alternate)
0388 - 038B	4 bytes	Audio - FM synthesizer
03B0 - 03BB	12 bytes	Video, Mono/EGA/VGA standard ports
03BC - 03BF	4 bytes	Parallel Port 1 (LPT1) in some systems
03BC - 03BF	4 bytes	Parallel Port 3 (LPT3)
03C0 - 03CF	16 bytes	Video, EGA/VGA standard ports
03D0 - 03DF	16 bytes	Video, CGA/EGA/VGA standard ports
03E6	1 byte	Third IDE command port
03E7, bits 6:0	7 bits	Third IDE status port
03E8 - 03EF	8 bytes	Serial Port 3 (COM3)
03F0 - 03F5	6 bytes	Primary floppy controller
03F6	1 byte	Primary IDE command port
03F7, bit 7	1 bit	Primary Floppy controller disk Change
03F7, bits 6:0	7 bits	Primary IDE status port
03F8 - 03FF	8 bytes	Serial Port 1 (COM1)
04D0 - 04D1	2 bytes	Edge/level triggered PCI interrupt controller
0530 - 0537	8 bytes	Windows sound system (default)
0604 - 060B	8 bytes	Windows sound system (alternate)
0678 - 067F	8 bytes	LPT2 in ECP mode
0778 - 077F	8 bytes	LPT1 in ECP mode
0A20 - 0A23	4 bytes	IBM Token-Ring adapter (default)
0A24 - 0A27	4 bytes	IBM Token-Ring adapter (alternate)
OCF8 - OCFB	4 bytes	PCI Configuration address Registers
OCF9	1 byte	Turbo and Reset control register
OCFC - OCFF	4 bytes	PCI configuration data registers
FF00 - FF07	8 bytes	IDE bus master registers
FF80 - FF9F	32 bytes	Universal Serial Bus (USB)
FFA0 - FFA7	8 bytes	Primary bus master IDE registers
FFA8 - FFAF	8 bytes	Secondary bus master IDE registers

To find out exactly what your devices are using, again I recommend consulting the documentation for the device or looking the device up in the Windows Device Manager.

Virtually all devices on your system buses use I/O port addresses. Most of these are fairly standardized, meaning you won't often have conflicts or problems with these settings. In the next section, you learn more about working with I/O addresses.

Resolving Resource Conflicts

The resources in a system are limited. Unfortunately, the demands on those resources seem to be unlimited. As you add more and more adapter cards to your system, you will find that the potential for resource conflicts increases. If your system is fully PnP-compatible, potential conflicts should be resolved automatically.

How do you know whether you have a resource conflict? Typically, one of the devices in your system stops working. Resource conflicts can exhibit themselves in other ways, though. Any of the following events could be diagnosed as a resource conflict:

- A device transfers data inaccurately.
- Your system frequently locks up.
- Your sound card doesn't sound quite right.
- Your mouse doesn't work.
- Garbage appears on your video screen for no apparent reason.
- Your printer prints gibberish.
- You cannot format a floppy disk.
- The PC starts in Safe mode (Windows 95).

Windows 9x and Windows 2000 will also show conflicts by highlighting a device in yellow or red in the Device Manager representation. By using the Windows Device Manager, you can usually spot the conflicts quickly.

In the following sections, you learn some of the steps that you can take to head off resource conflicts or track them down when they occur.

Caution

Be careful in diagnosing resource conflicts; a problem might not be a resource conflict at all, but a computer virus. Many computer viruses are designed to exhibit themselves as glitches or periodic problems. If you suspect a resource conflict, it may be worthwhile to run a virus check first to ensure that the system is clean. This procedure could save you hours of work and frustration.

Resolving Conflicts Manually

Unfortunately, the only way to resolve conflicts manually is to take the cover off your system and start changing switches or jumper settings on your adapter cards. Each of these changes then must be accompanied by a system reboot, which implies that they take a great deal of time. This situation brings us to the first rule of resolving conflicts: When you set about ridding your system of resource conflicts, make sure that you allow a good deal of uninterrupted time.

Also make sure that you write down your current system settings before you start making changes. That way, you will know where you began and can go back to the original configuration (if necessary).

Finally, dig out the manuals for all your adapter boards; you will need them. If you cannot find the manuals, contact the manufacturers to determine what the various jumper positions and switch settings mean. Additionally, you could look for more current information online at the manufacturers' Web sites.

Now you are ready to begin your detective work. As you try various switch settings and jumper positions, keep the following questions in mind; the answers will help you narrow down the conflict areas:

- *When did the conflict first become apparent?* If the conflict occurred after you installed a new adapter card, that new card probably is causing the conflict. If the conflict occurred after you started using new software, chances are good that the software uses a device that is taxing your system's resources in a new way.
- *Are there two similar devices in your system that do not work?* For example, if your modem, integrated serial ports, or mouse—devices that use a COM port—do not work, chances are good that these devices are conflicting with each other.
- *Have other people had the same problem, and if so, how did they resolve it?* Public forums—such as those on CompuServe, Internet newsgroups, and America Online—are great places to find other users who might be able to help you solve the conflict.

Whenever you make changes in your system, reboot and see whether the problem persists. When you believe that you have solved the problem, make sure that you test all your software. Fixing one problem often seems to cause another to crop up. The only way to make sure that all problems are resolved is to test everything in your system.

One of the best pieces of advice I can give you is to try changing one thing at a time, and then retest. That is the most methodical and simplest way to isolate a problem quickly and efficiently.

As you attempt to resolve your resource conflicts, you should work with and update a system-configuration template, as discussed in the following section.

Using a System-Configuration Template

A *system-configuration template* is helpful, because it is easier to remember something that is written down than it is to keep it in your head. To create a configuration template, you need to start writing down what resources are used by which parts of your system. Then, when you need to make a change or add an adapter, you can quickly determine where conflicts may arise. You can also use the Windows 95/98 or NT 5.0+ Device Manager to list and print this information.

I like to use a worksheet split into three main areas—one for interrupts, another for DMA channels, and a middle area for devices that do not use interrupts. Each section lists the IRQ or DMA channel on the left and the I/O port device range on the right. This way, you get the clearest picture of what resources are used and which ones are available in a given system.

Here is the system-configuration template I have developed over the years and still use almost daily:

This type of configuration sheet is resource-based instead of component-based. Each row in the template represents a different resource, and lists the component using the resource as well as the resources used. The chart has pre-entered all the fixed items in a modern PC whose configuration cannot be changed.

To fill out this type of chart, you would perform the following steps:

1. Enter the default resources used by standard components, such as serial and parallel ports, disk controllers, and video. You can use the filled out example I have provided to see how most standard devices are configured.
2. Enter the default resources used by additional add-on components such as sound cards, SCSI cards, network cards, proprietary cards, and so on.
3. Change any configuration items that are in conflict. Try to leave built-in devices at their default settings, as well as sound cards. Other installed adapters may have their settings changed, but be sure to document the changes.

Of course, a template like this is best used when first installing components, not after. Once you have it completely filled out to match your system, you can label it and keep it with the system. When you add any more devices, the template will be your guide as to how any new devices should be configured.

The following example is the same template filled out for a typical modern PC system:

System Resource Map

PC Make and Model: _____

Serial Number: _____

7 - _____

*Represents a resource setting that had to be changed to resolve a conflict.

As you can see from this template, only one IRQ and two DMA channels remain available, and that would be *no* IRQs if I enable the USB on the motherboard! As you can see, interrupt shortages are a big problem in modern systems. In that case I would probably find a way to recover one of the other interrupts, for example I am not really using COM1, so I could disable that port and gain back IRQ 4. In this sample configuration, the primary and secondary IDE connectors were built into the motherboard:

- Floppy controller
- Two serial ports
- One parallel port

Whether these devices are built into the motherboard or on a separate card makes no difference because the resource allocations are the same in either case. All default settings are normally used for these devices, and are indicated in the completed configuration. Next, the accessory cards were configured. In this example, the following cards were installed:

- SVGA video card (ATI Mach 64)
- Sound card (Creative Labs Sound Blaster 16)
- SCSI host adapter (Adaptec AHA-1542CF)
- Network interface card (SMC EtherEZ)

It helps to install the cards in this order. Start with the video card; next, add the sound card. Due to problems with software that must be configured to the sound card, it is best to install it early and make sure only default settings are used. It is better to change settings on other cards than the sound card.

After the sound card, the SCSI adapter was installed; however, the default I/O port addresses (330-331) and DMA channel (DMA 5) used were in conflict with other cards (mainly the sound card). These settings were changed to their next logical settings that did not cause a conflict.

Finally, the network card was installed, which also had default settings that conflicted with other cards. In this case, the Ethernet card came preconfigured to IRQ 3, which was already in use by COM2:. The solution was to change the setting, and IRQ 9 was the next logical choice in the card's configuration settings.

Even though this is a fully loaded configuration, only three individual items among all the cards had to be changed to achieve an optimum system configuration. As you can see, using a configuration template like the one shown can make what would otherwise be a jumble of settings lay out in an easy-to-follow manner. The only real problems you will run into once you work with these templates are cards that do not allow for enough adjustment in their settings, or cards which are lacking in documentation. As you can imagine, you will need the documentation for each adapter card, as well as the motherboard, in order to accurately complete a configuration table like the one shown.

Tip

Do not rely too much on third-party software diagnostics such as MSD.EXE, which claim to be capable of showing hardware settings such as IRQ and I/O port settings. While they can be helpful in certain situations, they are often wrong with respect to at least some of the information they are displaying about your system. One or two items shown incorrectly can be very troublesome if you believe the incorrect information and configure your system based on it!

A much better utility to view these settings is the Device Manager built-in to Windows 95/98 and Windows NT and Windows 2000. On a plug-and-play system, it will not only report settings, but allow you to change them. On older legacy hardware, you will be able to view the settings but not change them. To change the settings of legacy (non-plug and play) hardware, you'll have to manually move jumpers or switches and run the special configuration software that came with the card. Consult the card manufacturer or documentation for more information.

Heading Off Problems: Special Boards

A number of devices that you might want to install in a computer system require IRQ lines or DMA channels, which means that a world of conflict could be waiting in the box that the device comes in. As mentioned in the preceding section, you can save yourself problems if you use a system-configuration template to keep track of the way that your system is configured.

You also can save yourself trouble by carefully reading the documentation for a new adapter board before you attempt to install it. The documentation details the IRQ lines that the board can use as well as its DMA-channel requirements. In addition, the documentation will detail the adapter's upper-memory needs for ROM and adapter.

The following sections describe some of the conflicts that you may encounter when you install today's most popular adapter boards. Although the list of adapter boards covered in these sections is far from comprehensive, the sections serve as a guide to installing complex hardware with minimum hassle. Included are tips on soundboards, SCSI host adapters, and network adapters.

Soundboards

Sound cards are probably the biggest single resource hog in your system. They usually use at least one IRQ, two DMA channels, and multiple I/O port address ranges. This is because a sound card is actually several different pieces of hardware all on one board. Most sound cards are similar to the Sound Blaster 16 from Creative Labs.

Figure 4.52 shows the default resources used by the components on a typical Sound Blaster 16 card.

As you can see, these cards use quite a few resources. If you take the time to read your soundboard's documentation and determine its communications-channel needs, compare those needs to the IRQ lines and DMA channels that already are in use in your system, and then change the settings of the other adapters to avoid conflicts with the sound card, your installation will go quickly and smoothly.

Device	Interrupt	I/O Ports	16-bit DMA	8-bit DMA
Audio	IRQ5	220h-233h	DMA 5	DMA 1

Device	Interrupt
MIDI Port	330h-331h
FM Synthesizer	388h-38Bh
Game Port	200h-207h

Figure 4.52 Default resources for Sound Blaster 16 card.

Tip

The greatest single piece of advice I can give you for installing a sound card is to put the sound card in before all other cards—except for video. In other words, let the sound card retain all its default settings; never change a resource setting to prevent a conflict. Instead, always change the settings of other adapters when a conflict with the sound card arises. The problem here is that many educational and game programs that use sound are very poorly written with respect to supporting alternative resource settings on sound cards. Save yourself some grief, and let the sound card have its way!

One example of a potential soundboard conflict is the combination of a Sound Blaster 16 and an Adaptec SCSI adapter. The Sound and SCSI adapters will conflict on DMA 5 as well as on I/O ports 330-331. Rather than changing the settings of the sound card, it is best to alter the SCSI adapter to the next available settings that will not conflict with the sound card or anything else. The final settings are shown in the previous configuration template.

The cards in question (Sound Blaster 16 and AHA-1542CF) are not singled out here because there is something wrong with them, but instead because they happen to be the most popular cards of their respective types, and as such will often be paired together.

Most people would be using PCI versions of these cards today, but they will still require the same types of resource settings with the only exception being DMA channels. Unfortunately it wasn't DMA channels that we were really running out of! The interrupt shortage continues even with PCI cards because they must be mapped to ISA IRQs. The real solution will be in a year or so when we start to see a new breed of PC that lacks any ISA slots and which breaks ties with that bus forever. When that happens, we will be free of the interrupt restrictions we have been on for so many years.

Tip

The newer PCI sound cards are largely incompatible with older DOS-based software because they don't use DMA channels like their ISA counterparts. Either update your software to 32-bit Windows versions or you won't be able to use these newer PCI bus sound cards. Most of the newer PCI cards do include an emulation program that allows the card to work with older DMA dependent software, but the results are often problematic.

SCSI Adapter Boards

SCSI adapter boards use more resources than just about any other type of add-in device except perhaps a sound card. They will often use resources that are in conflict with sound cards or network cards. A typical SCSI host adapter requires an IRQ line, a DMA channel, a range of I/O port addresses, plus a 16KB range of unused upper memory for its ROM and possible scratch-pad RAM use. Fortunately, the typical SCSI adapter is also easy to reconfigure, and changing any of these settings should not affect performance or software operation.

Before installing a SCSI adapter, be sure to read the documentation for the card, and make sure that any IRQ lines, DMA channels, I/O ports, and upper memory that the card needs are available. If the system resources that the card needs are already in use, use your system-configuration template to determine how you can alter the settings on the SCSI card or other cards to prevent any resource conflicts before you attempt to plug in the adapter card.

Network Interface Cards (NICs)

Networks are becoming more and more popular all the time. A typical network adapter does not require as many resources as some of the other cards discussed here, but will require at least a range of I/O port addresses and an interrupt. Most NICs will also require a 16KB range of free upper memory to be used for the RAM transfer buffer on the network card. As with any other cards, make sure that all these resources are unique to the card and are not shared with any other devices.

Multiple-COM-Port Adapters

A serial port adapter usually has two or more ports on-board. These COM ports require an interrupt and a range of I/O ports each. There aren't too many problems with the I/O port addresses, because the ranges used by up to four COM ports in a system are fairly well defined. The real problem is with the interrupts. Most older installations of more than two serial ports have any additional ones sharing the same interrupts as the first two. This is incorrect, and will cause nothing but problems with software that runs under Windows or OS/2. With these older boards, make sure that each serial port in your system has a unique I/O port address range, and more importantly, a unique interrupt setting.

Because COM ports are required for so many peripherals that connect to the modern PC, and because the number of COM ports that can be used is strictly limited by the IRQ setup in the basic IBM system design, special COM-port cards are available that enable you to assign a unique IRQ to each of the COM ports on the card. For example, you can use such a card to leave COM1: and COM2: configured for IRQ 4 and IRQ 3, respectively, but to configure COM3: for IRQ 10 and COM4: for IRQ 12 (provided you do not have a motherboard-based mouse port in your system).

Many newer multiport adapter cards—such as those offered by Byte Runner Technologies—allow “intelligent” interrupt sharing among ports. In some cases, you can have up to 12 COM port settings without conflict problems. Check with your adapter card's manufacturer to determine if it allows for automatic or “intelligent” interrupt sharing.

Although most people have problems incorrectly trying to share interrupts when installing more than two serial ports in a system, there is a fairly common problem with the I/O port addressing that should be mentioned. Many of the high-performance video chipsets, such as those from S3 Inc. and ATI, use some additional I/O port addresses that will conflict with the standard I/O port addresses used by COM4:

In the example system-configuration just covered, you can see that the ATI video card uses some additional I/O port addresses, specifically 2EC-2EF. This is a problem because COM4: is normally configured as 2E8-2EF, which overlaps with the video card. The video cards that use these addresses are not normally adjustable for this setting, so you will either have to change the address of COM4: to a nonstandard setting or disable COM4: and restrict yourself to using only three serial ports in the system. If you do have a serial adapter that supports nonstandard I/O address settings for the serial ports, you must ensure that those settings are not used by other cards, and you must inform any software or drivers, such as those in Windows, of your nonstandard settings.

With a multiple-COM-port adapter card installed and properly configured for your system, you can have devices hooked to numerous COM ports, and up to four devices can be functioning at the same time. For example, you can use a mouse, modem, plotter, and serial printer at the same time.

USB (Universal Serial Bus)

USB ports are now found on most motherboards, and with Windows 98 we finally have an operating system that will properly support them. One problem is that USB will take another interrupt from your system, and many computers either don't have any free or are down to their last one. If your system supports PCI IRQ Steering, this shouldn't be much of a problem because IRQ should be sharable with other PCI devices. If you are out of interrupts, you should look at what other devices you can disable (such as COM or LPT ports) in order to gain back a necessary interrupt for other devices.

The big advantage of USB from an IRQ or resource perspective is that the USB bus uses only one IRQ no matter how many devices (up to 127) are attached. This means you can freely add or remove devices from the USB without worrying about running out of resources or having resource conflicts.

If you aren't using any USB devices, you should turn off the port using your motherboard CMOS setup so that the IRQ it was using will be freed. In the future, as we move to USB-based keyboards, mice, modems, printers, etc., the IRQ shortage will be less of a problem. Also the elimination of the ISA bus in our systems will go a long way to solve this problem as well.

Miscellaneous Boards

Some video cards ship with advanced software that allows special video features such as oversized desktops, custom monitors, switch modes on-the-fly, and so on. Unfortunately this software requires that the card be configured to use an interrupt. I suggest you dispense with this unnecessary software and configure the card to free up the interrupt for other devices.

Also related to video is the use of an MPEG decoder add-on card that works in addition to your normal graphics adapter. These are used more in specialized video production, editing, and in playing DVD movies, however, they do use additional system resources which must be available.

Plug-and-Play Systems

Plug and Play (PnP) represents a major revolution in recent interface technology. PnP first came on the market in 1995, and most new systems come ready to take advantage of it. In the past, PC users have been forced to muddle through a nightmare of dip switches and jumpers every time they wanted to add new devices to their systems. The results, all too often, were system resource conflicts and non-functioning cards.

PnP is not an entirely new concept. It was a key design feature of MCA and EISA interfaces, but the limited appeal of MCA and EISA meant that they never became industry standards. Therefore, mainstream PC users still worry about I/O addresses, DMA channels, and IRQ settings. But now that PnP specifications are available for ISA-, PCI-, SCSI-, IDE-, and PCMCIA-based systems, worry-free hardware setup is within the grasp of all new computer buyers.

Of course, PnP may well be within your grasp, but that does not necessarily mean you are ready to take advantage of it. For PnP to work, the following components are required:

- PnP hardware
- PnP BIOS
- PnP operating system (optional)

Each of these components needs to be PnP-compatible, meaning that it complies with the PnP specifications. The Plug-and-Play BIOS is covered in Chapter 5.

The Hardware Component

The *hardware component* refers to both computer systems and adapter cards. The term does not mean, however, that you cannot use your older ISA adapter cards (referred to as *legacy cards*) in a PnP system. You can use these cards; in fact, your PnP BIOS automatically reassigns PnP-compatible cards around existing legacy components.

PnP adapter cards communicate with the system BIOS and the operating system to convey information about what system resources are needed. The BIOS and operating system, in turn, resolve conflicts (wherever possible) and inform the adapter cards which specific resources it should use. The adapter card then can modify its configuration to use the specified resources.

The BIOS Component

The BIOS component means that most users of older PCs need to update their BIOSes or purchase new machines that have PnP BIOSes. For a BIOS to be compatible, it must support 13 additional system function calls, which can be used by the OS component of a PnP system. The PnP BIOS specification was developed jointly by Compaq, Intel, and Phoenix Technologies.

The PnP features of the BIOS are implemented through an expanded POST. The BIOS is responsible for identification, isolation, and possible configuration of PnP adapter cards. The BIOS accomplishes these tasks by performing the following steps:

1. Disables any configurable devices on the motherboard or on adapter cards.
2. Identifies any PnP PCI or ISA devices.
3. Compiles an initial resource-allocation map for ports, IRQs, DMAs, and memory.
4. Enables I/O devices.
5. Scans the ROMs of ISA devices.
6. Configures initial program-load (IPL) devices, which are used later to boot the system.
7. Enables configurable devices by informing them which resources have been assigned to them.
8. Starts the bootstrap loader.
9. Transfers control to the operating system.

The Operating System Component

The operating system component can be implemented by most newer systems, such as OS/2, Windows 95, Windows 98, or DOS extensions. Extensions of this type should be familiar to most DOS users; extensions have been used for years to provide support for CD-ROM drives. Extension software is available now for existing operating systems, and you can expect all new PC operating systems to have PnP support built in. If you are using Windows NT 4.0, PnP drivers may have been loaded automatically. If not, the driver can be found on the Windows NT 4.0 CD in the `DRVLIB\PNPISA\` directory. Open the correct subdirectory for your chipset and install the file `PNPISA.INF`. Windows 2000 has full support for PnP built-in.

It is the responsibility of the operating system to inform users of conflicts that cannot be resolved by the BIOS. Depending on the sophistication of the operating system, the user then could configure the offending cards manually (onscreen) or turn the system off and set switches on the physical cards. When the system is restarted, the system is checked for remaining (or new) conflicts, any of which are brought to the user's attention. Through this repetitive process, all system conflicts are resolved.

Note

Plug and Play is still going through some revisions. Windows 95 requires at least version 1.0a of the ISA PnP BIOS. If your system does not have the most current BIOS, I suggest you install a BIOS upgrade. With the Flash ROM used in most PnP systems, you can download the new BIOS image from the system vendor or manufacturer and run the supplied BIOS update program.

Knowing What to Look For (Selection Criteria)

As a consultant, I am often asked to make a recommendation for purchases. Making these types of recommendations is one of the most frequent tasks a consultant performs. Many consultants charge a large fee for this advice. Without guidance, many individuals don't have any rhyme or reason to their selections and instead base their choices solely on magazine reviews or, even worse, on some personal bias. To help eliminate this haphazard selection process, I have developed a simple checklist that will help you select a system. This list takes into consideration several important system aspects overlooked by most checklists. The goal is to ensure that the selected system truly is compatible and has a long life of service and upgrades ahead.

It helps to think like an engineer when you make your selection. Consider every aspect and detail of the motherboards in question. For instance, you should consider any future uses and upgrades. Technical support at a professional (as opposed to a user) level is extremely important. What support will be provided? Is there documentation, and does it cover everything else?

In short, a checklist is a good idea. Here is one for you to use in evaluating any PC-compatible system. You might not have to meet every one of these criteria to consider a particular system, but if you miss more than a few, consider staying away from that system. The items at the top of the list are the most important, and the items at the bottom are perhaps of lesser importance (although I think each item is important). The rest of this chapter discusses in detail the criteria in this checklist:

- *Processor.* A modern Pentium-class motherboard should use as a minimum the Pentium MMX processor, which requires a Socket 7 type socket for the processor to plug into. Even better would be a board incorporating the 100MHz Super-7 standard developed by AMD and Cyrix for their newest Socket 7 processors such as the AMD K6-3. There should also be a built-in adjustable voltage regulator allowing for different voltage CPUs to be accommodated without purchasing an additional regulator module. For even more performance, I recommend a motherboard that supports the Slot 1 or Socket 370 design. Slot 1 boards will allow you to use any Celeron, Pentium II, or Pentium III processor and are the most powerful and flexible boards around. Socket 370 boards can only use the socketed Celeron processors for now and are good for lower end systems.

The lowest cost PII/III class processor is the Celeron introduced by Intel in mid-1998. This is a PII processor originally without the level 2 cache, but later incorporating a full-core speed L2 cache that actually makes it faster than a regular Pentium II for much less cost. The Celeron has turned out to be a real performance bargain because of this improved L2 cache design, where the cache is integrated directly on the processor die. All Pentium Pro motherboards use Socket 8, and all non-server Pentium II/III systems use Slot 1 in which to install the processor.

- *Processor Sockets.* A Pentium motherboard should have at least one ZIF socket that follows the Intel Socket 7 (321-pin) specification. The Socket 7 with a built-in VRM (Voltage Regulator Module) rather than a socket for one that plugs in is best. This is because if you change the processor later, the built-in VRM can be reconfigured with jumpers, while if you have only a VRM socket, you will have to purchase a new VRM to go with each new voltage processor you try.

Pentium Pro (P6) motherboards use Socket 8, and many are set up for multiple processors. Pentium II/III boards use either Slot 1 or Slot 2. The Slot 1 systems are for normal use, while Slot 2 systems are only for the higher end Pentium II/III Xeon server processors. There are Slot 1 and Slot 2 boards available with multiple processor sockets. Before going to the expense of buying a multiprocessor board, ensure that your operating system is capable of handling it. For instance, while Windows 95 or 98 cannot really benefit from more than one CPU, Windows NT/2000, OS/2, and some others may run considerably faster.

- **Motherboard Speed.** A Pentium or Pentium Pro motherboard should run at 66MHz minimum, some can be set to an overclocked (but often fully functional) speed of 75MHz. Pentium II/III motherboards are available to run at either 66MHz or 100MHz, and up to 133MHz for the newer boards. Notice that all the Pentium processors sold today run at a multiple of the motherboard speed. For example, the Pentium II 350, 400, and higher megahertz processors run at a motherboard speed of 100MHz, and would therefore require a motherboard capable of 100MHz operation. Pentium 333MHz and lower speed processors run at 66MHz maximum. Currently all the Celeron processors are intended to run at the 66MHz board speed. All components on the motherboard (especially cache memory on Pentium boards) should be rated to run at the maximum allowable motherboard speed.
- **Cache Memory.** All classic Pentium motherboards should have 256–512KB of L2 cache on-board, better ones will have 1MB or even 2MB. P6 processors such as the Pentium Pro, Pentium II/III, and Celeron use a built-in L1/L2 cache, which means that there will be no cache on a P6 motherboard. The Pentium Pro can have 256KB, 512KB, or 1MB of Level 2 cache built-in. The Pentium II/III can have either 128KB (Celeron) or 512KB, and 1MB or more in the Xeon processors. The Level 2 cache on a classic Pentium board should be populated with chips that are fast enough to support the maximum motherboard speed, which should be 15ns or faster for 66MHz maximum motherboard speeds, and 13ns or better for 75MHz operation. For Pentium boards, the cache should be a Synchronous SRAM (Static RAM) type, which is also called *Pipelined Burst SRAM*.
- **SIMM/DIMM Memory.** If the board is being used to upgrade an older system which used 72-pin SIMMs, it may be desirable to get the type that has both SIMM and DIMM sockets. If you are getting all new memory for the board (recommended), I highly recommend only using boards which take SDRAM (Synchronous DRAM) 168-pin DIMMs (Dual In-line Memory Modules). Due to the 64-bit design of these boards, the 72-pin SIMMs must be installed in matched pairs, while DIMMs are installed one at a time (one per 64-bit bank). Be sure that the memory is compatible with the chipset you are using, and more specifically is rated for the 66MHz or 100MHz speed it will be running. Carefully consider the total amount of memory you will need, and how much the board supports. Classic Pentium systems with the 430FX, VX, or TX chipset only support a maximum of 64MB of cacheable memory, which effectively limits you to that amount. Pentium II systems will allow caching for all the memory you can fit into the board, and most will handle 384MB or more of SDRAM DIMM memory. The 333MHz and lower Pentium II processors can cache up to 512MB of RAM (note most motherboards won't handle that much) whereas the newer 350MHz and faster Pentium IIs will cache up to 4GB of system RAM! While 32MB is regarded as a minimum for today's memory hungry applications, you might actually require much more. I recommend installing 64MB in most new systems. For maximum performance, look for systems that support 3.3v SDRAM (Synchronous DRAM) as a minimum. Future systems will use even faster RDRAM (Rambus DRAM) RIMMs (Rambus Inline Memory Modules) with speeds of 800MHz or more!

Mission-critical systems should use parity or ECC (Error Correcting Code) DIMMs and ensure that the motherboard fully supports ECC operation. Most Pentium (430 series)

chipsets *do not* support ECC, while most Pentium II chipsets do. Note that the low-end 440EX boards normally used in Celeron processor-based systems do not support ECC and should not be used for mission-critical applications.

Finally, note that most Pentium and Pentium II motherboards support either 3 or 4 DIMM sockets. Be sure that you populate them wisely so you don't have to resort to removing memory later to add more, which is not very cost-effective.

- **Bus Type.** Pentium, Pentium Pro, and Pentium II motherboards should have one or more ISA bus slots and at least three or four PCI local bus slots. Make sure the PCI slots conform to the PCI 2.1 revision (primarily based on the chipset). Take a look at the layout of the slots to ensure that cards inserted in them will not block access to memory sockets or be blocked by other components in the case. Newer systems should also feature one AGP (Accelerated Graphics Port) slot for a high performance AGP video card.
- **BIOS.** The motherboard should use an industry standard BIOS such as those from AMI, Phoenix, or Award. The BIOS should be of a Flash ROM or EEPROM (Electrically Erasable Programmable Read Only Memory) design for easy updating. Look for a BIOS Recover jumper or mode setting, as well as possibly a Flash ROM write-protect jumper on some systems. The BIOS should support the Plug-and-Play (PnP) specification and Enhanced IDE or Fast ATA hard drives. There should also be support for the newer LS-120 (120M) floppy drives as well as IDE CD-ROM drives as boot devices. APM (Advanced Power Management) support should be built into the BIOS as well.
- **Form Factor.** For maximum flexibility, performance, reliability, and ease-of-use, the ATX form factor cannot be beat. ATX has several distinct performance and functional advantages over Baby-AT, and is vastly superior to any proprietary designs such as LPX. Additionally, the new NLX form factor might be a consideration for low profile or low cost desktop systems.
- **Built-in interfaces.** Ideally, a motherboard should contain as many built-in standard controllers and interfaces as possible (except perhaps video). A motherboard should have a built-in floppy controller, built-in primary and secondary local bus (PCI or VL-Bus), Enhanced IDE (also called Fast ATA) connectors, two built-in, high-speed serial ports (must use 16550A type buffered UARTs), two built-in USB (Universal Serial Bus) ports, and a built-in high speed parallel port (must be EPP/ECP-compliant). A built-in PS/2 type (6-pin mini-DIN) mouse port should be included as well.

The USB ports have taken awhile to catch on, but they will become a "must-have" in the near future as more and more USB peripherals become available. A built-in SCSI port is a bonus as long as it conforms to ASPI (Advanced SCSI Programming Interface) standards. Built-in network adapters are also nice as long as they are the type that matches your network needs. A built-in sound card is a great feature, usually offering full Sound Blaster compatibility and functions, possibly offering additional features as well. If your sound needs are more demanding, you may find the built-in solutions less desirable, and want to have a separate sound card in your system. Built-in video adapters are also a bonus in some situations, but because there are many different video chipset and adapter designs to choose from, generally there are better choices in external local bus video adapters. This is especially true if you need the highest performance video available.

Normally built-in devices can be disabled to allow future add-ons, but there can be problems.

- **Plug and Play (PnP).** The motherboard and BIOS should fully support the Intel PnP specification. This will allow automatic configuration of PCI adapters as well as PnP ISA adapters.

Tip

Even if a motherboard doesn't list that it's PnP-compatible, it may be. PCI motherboards are required to be PnP-compatible, as it is a part of the PCI standard.

- **Power Management.** The motherboard should fully support SL Enhanced processors with APM (Advanced Power Management) and SMM (System Management Mode) protocols that allow for powering down various system components to different levels of readiness and power consumption. The latest standards for power management are called ACPI (Advanced Configuration & Power Interface) version 1.0; make sure any new board you purchase supports that as a minimum. An Energy-Star compliant system is also a bonus because it will use less than 30 watts of electrical energy when in Sleep mode, saving energy as well as your electric bill.
- **Motherboard chipset.** Pentium II motherboards should use a high performance chipset that supports SDRAM DIMMs—preferably one that allows ECC memory as well, such as the Intel 440LX or 440BX. The 440EX, which is designed for low cost and low-end systems only, does not support ECC memory and should not be used in mission-critical systems. Note that for classic Pentium systems, most of the available Intel chipsets do not support parity or ECC memory. In that case, boards with chipsets from ALi (Acer Laboratories Inc.), VIA technologies or SiS (Silicon integrated Systems) should be considered. These companies have continued making high performance, classic Pentium chipsets, and many of their offerings do support SDRAM DIMMs with ECC.
- **Documentation.** Good technical documentation is a requirement. Documents should include information on any and all jumpers and switches found on the board; connector pinouts for all connectors; specifications for cache RAM chips, SIMMs, and other plug-in components; and any other applicable technical information. I would also acquire separate documentation from the BIOS manufacturer covering the specific BIOS used in the system, as well as the data books covering the specific chipset used in the motherboard. Additional data books for any other controller or I/O chips on-board are a bonus, and can be acquired from the respective chip manufacturers.

Another nice thing to have is available online support and documentation updates, although this should not be accepted in place of good hardcopy manuals.

You may notice that these selection criteria seem fairly strict, and may disqualify many motherboards on the market, including what you already have in your system! These criteria will, however, guarantee you the highest quality motherboard offering the latest in PC technology that will be upgradable, expandable, and provide good service for many years.

Most of the time I recommend purchasing boards from better-known motherboard manufacturers such as Intel, Acer, ABIT, AsusTek, Elitegroup, FIC (First International Computer), and others. These boards might cost a little more, but there is some safety in the more well-known brands. That is, the more boards that they sell, the more likely that any problems will have been discovered by others and solved long before you get yours. Also, if service or support is needed, the larger vendors are more likely to be around in the long run.

Documentation

As mentioned, extensive documentation is an important factor to consider when you're planning to purchase a motherboard. Most motherboard manufacturers design their boards around a particular chipset, which actually counts as the bulk of the motherboard circuitry. There are a number of manufacturers offering chipsets, such as Intel, VIA, ALi, SiS, and others. I recommend obtaining the data book or other technical documentation on the chipset directly from the chipset manufacturer.

One of the more common questions I hear about a system relates to the BIOS Setup program. People want to know what the "Advanced Chipset Setup" features mean and what will the effects of changing them be. Often they go to the BIOS manufacturer thinking that the BIOS documentation will offer help. Usually, however, people find that there is no real coverage of what the chipset setup features are in the BIOS documentation. You will find this information in the data book provided by the chipset manufacturer. Although these books are meant to be read by the engineers who design the boards, they contain all the detailed information about the chipset's features, especially those that might be adjustable. With the chipset data book, you will have an explanation of all the controls in the Advanced Chipset Setup section of the BIOS Setup program.

Besides the main chipset data books, I also recommend collecting any data books on the other major chips in the system. This would include any floppy or IDE controller chips, Super I/O chips, and of course the main processor. You will find an incredible amount of information on these components in the data books.

Caution

Most chipset manufacturers only make a particular chip for a short time, rapidly superseding it with an improved or changed version. The data books are only available during the time the chip is being manufactured, so if you wait too long, you will find that such documents may no longer be available. The time to collect documentation on your motherboard is *now!*

Using Correct Speed-Rated Parts

Some vendors use substandard parts in their systems to save money. Because the CPU is one of the most expensive components on the motherboard, and motherboards are sold to system assemblers without the CPU installed, it is tempting for the assembler to install a CPU rated for less than the actual operating speed. A system could be sold as a 266MHz system, for example, but when you look "under the hood," you may find a CPU rated for only 233MHz. This is called *overclocking*, and many vendors have practiced this over the last few years. Some even go so far as to remark the CPUs, so that even if you look, the part appears to have the correct rating. The only way to stop that is to purchase systems from known, reliable vendors, and purchase processors from distributors that are closely connected with the manufacturer. Overclocking is fine if you want to do it yourself and understand the risks, but when I purchase a new system, I expect that all the parts included be rated to run at the speed they are set to.

When a chip is run at a speed higher than it is rated for, it will run hotter than it would normally. This can cause the chip to overheat occasionally, which would appear as random lockups, glitches, and frustration. I highly recommend that you check to be sure you are getting the right speed-rated parts you are paying for.

Also make sure you use the recommended heat sink compound (thermal grease). This can improve the efficiency of your heat sink by up to 30 percent.

This practice is easy to fall into because the faster rated chips cost more money. Intel and other chip manufacturers usually rate their chips very conservatively. Over the years I have taken several 25MHz 486 processors and run them at 33MHz, and they seemed to work fine. The Pentium 166 and even some 133 chips I have seem to run fine at 200MHz. Although I might purchase a Pentium 166 system and make a decision to run it at 200MHz, if I were to experience lockups or glitches in operation, I would immediately return it to 166MHz and retest. If I purchase a 200MHz system from a vendor, I fully expect it to have 200MHz parts, not 166MHz parts running past their rated speed! These days, many chips will have some form of heat sink on them, which helps to prevent overheating, but which can also sometimes cover up for a “pushed” chip. Fortunately since the Pentium processor, Intel has been marking all their chips on the bottom as well as the top.

The practice of overclocking may be all but over for Intel processor systems. Intel has recently began building overclock protection into their CPUs, which prevents them from running at any speed *higher* than they are rated at. They will run at lower speeds, but not higher ones. This was done mainly to combat remarking CPUs and deceiving customers, although unfortunately it also prevents those that want to from hot-rodding their chips.

The AMD and Cyrix chips may not be marked on the bottom like Intel’s chips are, and of special note is that the ink used on the AMD chips is *very* easy to wipe off. Since most AMD chips seem to be capable of running well over their rated speed, this has contributed to a great deal of remarking of those chips. If you purchase an AMD K6 processor or a system with that processor, verify that the markings are the original AMD markings and that the speed rating on the chip is what you really paid for.

The bottom line: If the price is too good to be true, ask before you buy. Are the parts really manufacturer-rated for the system speed?

To determine the rated speed of a CPU chip, look at the writing on the chip. Most of the time, the part number will end in a suffix of *-xxx* where the *xxx* is a number indicating the maximum speed. For example, *-333* indicates that the chip is rated for 333MHz operation.

Caution

Be careful when running software to detect processor speed. Such programs can only tell you what speed the chip is currently running at, not what the true rating is. Also ignore the speed indicator lights on the front of some cases. These digital displays can literally be set via jumpers to read any speed you desire! They have no true relation to actual system speed.

Most of the better diagnostics on the market such as the Norton Utilities from Symantec will read the processor ID and stepping information. You can consult the processor manufacturer or Chapter 3, “Microprocessor Types and Specifications,” for tables listing the various processor steppings to see exactly how yours stacks up.

BIOS

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

BIOS Basics

BIOS Hardware/Software

Motherboard BIOS

Upgrading the BIOS

CMOS Setting Specifications

Year 2000 BIOS Issues

Plug-and-Play BIOS

BIOS Error Messages

BIOS Basics

It is often difficult for people to understand the difference between hardware and software in a PC system. The differences can be difficult because they are both very much intertwined in the system design, construction, and operation. Understanding these differences is essential to understanding the role of the BIOS in the system.

BIOS is a term that stands for basic input/output system. BIOS is really the link between hardware and software in a system. Most people know the term BIOS by another name—*device drivers*, or just *drivers*.

The BIOS is a single term that describes all the drivers in a system working together to act as an interface between the hardware and the operating system software. What can be confusing is that some of the BIOS is burned or flashed into a ROM chip that is both nonvolatile (it doesn't get erased when the power is turned off) and read-only. This is a core part of the BIOS, but not all of it. The BIOS also includes ROM chips installed on adapter cards, as well as all the additional drivers loaded when your system boots up.

The combination of the motherboard BIOS, the adapter card BIOS, and the device drivers loaded from disk contribute to the BIOS as a whole. The portion of the BIOS that is contained in ROM chips both on the motherboard and in some adapter cards is sometimes called *firmware*, which is a name given to software stored in chips rather than on disk. This causes some people to incorrectly think of the BIOS as a hardware component.

A PC system can be described as a series of layers—some hardware and some software—that interface with each other. In the most basic sense, you can break a PC down into four primary layers, each of which can be broken down further into subsets. Figure 5.1 shows the four layers in a typical PC.

Figure 5.1 PC system layers.

The purpose of the layered design is to allow for a given operating system and applications to run on different hardware. Figure 5.1 shows how two different machines with different hardware can each use a custom BIOS to interface the unique hardware to a common operating system and applications. Thus, two machines with different processors, storage media, video display units, and so on can run the same software.

In this layered architecture, the application programs talk to the operating system via what is called an API (Application Program Interface). The API varies according to the operating system you are using and consists of the different commands and functions that the operating system can perform for an application. For example, an application can call on the operating system to load or save a file. This prevents the application itself from having to know how to read the disk, send data to a printer, or perform any other of the many functions the operating system can provide. Because the application is completely insulated from the hardware, I can essentially run the same applications on different systems; the application is designed to talk to the operating system rather than the hardware.

The operating system then interfaces or talks to the BIOS layer. The BIOS consists of all the individual driver programs that operate between the operating system and the actual hardware. As such, the operating system never talks to the hardware directly; instead, it must always go through the appropriate driver. This allows for a consistent way to talk to the hardware. It is normally the responsibility of the hardware manufacturer to provide drivers for its hardware. Because the drivers must act between both the hardware and the operating system, the drivers are normally operating-system specific. Thus, the hardware manufacturer must offer different drivers so that its hardware will work under DOS, Windows 9x, Windows NT, Windows 2000, OS/2, Linux, and so on.

Because the BIOS layer looks the same to the operating system no matter what hardware is above it (or underneath, depending on your point of view), we can have the same operating system running on a variety of PCs. For example, you can run Windows 98 on two systems with different processors, hard disks, video adapters, and so on, yet Windows 98 will look and feel pretty much the same on both of them. This is because the drivers provide the same basic functions no matter which specific hardware is used.

As you can see from Figure 5.1, the application and operating systems layers can be identical from system to system, but the hardware can differ radically. Because the BIOS consists of software drivers that act to interface the hardware to the software, the BIOS layer adapts to the unique hardware on one end, but looks consistently the same to the operating system at the other end.

The hardware layer is where most differences lie between different systems. It is up to the BIOS to mask the differences between unique hardware so that the given operating system (and subsequently the application) can be run. In this chapter, we are focusing on the BIOS layer of the PC.

BIOS Hardware/Software

The BIOS itself is software that consists of all the various drivers that interface the hardware to the operating system. The BIOS is unique compared to normal software in that it doesn't all load from disk; some of it is preloaded into chips installed in the system or on adapter cards.

The BIOS in a PC comes from three possible sources:

- Motherboard ROM BIOS
- Adapter Card BIOS (such as that found on a video card)
- Loaded from disk (drivers)

The motherboard BIOS is most often associated with hardware rather than software. This is because the BIOS on the motherboard is contained in a ROM (read-only memory) chip on the board, which contains the initial software drivers needed to get the system running. Years ago, when running only DOS on basic PCs, this was enough so that no other drivers were needed; the motherboard BIOS had everything that was necessary. The motherboard BIOS normally includes drivers for all the basic system components, including the keyboard, the floppy drive, the hard drive, the serial and parallel ports, and more. As systems became more complex, new hardware was added for which no motherboard BIOS drivers existed. These included devices such as newer video adapters, CD-ROM drives, SCSI hard disks, and so on.

Rather than requiring a new motherboard BIOS that would specifically support the new devices, it was far simpler and more practical to copy any new drivers that were needed onto the system hard disk and configure the operating system to load them at boot time. This is how most CD-ROM drives, sound cards, scanners, printers, PC-card (PCMCIA) devices, and so on are supported. Because these devices don't need to be active during boot time, the system can boot up from the hard disk and wait to load the drivers during the initial operating system load.

Some drivers, however, must be active during boot time. For example, how will you be able to see anything on the screen if your video card doesn't have a set of drivers in a ROM somewhere, rather than waiting to load them from the hard disk? The solution to this could be to provide a motherboard ROM with the appropriate video drivers built in; however, this is impractical because of the variety of cards, each needing its own drivers. You would end up with hundreds of different motherboard ROMs, depending on which video card you had. Instead, when IBM was designing the original PC, it created a better solution. It designed the PC's motherboard ROM to scan the slots looking for adapter cards with ROMs on them. If a card was found with a ROM on it, the ROM was executed during the initial system startup phase, well before the system began loading the operating system from the hard disk.

By putting the ROM-based drivers right on the card, you didn't have to change your motherboard ROM to have built-in support for new devices, especially those that needed to be active during boot time. A few different cards (adapter boards) will almost always have a ROM onboard, including the following:

- *Video cards.* All will have an onboard BIOS.
- *SCSI adapters.* Those that support booting from SCSI hard drives have an onboard BIOS. Note that, in most cases, the SCSI BIOS does not support any SCSI devices other than a hard disk; if you use a SCSI CD-ROM, scanner, zip drive, and so on, you still need to load the appropriate drivers for those devices from your hard disk.
- *Network cards.* Those that support booting directly from a file server will have what is usually called a boot ROM or IPL (Initial Program Load) ROM onboard. This allows for PCs to be configured on a LAN as diskless workstations—also called Net PCs, NCs (Network Computers), or even smart terminals.
- *IDE or floppy upgrade boards.* Boards that allow you to attach more or different types of drives that what is normally supported by the motherboard alone. These cards require an onboard BIOS to enable these drives to be bootable.

- **Y2K boards.** Boards that incorporate BIOS fixes to update the century byte in the CMOS RAM. These boards have a small driver contained in a BIOS, which monitors the year byte for a change from 99 to 00. When this is detected, the driver updates the century byte from 19 to 20, correcting a flaw in some older motherboard BIOSes.

BIOS and CMOS RAM

Some people confuse BIOS with the CMOS RAM in a system. This confusion is aided by the fact that the Setup program in the BIOS is used to set and store the configuration settings in the CMOS RAM. They are, in fact, two totally separate components.

The BIOS on the motherboard is stored in a fixed ROM chip. Also on the motherboard is a chip called the RTC/NVRAM chip, which stands for Real-Time Clock/Non-Volatile Memory. This is actually a digital clock chip with a few extra bytes of memory thrown in.

The first one ever used in a PC was the Motorola MC146818 chip, which had 64 bytes of storage, of which 10 bytes were dedicated to the clock function. Although it is called nonvolatile, it is actually volatile, meaning that without power, the time/date settings and the data in the RAM portion will, in fact, be erased. It is called non-volatile because it is designed using CMOS (complementary metal-oxide semiconductor) technology, which results in a chip that runs on very little power, and that power is provided by a battery in the system, not by the AC wall current. This is also why most people incorrectly call this chip the CMOS RAM chip; although not technically accurate, that is easier to say than the RTC/NVRAM chip. Most RTC/NVRAM chips run on as little as 1 micro-amp (millionth of an amp), which means they use very little battery power to run. Most will last five years before the lithium battery runs out and the information stored gets erased.

When you enter your BIOS Setup, configure your hard disk parameters or other BIOS Setup settings, and save them, these settings are written to the storage area in the RTC/NVRAM (otherwise called CMOS RAM) chip. Every time your system boots up, it reads the parameters stored in the CMOS RAM chip to determine how the system should be configured. A relationship exists between the BIOS and CMOS RAM, but they are two distinctly different parts of the system.

Motherboard BIOS

All motherboards must have a special chip containing software we call the BIOS or ROM BIOS. This ROM chip contains the startup programs and drivers that are used to get the system running and act as the interface to the basic hardware in the system. A POST (power on self test) in the BIOS also tests the major components in the system when you turn it on, and normally a setup program used to store system configuration data in the CMOS (complementary metal-oxide semiconductor) memory powered by a battery on the motherboard. This CMOS RAM is often called NVRAM (Non-Volatile RAM) because it runs on about 1 millionth of an amp of electrical current and can store data for years when powered by a tiny lithium battery.

▶▶ See "ROM Hardware," p. 350.

The BIOS is a collection of programs embedded in one or more chips, depending on the design of your computer. That collection of programs is the first thing loaded when you start your computer, even before the operating system. Simply put, the BIOS in most PCs has four main functions:

- *POST (power on self test)*. The POST tests your computer's processor, memory, chipset, video adapter, disk controllers, disk drives, keyboard, and other crucial components.
- *BIOS Setup*. System configuration and setup program. This is usually a menu-driven program activated by pressing a special key during the POST, which allows you to configure the motherboard and chipset settings along with the date and time, passwords, disk drives, and other basic system settings. You also can control the power-management settings and boot-drive sequence from the BIOS Setup. Some older 286 and 386 systems did not have the Setup program in ROM and required that you boot from a special setup disk.
- *Bootstrap loader*. A routine that reads the disk drives looking for a valid master boot sector. If one meeting certain minimum criteria (ending in the signature bytes 55AAh) is found, then the code within is executed. This master boot sector program then continues the boot process by loading an operating system boot sector, which then loads the operating system core files.
- *BIOS (basic input/output system)*. This refers to the collection of actual drivers used to act as a basic interface between the operating system and your hardware when the system is booted and running. When running DOS or Windows in safe mode, you are running almost solely on ROM-based BIOS drivers because none are loaded from disk.

ROM Hardware

Read-only memory, or ROM, is a type of memory that can permanently or semi-permanently hold data. It is called read-only because it is either impossible or difficult to write to. ROM is also often called nonvolatile memory because any data stored in ROM will remain even if the power is turned off. As such, ROM is an ideal place to put the PC's startup instructions—that is, the software that boots the system—the BIOS.

Note that ROM and RAM are not opposites, as some people seem to believe. In fact, ROM is technically a subset of the system's RAM. In other words, a portion of the system's random access memory address space is mapped into one or more ROM chips. This is necessary to contain the software that enables the PC to boot up; otherwise, the processor would have no program in memory to execute when it is powered on.

For example, when a PC is turned on, the processor automatically jumps to address FFFF0h, expecting to find instructions to tell the processor what to do. This location is exactly 16 bytes from the end of the first megabyte of RAM space, as well as the end of the ROM itself. If this location were mapped into regular RAM chips, any data stored there would have disappeared when the power was previously turned off, and the processor would subsequently find no instructions to run the next time power was turned on. By placing a ROM chip at this address, a system startup program can be permanently loaded into the ROM and will be available every time the system is turned on.

▶▶ See "The Boot Process," p. 1353.

▶▶ For more information about Dynamic RAM, see "DRAM," p. 418.

Normally the system ROM will start at address F0000h, which is 64KB prior to the end of the first megabyte. Because the ROM chip is normally 64KB in size, the ROM programs occupy the entire last 64KB of the first megabyte, including the critical FFFF0h startup instruction address.

Some think it is strange that the PC would start executing instructions 16 bytes from the end of the ROM, but this design was intentional. All the ROM programmer has to do is to place a JMP (jump) instruction at that address that instructs the processor to jump to the actual beginning of the ROM—in most cases close to F0000h—which is about 64KB earlier in the memory map. It's like deciding to read every book starting 16 pages from the end, and then having all book publishers agree to place an instruction there to jump back the necessary number of pages to get to page 1. By setting the startup location in this way, Intel allowed the ROM to grow to be any size, all the while keeping it at the upper end of addresses in the first megabyte of the memory address space.

The main ROM BIOS is contained in a ROM chip on the motherboard, but adapter cards with ROMs are also on them as well. ROMs on adapter cards contain auxiliary BIOS routines and drivers needed by the particular card, especially for those cards that must be active early in the boot process, such as video cards, for example. Cards that don't need drivers active during boot (such as sound cards) will not normally have a ROM because those drivers can be loaded from the hard disk later in the boot process.

Because the BIOS is the main portion of the code stored in ROM, we often call the ROM the ROM BIOS. In older PCs, the motherboard ROM BIOS could consist of up to five or six total chips, but most PCs have only required a single chip for many years now.

Adapter cards that require drivers during the boot process need to have ROM onboard. This includes cards such as video cards, most SCSI (small computer systems interface) cards (if you want to boot from a SCSI hard drive), enhanced IDE controller cards, and some network cards (for booting from the server). The ROM chip on these cards contains drivers and startup programs that will be executed by the motherboard ROM at boot time. This, for example, is how a video card can be recognized and initialized, even though your motherboard ROM does not contain specific drivers for it. You wouldn't want to load the initial VGA mode drivers from disk because the screen would remain dark until those drivers were loaded.

Adapter card ROMs are automatically scanned and read by the motherboard ROM during the early part of the boot process, during the POST (power on self test). The motherboard ROM scans a special area of RAM reserved for adapter ROMs (addresses C0000-DFFFFh) looking for a 55AAh signature byte pair that indicates the start of a ROM.

All adapter ROMs must start with 55AAh or they won't be recognized by the motherboard. The third byte indicates the size of the ROM in 512-byte units called paragraphs, and the fourth byte is the actual start of the driver programs. The size byte is used by the motherboard ROM for testing purposes. The motherboard ROM adds all the bytes in the ROM and divides the sum by the number of bytes. The result should produce a remainder of 100h. Thus, when creating a ROM for an adapter, the programmer uses a "fill" byte at the end to get the checksum to come out right. Using this checksum the motherboard tests each adapter ROM during the POST and flags any that appear to have been corrupted.

The motherboard BIOS automatically runs the programs in any adapter ROMs it finds during the scan. You see this in most systems when you turn your system on, and during the POST, you see the video card BIOS initialize and announce its presence.

ROM Shadowing

ROM chips by their nature are very slow, with access times of 150ns (nanoseconds, or billionths of a second), compared to DRAM access times of 60ns or less. Because of this, in many systems the ROMs are *shadowed*, which means they are copied into DRAM chips at startup to allow faster access during normal operation. The shadowing procedure copies the ROM into RAM and then assigns that RAM the same address as the ROM originally used, disabling the actual ROM in the process. This makes the system seem as though it has 60ns (or whatever the RAM speed is) ROM.

The performance gain from shadowing is often very slight, and it can cause problems if not set up properly, so in most cases, it is wise to shadow only the motherboard and maybe the video card BIOS, and leave the others alone.

Mostly, shadowing is useful only if you are running 16-bit operating systems such as DOS or Windows 3.x. If you are running a 32-bit operating system such as Windows 95, Windows 98, Windows 2000, or Windows NT, shadowing is virtually useless because those operating systems do not use the 16-bit ROM code while running. Instead, those operating systems load 32-bit drivers into RAM, which replace the 16-bit BIOS code used only during system startup.

Shadowing controls are found in the CMOS Setup program in the motherboard ROM, which is covered in more detail later in this chapter.

There are four types of ROM chips:

- *ROM*. Read-only memory
- *PROM*. Programmable ROM
- *EPROM*. Erasable PROM
- *EEPROM*. Electrically-erasable PROM, also called a flash ROM

No matter which type of ROM your system uses, the data stored in a ROM chip is nonvolatile and will remain indefinitely unless intentionally erased or overwritten (in those where that is possible).

Table 5.1 lists the identifying part numbers typically used for each type of ROM chip, along with any other identifying information.

Table 5.1 ROM Chip Part Numbers

ROM Type	Part Number	Other
ROM	No longer in use	
PROM	27nnnn	
EPROM	27nnnn	Quartz Window
EEPROM	28xxxx or 29xxxx	

Mask ROM

Originally, most ROMs were manufactured with the binary data (0s and 1s) already “cast in” or integrated into the die. The die represents the actual silicon chip itself. These are called Mask ROMs because the data is formed into the mask from which the ROM die is photolithographically produced. This type of manufacturing method is economical if you are making hundreds of thousands of ROMs with the same information. If you have to change a single bit, however, you must remake the mask, which is an expensive proposition. Because of costs and inflexibility, nobody uses Mask ROMs anymore.

Mask ROMs are exactly analogous to prerecorded CD-ROMs. Some people think a CD-ROM is first manufactured as a blank and then the data is written to it by laser, but that is not true. A CD-ROM is literally a piece of plastic that is stamped in a press, and the data is directly molded in, not written. The only actual recording was done with the master disc from which the molds or stamps are made.

PROM

PROMs are a type of ROM that is blank when new and that must be programmed with whatever data you want. The PROM was invented in the late 1970s by Texas Instruments and has been available in sizes from 1KB (8Kb) to 2MB (16Mb) or more. They can be identified by their part numbers, which are usually 27nnnn—where the 27 indicates the TI type PROM, and the nnnn indicates the size of the chip in kilobits (not bytes). For example, most PCs that used PROMs came with 27512 or 271000 chips, which indicate 512Kb (64KB) or 1Mb (128KB).

Note

Since 1981, all cars sold in the US have used onboard computers with some form of ROM containing the control software. My '89 Pontiac Turbo Trans Am came with an onboard computer containing a 2732 PROM, which was a 32Kb (4KB) chip in the ECM (Electronic Control Module or vehicle computer) under the dash. This chip contained a portion of the vehicle operating software as well as all the data tables describing spark advance, fuel delivery, and other engine and vehicle operating parameters. Many devices with integrated computers use PROMs to store their operating programs.

Although we say these chips are blank when new, they are technically preloaded with binary 1s. In other words, a 1Mb ROM chip used in a modern PC would come with 1 million (actually 1,048,576) bit locations, each containing a binary 1. A blank PROM can then be programmed, which is the act of writing to it. This normally requires a special machine called a device programmer, a ROM programmer, or a ROM burner (see Figure 5.2).

We sometimes refer to programming the ROM as “burning” it, because that is technically an apt description of the process. Each binary 1 bit can be thought of as a fuse, which is intact. Most chips run on 5 volts, but when we program a PROM, we place a higher voltage (normally 12 volts) at the various addresses within the chip. This higher voltage actually blows or burns the fuses at the locations we desire, thus turning any given 1 into a 0. Although we can turn a 1 into a 0, you should note that the process is irreversible; that is, we cannot turn a 0 back into a 1.

Figure 5.2 Typical gang (multisocket) device programmer (PROM burner).

The device programmer examines the program you want to write into the chip and then selectively changes only the 1s to 0s where necessary in the chip.

PROM chips are often referred to as OTP (one time programmable) chips for this reason. They can be programmed once and never erased. Most PROMs are very inexpensive, about \$3 for a typical PC motherboard PROM, so if you want to change the program in a PROM, you discard it and program a fresh one with the new data.

The act of programming a PROM takes anywhere from a few seconds to a few minutes, depending on the size of the chip and the algorithm used by the programming device. Figure 5.2 shows an illustration of a typical PROM programmer that has multiple sockets. This is called a gang programmer and can program several chips at once, saving time if you have several chips to write with the same data. Less expensive programmers are available with only one socket, which is fine for most individual use.

I use and recommend a very inexpensive programmer from a company called Andromeda Research (see Vendor List on the CD). Besides being economical, their unit has the advantage of connecting to a PC via the parallel port for fast and easy data transfer of files between the PC and the programming unit. Their unit is also portable and comes built into a convenient carrying case. It is operated by an included menu-driven program you install on the connected PC. The program contains several features, including a function that allows you to read the data from a chip and save it in a file on your system, as well as to write a chip from a data file, verify that a chip matches a file, and verify that a chip is blank before programming begins.

Chapter 4, “Motherboards and Buses,” shows how I used my PROM programmer to modify the BIOS in some of my older PCs. With today’s systems primarily using flash ROMs, this capability is somewhat limited, but I include the information because I think it is very interesting.

Note

I even used my PROM programmer to reprogram the PROM in my 1989 Turbo Trans Am, changing the factory preset speed and rpm limiters, turbocharger boost, torque converter lockup points, spark advance, fuel delivery, idle speed, and much more! I also incorporated a switch box under the dash that allows me to switch among four different chips, even while the vehicle is running. One chip I created I call the “valet chip,” which, when engaged,

cuts off the fuel injectors at a preset speed of 36 miles per hour and restarts them when the vehicle coasts down to 35mph. I imagine this type of modification would be useful for those with teenagers driving, because you could set the mph or engine rpm limit to whatever you want! Another chip I created cuts off fuel to the engine altogether, which I engage for security purposes when the vehicle is parked. No matter how clever, a thief will not be able to steal this car unless he tows it away. If you are interested in such a chip-switching device or custom chips for your Turbo Trans Am or Buick Grand National, contact Casper's Electronics (see the Vendor List on the CD-ROM accompanying this book). For other vehicles with replaceable PROMs, companies such as Superchips, Hypertech, or Evergreen offer custom PROMs for improved performance (see the Vendor List on the CD). I installed a Superchips chip in a Ford Explorer I had, and it made a dramatic improvement in engine operation and vehicle performance.

EPROM

One variation of the PROM that has been very popular is the EPROM. An EPROM is a PROM that is erasable. An EPROM chip can be easily recognized by the clear quartz crystal window set in the chip package directly over the die (see Figure 5.3). You can actually see the die through the window! EPROMs have the same 27xxxx part-numbering scheme as the standard PROM, and they are functionally and physically identical except for the clear quartz window above the die.

Figure 5.3 An EPROM showing the quartz window for ultraviolet erasing.

The purpose of the window is to allow ultraviolet light to reach the chip die because the EPROM is erased by exposure to intense UV light. The window is quartz crystal because regular glass blocks UV light. You can't get a suntan through a glass window!

Note

The quartz window makes the EPROMS more expensive than the OTP (One Time Programmability) PROMs. This extra expense is needless if erasability is not important.

The UV light erases the chip by causing a chemical reaction, which essentially melts the fuses back together! Thus, any binary 0s in the chip become 1s, and the chip is restored to new condition with binary 1s in all locations. To work, the UV exposure must be at a specific wavelength (2,537 angstroms), at a fairly high intensity (12,000 uw/cm²), in close proximity (2–3cm, or about 1 inch), and last for between 5 and 15 minutes duration. An EPROM eraser (see Figure 5.4) is a device that contains a UV light source (usually a sunlamp-type bulb) above a sealed compartment drawer where you place the chip or chips.

Figure 5.4 shows a professional type EPROM eraser that can handle up to 50 chips at a time. I use a much smaller and less expensive one called the DataRase by Walling Co. (see the Vendor List on the CD). This device erases up to four chips at a time and is both economical and portable.

Figure 5.4 A professional EPROM eraser.

The quartz crystal window on an EPROM is normally covered by tape, which prevents accidental exposure to UV light. UV light is present in sunlight, of course, and even in standard room lighting, so that over time a chip exposed to the light may begin to degrade. For this reason after a chip is programmed, it is a good idea to put a sticker over the window to protect it.

EEPROM/Flash ROM

A newer type of ROM is the EEPROM, which stands for Electrically Erasable PROM. These chips are also called flash ROMs and are characterized by their capability to be erased and reprogrammed directly in the circuit board they are installed in, with no special equipment required. By using an EEPROM, or flash ROM, it is possible to erase and reprogram the motherboard ROM in a PC without removing the chip from the system or even opening up the system chassis!

With a flash ROM or EEPROM, you don't need a UV eraser or device programmer to program or erase chips. Not only do virtually all PC motherboards built since 1994 use flash ROMs or EEPROMs, most automobiles built since then also use them as well. For example my '94 Chevy Impala SS has a PCM (Powertrain Control Module) with an integral flash ROM.

The EEPROM or flash ROM can be identified by a 28xxxx or 29xxxx part number, as well as by the absence of a window on the chip. Having an EEPROM or flash ROM in your PC motherboard means you can now easily upgrade the motherboard ROM without having to swap chips. In most cases, you will download the updated ROM from the motherboard manufacturer's Web site and then run a special program they provide to update the ROM. This procedure is described in more detail later in this chapter.

I recommend that you periodically check with your motherboard manufacturer to see whether an updated BIOS is available for your system. An updated BIOS may contain bug fixes or enable new features not originally found in your system. You might find fixes for a potential year 2000 date problem, for example, or new drivers to support booting from LS-120 (120MB floppy) drives.

Note

For the auto enthusiasts out there, you might want to do the same for your car; that is, check to see whether ROM upgrades are available for your vehicle's computer. Now that updates are so easy and inexpensive, vehicle manufacturers are releasing bug-fix ROM upgrades that correct operational problems or improve vehicle performance. In most cases, you will have to check with your dealer to see whether any new vehicle ROMs are available. If you have a GM car, GM has a site on the Web where you can get information about the BIOS revisions available for your car, which it calls Vehicle Calibrations. The GM Vehicle Calibration Information site address is

<http://207.74.147.14/vci/>

When you enter your VIN (vehicle identification number), this page displays the calibration history for the vehicle, which is a list of all the different flash ROM upgrades (calibrations) developed since the vehicle was new. For example, when I entered the VIN on my 1994 Impala, I found that five flash ROM calibrations had been released over the years, and my car had only the second revision installed originally, meaning there had been three newer ROMs than the one I had! The fixes in the various calibration updates are also listed. A trip to the dealer with this information enabled them to use their diagnostic computer to connect to my car and reflash the PCM with the latest software, which, in my case, fixed several problems including engine surging under specific conditions, shift clunks, erroneous "check engine" light warnings, and several other minor problems.

With the flash ROM capability, I began experimenting with running calibrations originally intended for other vehicles, and I now run a modified Camaro calibration loaded into the flash ROM in my Impala. The spark-advance curve and fuel delivery parameters are much more aggressive in the Camaro calibration, as are the transmission shift points and other features. If you are interested in having a custom program installed in your flash ROM equipped vehicle, I recommend you contact Wright Automotive or Evergreen Performance (see the Vendor List on the CD).

These days, many objects with embedded computers controlling them are using flash ROMs. Pretty soon you'll be taking your toaster in for flash ROM upgrades as well! The method for locating and updating your PC motherboard flash ROMs is shown in Chapter 4.

Other devices may have flash ROMs as well; for example, I have updated the flash ROMs in my Motorola ISDN modem as well as in my Kodak digital camera. Both of these items had minor quirks that were fixed by updating their internal ROM code, which was as easy as downloading a file from their respective Web sites and running the update program included in the file.

Flash ROMs are also frequently used to add new capabilities to peripherals or to update peripherals, such as modems, to the latest standards; for example, updating a modem from X2 or Kflex to v.90.

ROM BIOS Manufacturers

A number of popular BIOS manufacturers in the market today supply the majority of motherboard and system manufacturers with the code for their ROMs. This section discusses the various versions available.

Several companies have specialized in the development of a compatible ROM BIOS product. The three major companies that come to mind in discussing ROM BIOS software are American Megatrends, Inc. (AMI), Award Software, and Phoenix Software. Each company licenses its ROM

BIOS to motherboard manufacturers so those manufacturers can worry about the hardware rather than the software. To obtain one of these ROMs for a motherboard, the OEM (Original Equipment Manufacturer) must answer many questions about the design of the system so that the proper BIOS can be either developed or selected from those already designed. Combining a ROM BIOS and a motherboard is not a haphazard task. No single, generic, compatible ROM exists, either. AMI, Award, Microid Research, and Phoenix ship many variations of their BIOS code to different board manufacturers, each one custom-tailored to that specific motherboard.

Recently, some big changes have occurred in the BIOS industry. Phoenix landed a contract with Intel and now provides all of Intel's motherboard BIOSes, replacing AMI, who previously had the contract. This is a big deal because Intel sells about 80 percent or more of all PC motherboards. What that basically means is that if you purchase a PC today, you will probably be getting an Intel-made motherboard with the new Phoenix BIOS.

Another development is that in late 1998, Phoenix bought Award, and all its new products will be under the Phoenix name. Thus, the big-three BIOS developers are now reduced to the big two—Phoenix and AMI. Many of the offshore motherboard manufacturers still continue to use the AMI or Award BIOS. However, Phoenix is currently the leading BIOS company. It is not only developing the BIOS for most newer systems on the market, but it also is the primary BIOS developer responsible for new BIOS development and new BIOS standards.

OEMs

Many OEMs (original equipment manufacturers) have developed their own compatible ROMs independently. Companies such as Compaq and AT&T have developed their own BIOS products that are comparable to those offered by AMI, Phoenix, Award, and others. These companies also offer upgrades to newer versions that often can offer more features and improvements or fix problems with the older versions. If you use a system with a proprietary ROM, make sure that it is from a larger company with a track record and one that will provide updates and fixes as necessary. Ideally, upgrades should be available for download from the Internet.

Most OEMs have their BIOS written for them by a third-party company. For example, Hewlett Packard contracts with Phoenix, a well-known BIOS supplier, to develop the motherboard BIOSes used in all the HP Vectra PCs. Note that even though Phoenix may have done the development, you still have to get any upgrades or fixes from Hewlett Packard. This is really true for all systems because all motherboard manufacturers customize the BIOS for their boards.

Intel, today the largest manufacturer of motherboards in the world, used to use AMI for its BIOS, but during 1997, it switched over to Phoenix for all its newer systems. Today Intel supplies versions of the Phoenix BIOS with all its boards. Phoenix is again the largest BIOS supplier in the world; it is found in the majority of motherboards today.

AMI

Although AMI customizes the ROM code for a particular system, it does not sell the ROM source code to the OEM. An OEM must obtain each new release as it becomes available. Because many

OEMs don't need or want every new version developed, they might skip several version changes before licensing a new one. The AMI BIOS is currently the most popular BIOS in PC systems. Newer versions of the AMI BIOS are called Hi-Flex because of the high flexibility found in the BIOS configuration program. The AMI Hi-Flex BIOS is used in Intel, AMI, and many other manufacturers' motherboards. One special AMI feature is that it is the only third-party BIOS manufacturer to make its own motherboard.

During powerup, the BIOS ID string is displayed on the lower-left part of the screen. This string tells you valuable information about which BIOS version you have and about certain settings that are determined by the built-in setup program.

Tip

A good trick to help you view the BIOS ID string is to shut down and either unplug your keyboard or hold down a key as you power back on. This causes a keyboard error, and the string will remain displayed.

The primary BIOS Identification string (ID String 1) is displayed by any AMI BIOS during the POST (power on self test) at the bottom-left corner of the screen, below the copyright message. Two additional BIOS ID strings (ID Strings 2 and 3) can be displayed by the AMI Hi-Flex BIOS by pressing the Insert key during POST. These additional ID strings display the options that are installed in the BIOS.

The general BIOS ID String 1 format for older AMI BIOS versions is shown in Table 5.2.

Table 5.2 ABBB-NNNN-mmddyy-KK

Position	Description
A	BIOS Options: D = Diagnostics built in S = Setup built in E = Extended Setup built in
BBB	Chipset or Motherboard Identifier: C&T = Chips & Technologies chipset NET = C&T NEAT 286 chipset 286 = Standard 286 motherboard SUN = Suntac chipset PAQ = Compaq motherboard INT = Intel motherboard AMI = AMI motherboard G23 = G2 chipset 386 motherboard
NNNN	The manufacturer license code reference number
mmddyy	The BIOS release date, mm/dd/yy
KK	The AMI keyboard BIOS version number.

The BIOS ID String 1 format for AMI Hi-Flex BIOS versions is shown in Table 5.3.

Table 5.3 AB-CCcc-DDDDDD-EFGHIJKL-mmddy-MM MMMMMMM-N

Position	Description
A	Processor Type: 0 = 8086 or 8088 2 = 286 3 = 386 4 = 486 5 = Pentium 6 = Pentium Pro/II
B	Size of BIOS: 0 = 64KB BIOS 1 = 128KB BIOS
CCcc	Major and minor BIOS version number
DDDDDD	Manufacturer license code reference number 0036xx = AMI 386 motherboard, xx = Series # 0046xx = AMI 486 motherboard, xx = Series # 0056xx = AMI Pentium motherboard, xx = Series # 0066xx = AMI Pentium Pro motherboard, xx = Series #
E	1 = Halt on POST Error
F	1 = Initialize CMOS every boot
G	1 = Block pins 22 and 23 of the keyboard controller
H	1 = Mouse support in BIOS/keyboard controller
I	1 = Wait for <F1> key on POST errors
J	1 = Display floppy error during POST
K	1 = Display video error during POST
L	1 = Display keyboard error during POST
mmddy	BIOS Date, mm/dd/yy
MMMMMMMM	Chipset identifier or BIOS name
N	Keyboard controller version number

AMI Hi-Flex BIOS ID String 2 is shown in Table 5.4.

Table 5.4 AAB-C-DDDD-EE-FF-GGGG-HH-II-JJJ

Position	Description
AA	Keyboard controller pin number for clock switching.
B	Keyboard controller clock switching pin function: H = High signal switches clock to high speed. L = High signal switches clock to low speed. C = Clock switching through chipset registers: 0 = Disable. 1 = Enable.
DDDD	Port address to switch clock high.
EE	Data value to switch clock high.
FF	Mask value to switch clock high.
GGGG	Port address to switch clock low.
HH	Data value to switch clock low.
II	Mask value to switch clock low.
JJJ	Pin number for Turbo Switch Input.

AMI Hi-Flex BIOS ID String 3 is shown in Table 5.5.

Table 5.5 AAB-C-DDD-EE-FF-GGGG-HH-II-JJ-K-L

Position	Description
AA	Keyboard controller pin number for cache control.
B	Keyboard controller cache control pin function: H = High signal enables the cache. L = High signal disables the cache.
C	1 = High signal is used on the keyboard controller pin.
DDD	Cache control through chipset registers: 0 = Cache control off. 1 = Cache control on.
EE	Port address to enable cache.
FF	Data value to enable cache.
GGGG	Mask value to enable cache.
HH	Port address to disable cache.
II	Data value to disable cache.
JJ	Mask value to disable cache.
K	Pin number for resetting the 82335 memory controller.
L	BIOS Modification Flag: 0 = The BIOS has not been modified. 1–9, A–Z = Number of times the BIOS has been modified.

The AMI BIOS has many features, including a built-in setup program activated by pressing the Delete or Esc key in the first few seconds of booting up your computer. The BIOS prompts you briefly as to which key to press and when to press it. The AMI BIOS offers user-definable hard disk types, essential for optimal use of many IDE or ESDI drives. The 1995 and newer BIOS versions also support enhanced IDE drives and will autoconfigure the drive parameters.

A unique feature of some of the AMI BIOS versions was that in addition to the setup, they had a built-in, menu-driven diagnostics package, essentially a very limited version of the standalone AMIDIAG product. The internal diagnostics are not a replacement for more comprehensive disk-based programs, but they can help in a pinch. The menu-driven diagnostics do not do extensive memory testing, for example, and the hard disk low-level formatter works only at the BIOS level rather than at the controller register level. These limitations often have prevented it from being capable of formatting severely damaged disks. Most newer AMI BIOS versions no longer include the full diagnostics.

AMI doesn't produce BIOS documentation; it leaves that up to the motherboard manufacturers who include their BIOS on the motherboard. However, AMI has published a detailed version of its documentation called the *Programmer's Guide to the AMIBIOS*, published by Windcrest/McGraw-Hill and available under the ISBN 0-07-001561-9. This is a book written by AMI engineers that describes all the BIOS functions, features, error codes, and more. I recommend

this book for users with an AMI BIOS in their system because this provides a complete version of the documentation for which they may have been looking.

The AMI BIOS is sold through distributors, a list of which is available at its Web site. However, keep in mind that you cannot buy upgrades and replacements directly from AMI, and AMI produces upgrades only for its own motherboards. If you have a non-AMI motherboard with a customized AMI BIOS, you will have to contact the motherboard manufacturer for an upgrade.

Award

Award is unique among BIOS manufacturers because it sells its BIOS code to the OEM and allows the OEM to customize the BIOS. Of course, then the BIOS no longer is Award BIOS, but rather a highly customized version. AST uses this approach on its systems, as do other manufacturers, for total control over the BIOS code without having to write it from scratch. Although AMI and Phoenix customize the ROM code for a particular system, they do not sell the ROM's source code to the OEM. Some OEMs that seem to have developed their own ROM code started with a base of source code licensed to them by Award or some other company.

The Award BIOS has all the normal features you expect, including a built-in setup program activated by pressing Ctrl+Alt+Esc or a particular key on startup (normally prompted on the screen). This setup offers user-definable drive types, required to fully use IDE or ESDI hard disks. The POST is good, and Award runs technical support on its Web site at <http://www.award.com>.

Award was purchased by Phoenix in late 1998, and in the future, its BIOS will be available under the Phoenix name. However, it will continue to support its past BIOS versions and develop updates if necessary.

Phoenix

The Phoenix BIOS for many years has been a standard of compatibility by which others are judged. It was one of the first third-party companies to legally reverse-engineer the IBM BIOS using a "clean room" approach. In this approach, a group of engineers studied the IBM BIOS and wrote a specification for how that BIOS should work and what features should be incorporated. This information then was passed to a second group of engineers who had never seen the IBM BIOS. They could then legally write a new BIOS to the specifications set forth by the first group. This work would then be unique and not a copy of IBM's BIOS; however, it would function the same way.

The Phoenix BIOS excels in two areas that put it high on my list of recommendations. One is that the POST is excellent. The BIOS outputs an extensive set of beep codes that can be used to diagnose severe motherboard problems that would prevent normal operation of the system. In fact, with beep codes alone, this POST can isolate memory failures in Bank 0 right down to the individual SIMM or DIMM module. The Phoenix BIOS also has an excellent setup program free from unnecessary frills, but one that offers all the features the user would expect, such as user-definable drive types, and so on. The built-in setup is activated by pressing Ctrl+Alt+S, Ctrl+Alt+Esc, or a particular key on startup, such as F2 on most newer systems, depending on the version of BIOS you have.

The second area in which Phoenix excels is the documentation. Not only are the manuals that you get with the system detailed, but Phoenix has also written a set of BIOS technical-reference manuals that are a standard in the industry. The set consists of three books, titled *System BIOS for IBM PC/XT/AT Computers and Compatibles*, *CBIOS for IBM PS/2 Computers and Compatibles*, and *ABIOS for IBM PS/2 Computers and Compatibles*. In addition to being an excellent reference for the Phoenix BIOS, these books serve as an outstanding overall reference to the BIOS in general.

Phoenix has extensive technical support and documentation on its Web site at <http://www.phoenix.com>, as does its largest nationwide distributor, Micro Firmware, Inc. at <http://www.firmware.com>, or check the phone numbers listed in the Vendor list on the CD. Micro Firmware offers upgrades to some older systems with a Phoenix BIOS, including many Packard Bell, Gateway 2000 (with Micronics motherboards), Micron Technologies, and other systems. For most systems, especially newer ones, you will need to get any BIOS updates from the system or motherboard manufacturer.

These companies' products are established as ROM BIOS standards in the industry, and frequent updates and improvements ensure that a system containing these ROMs will have a long life of upgrades and service.

Microid Research (MR) BIOS

Microid Research is an interesting BIOS supplier. It primarily markets upgrade BIOSes for older Pentium and 486 motherboards that were abandoned by their original manufacturers. As such, it is an excellent upgrade for adding new features and performance to an older system. Microid Research BIOS upgrades are sold through Unicore Software.

Upgrading the BIOS

In this section, you learn that ROM BIOS upgrades can improve a system in many ways. You also learn that the upgrades can be difficult and may require much more than plugging in a generic set of ROM chips.

The ROM BIOS, or read-only memory basic input/output system, provides the crude brains that get your computer's components working together. A simple BIOS upgrade can often give your computer better performance and more features.

The BIOS is the reason that different operating systems can operate on virtually any PC-compatible system despite hardware differences. Because the BIOS communicates with the hardware, the BIOS must be specific to the hardware and match it completely. Instead of creating their own BIOSes, many computer makers buy a BIOS from specialists such as American Megatrends, Inc. (AMI), Award Software (now part of Phoenix), Microid Research, or Phoenix Technologies Ltd. A motherboard manufacturer that wants to license a BIOS must undergo a lengthy process of working with the BIOS company to tailor the BIOS code to the hardware. This process is what makes upgrading a BIOS somewhat problematic; the BIOS usually resides on ROM chips on the motherboard and is specific to that motherboard model or revision. In other words, you must get your BIOS upgrades from your motherboard manufacturer.

Often, in older systems, you must upgrade the BIOS to take advantage of some other upgrade. To install some of the larger and faster IDE (Integrated Drive Electronics) hard drives and LS-120 (120MB) floppy drives in older machines, for example, you may need a BIOS upgrade. Some machines are still being sold with older BIOSes that do not support hard drives larger than 8GB, for example.

The following list shows the primary functions of a ROM BIOS upgrade:

- Adding LS-120 (120MB) floppy drive support (also known as a SuperDrive)
- Adding support for hard drives greater than 8GB
- Adding support for Ultra-DMA/33 IDE hard drives
- Adding support for bootable ATAPI CD-ROM drives
- Adding or improving Plug-and-Play support and compatibility
- Correcting year-2000 and leap-year bugs
- Correcting known bugs or compatibility problems with certain hardware and software
- Adding support for newer types of processors

If you are installing newer hardware or software, and even though you follow all the instructions properly, you can't get it to work, specific problems may exist with the BIOS that an upgrade might fix. This is especially true for newer operating systems. Many systems need to have a BIOS update to properly work with the plug-and-play features of Windows 95 and 98, and the same is true for Windows 2000. Because these things are random and vary from board to board, it pays to periodically check the board manufacturer's Web site to see if any updates are posted and what problems they will fix.

Where to Get Your BIOS Update

For most BIOS upgrades, you must contact the motherboard manufacturer by phone or download the upgrade from its Web site. The BIOS manufacturers do not offer BIOS upgrades because the BIOS in your motherboard did not actually come from them. In other words, although you think you have a Phoenix, AMI, or Award BIOS, you really don't! Instead, you have a custom version of one of these BIOSes, which was licensed by your motherboard manufacturer and uniquely customized for its board. As such, you must get any BIOS upgrades from the motherboard manufacturer because they must be customized for your board as well.

In the case of Phoenix or Award, another option may exist. A company called Unicore specializes in providing Award BIOS upgrades. Unicore may be able to help you out if you can't find your motherboard manufacturer or if it is out of business. Phoenix has a similar deal with MicroFirmware, a company it has licensed to provide various BIOS upgrades. If you have a Phoenix or an Award BIOS and your motherboard manufacturer can't help you, contact one of these companies for a possible solution. Microid Research (sold through Unicore) is another source of BIOS upgrades for a variety of older and otherwise obsolete boards. They are available for boards that originally came with AMI, Award, or Phoenix BIOSes, and they add new features to older boards that have been abandoned by their original manufacturers. Contact them or Unicore for more information.

When seeking a BIOS upgrade for a particular motherboard (or system), you will need to know the following information:

- The make and model of the motherboard (or system)
- The version of the existing BIOS
- The type of CPU (for example, Pentium MMX, AMD K6, Cyrix/IBM 6x86MX, MII, Pentium II, and so on)

You can usually identify the BIOS you have by watching the screen when the system is first powered up. It helps to turn the monitor on first because some take a few seconds to warm up, and often the BIOS information is displayed for only a few seconds.

Tip

Look for any copyright notices or part number information. Sometimes you can press the Pause key on the keyboard to freeze the POST, allowing you to take your time to write down the information. Pressing any other key will then cause the POST to resume.

You can also often find the BIOS ID information in the BIOS Setup screens.

After you have this information, you should be able to contact the motherboard manufacturer to see whether a new BIOS is available for your system. If you go to the Web site, check to see whether a version exists that is newer than the one you have. If so, you can download it and install it in your system.

Determining Your BIOS Version

Most BIOSes display version information on the screen when the system is first powered up. In some cases the monitor takes too long to warm up, and you may miss this information because it is only displayed for a few seconds. Try turning your monitor on first, and then your system, which will make it easier to see. You can usually press the Pause key on the keyboard when the BIOS ID information is being displayed; this freezes it so you can record the information. Pressing any other key will allow the system startup to resume.

Backing Up Your BIOS's CMOS Settings

A motherboard BIOS upgrade will usually wipe out the BIOS Setup settings in the CMOS RAM. Therefore, you should record these settings, especially the important ones such as hard disk parameters. Some software programs, such as the Norton Utilities, can save and restore CMOS settings, but unfortunately, these types of programs are often useless in a BIOS upgrade situation. This is because sometimes the new BIOS will offer new settings or change the positions of the stored data in the CMOS RAM, which means you don't want to do an exact restore. Also with the variety of different BIOSes out there, I have yet to find a CMOS RAM backup and restore program that worked on more than just a few specific systems.

You are better off manually recording your BIOS Setup parameters, or possibly connecting a printer to your system and using the Shift+Prts (Print Screen) function to print out each of the setup screens. Some shareware programs could print or even save and restore the BIOS Setup

settings stored in the CMOS RAM, but these were BIOS version specific and would not work on any system. Most of these programs were useful during the 286-386 era, but the increasing variety of newer systems, especially those with Plug-and-Play capabilities, have rendered most of these older programs useless.

Keyboard-Controller Chips

In addition to the main system ROM, older AT-class (286 and later) computers also have a keyboard controller or keyboard ROM, which is a keyboard-controller microprocessor with its own built-in ROM. This is often found in the Super I/O or South Bridge chips on most newer boards. The keyboard controller was originally an Intel 8042 microcontroller, which incorporates a microprocessor, RAM, ROM, and I/O ports. This was a 40-pin chip that often had a copyright notice identifying the BIOS code programmed into the chip. Modern motherboards have this function integrated into the chipset, specifically the Super I/O or South Bridge chips, so you won't see the old 8042 chip anymore.

The keyboard controller controls the reset and A20 lines and also deciphers the keyboard scan codes. The A20 line is used in extended memory and other protected-mode operations. In many systems, one of the unused ports is used to select the CPU clock speed. Because of the tie-in with the keyboard controller and protected-mode operation, many problems with keyboard controllers became evident on these older systems when upgrading from DOS to Windows 95/98, NT, or Windows 2000.

Problems with the keyboard controller were solved in most systems in the early 1990s, so you shouldn't have to deal with this issue in systems newer than that. With older systems, when you upgraded the BIOS in the system, the BIOS vendor often included a new keyboard controller.

Using a Flash BIOS

Virtually all PCs built since 1996 include a flash ROM to store the BIOS. A flash ROM is a type of EEPROM (Electrically Erasable Programmable Read-Only Memory) chip that you can erase and reprogram directly in the system without special equipment. Older EPROMs required a special ultraviolet light source and an EPROM programmer device to erase and reprogram them, whereas flash ROMs can be erased and rewritten without even removing them from the system.

Using flash ROM enables a user to download ROM upgrades from a Web site or to receive them on disk; you then can load the upgrade into the flash ROM chip on the motherboard without removing and replacing the chip. Normally, these upgrades are downloaded from the manufacturer's Web site, and then an included utility is used to create a bootable floppy with the new BIOS image and the update program. It is important to run this procedure from a boot floppy so that no other software or drivers are in the way that might interfere with the update. This method saves time and money for both the system manufacturer and the end user.

Sometimes the flash ROM in a system is write-protected, and you must disable the protection before performing an update, usually by means of a jumper or switch that controls the lock on the ROM update. Without the lock, any program that knows the right instructions can rewrite the ROM in your system—not a comforting thought. Without the write-protection, it is

conceivable that virus programs could be written that copy themselves directly into the ROM BIOS code in your system. Even without a physical write-protect lock, modern flash ROM BIOSes have a security algorithm that helps to prevent unauthorized updates. This is the technique that Intel uses on its motherboards.

Note that motherboard manufacturers will not notify you when they upgrade the BIOS for a particular board. You must periodically log in to their Web sites to check for updates. Normally, any flash updates are free.

Before proceeding with a BIOS upgrade, you must first locate and download the updated BIOS from your motherboard manufacturer. Consult the Vendor List on the CD to find the Web site address or other contact information for your motherboard manufacturer. Log in to their Web site and follow the menus to the BIOS updates page, and then select and download the new BIOS for your motherboard.

The BIOS upgrade utility is contained in a self-extracting archive file that can initially be downloaded to your hard drive, but it must be extracted and copied to a floppy before the upgrade can proceed. Different motherboard manufacturers have slightly different procedures and programs to accomplish a flash ROM upgrade, so it is best if you read the directions usually included with the update. I include instructions here for Intel motherboards because they are by far the most common.

The Intel BIOS upgrade utility will fit on a floppy disk and provides the capability to save, verify, and update the system BIOS. The upgrade utility also provides the capability to install alternative languages for BIOS messages and the SETUP utility.

The first step in the upgrade after downloading the new BIOS file is to enter the CMOS setup and write down your existing CMOS settings because they will be erased during the upgrade. Then you create a DOS boot floppy and uncompress or extract the BIOS upgrade files to the floppy from the file you downloaded. Then you reboot on the newly created upgrade disk and follow the menus for the actual reflash procedure.

Here is a step-by-step procedure for the process:

- 1.** Save your CMOS RAM setup configuration. You can do so by pressing the appropriate key during boot (F1 with an AMI BIOS, F2 with a Phoenix BIOS) and write down all your current CMOS settings. You may also be able to print the screens if you have a printer connected, using the PrtSc key on the keyboard. You will need to reset these settings after you have upgraded to the latest BIOS. Write down all settings that are unique to the system. These settings will be needed later to reconfigure the system. Pay special attention to any hard drive settings; these are very important. If you fail to restore these properly, you may not be able to boot from the drive or access the data on it.
- 2.** Exit the BIOS Setup and restart the system. Allow the system to fully start Windows and bring up a DOS prompt window or boot directly to a DOS prompt via the Windows Start menu (for example, press F8 when you see "Starting Windows," and select Command Prompt).

3. Place a floppy disk in the A: floppy drive and format the floppy using the /S option on the FORMAT command as follows:
C:\>FORMAT A: /S
4. Alternatively, if you have an otherwise blank preformatted floppy in the floppy drive, use the SYS command to make it bootable as follows:
C:\>SYS A:
5. The file you originally downloaded from the Intel Web site is a self-extracting compressed archive that includes other files that need to be extracted. Put the file in a temporary directory, then from within this directory, double-click the BIOS file you downloaded or type the file name of the file and press Enter. This causes the file to self-extract. For example, if the file you downloaded was called SEBIOS04.EXE (for the Intel SE440BX motherboard), you would enter the following command:
C:\TEMP>SEBIOS04 <enter>
6. The extracted files resulting from this should contain a file named BIOS.EXE and a software license text file. You then do another extract on the BIOS.EXE file to the bootable floppy you created using the following command:
C:\TEMP>BIOS A:
7. Now you can restart the system with the bootable floppy in drive A: containing the new BIOS files you just extracted. Upon booting from this disk, the IFLASH program will automatically start; press Enter when prompted.
8. Highlight Save Flash Memory Area to a File and press Enter. Follow the prompts to enter a filename. This creates a backup of your existing BIOS, which will be valuable should the new BIOS cause unexpected problems.
9. Highlight Update Flash Memory From a File and press Enter. Follow the prompts to select the name of the BIOS image file you will use to update the flash ROM. Press the Tab key to highlight the filename, and press Enter.
10. The system now gives a warning stating that continuing will destroy the current contents of the flash memory area. Press Enter to continue—the update should take about three minutes. Do not interrupt this procedure or the flash BIOS will be corrupted.
11. When you're told that the BIOS has been successfully loaded, remove the bootable floppy from the drive and press Enter to reboot the system.
12. Press F1 or F2 to enter Setup. On the first screen within SETUP, check the BIOS version to ensure that it is the new version.
13. In Setup, load the default values. If you have an AMI BIOS, press the F5 key; with a Phoenix BIOS, go to the Exit submenu and highlight Load Setup Defaults, and then press Enter.

Caution

If you do not set the values back to default, the system may function erratically.

14. If the system had unique settings, re-enter those settings now. Press F10 to save the values, exit Setup, and restart the system. Your system should now be fully functional with the new BIOS.

Note

If you encounter a CMOS checksum error or other problems after rebooting, try rebooting the system again. CMOS checksum errors require that you enter Setup, check and save your settings, and exit Setup a second time.

Flash BIOS Recovery

When you performed the flash reprogramming, you should have seen a warning message on the screen similar to the following:

The BIOS is currently being updated. DO NOT REBOOT OR POWER DOWN until the update is completed (typically within three minutes)...

If you fail to heed this warning or something interrupts the update procedure, you will be left with a system that has a corrupted BIOS. This means you will not be able to restart the system and redo the procedure, at least not easily. Depending on the motherboard, you may have to replace the flash ROM chip with one that was preprogrammed by the motherboard manufacturer because your board will be nonfunctional until a noncorrupted ROM is present. This is why I still keep my trusty ROM burner around; it is very useful for those motherboards with socketed flash ROM chips. In minutes, I can use the ROM burner to reprogram the chip and reinstall it in the board. If you need a ROM programmer, I recommend either Andromeda Research or Bytek (see the Vendor List on the CD).

In most systems today, the flash ROM is soldered into the motherboard so it cannot be replaced, rendering the reprogramming idea moot. However, this doesn't mean that the only way out is a complete motherboard replacement. Most motherboards with soldered-in flash ROMs have a special BIOS Recovery procedure that can be performed. This hinges on a special unerasable part of the flash ROM that is reserved for this purpose.

In the unlikely event that a flash upgrade is interrupted catastrophically, the BIOS may be left in an unusable state. Recovering from this condition requires the following steps. A minimum of a power supply, a speaker, and a floppy drive configured as drive A: should be attached to the motherboard for this procedure to work.

1. Change the Flash Recovery jumper to the recovery mode position. Virtually all Intel motherboards and many third-party motherboards have a jumper or switch for BIOS recovery, which is normally labeled "Recover/Normal." Figure 5.5 shows this jumper on the Intel SE440BX, a typical motherboard.
2. Install the bootable BIOS upgrade disk you previously created to do the flash upgrade into drive A: and reboot the system.

Because of the small amount of code available in the nonerasable flash boot block area, no video prompts are available to direct the procedure. In other words, you will see nothing on the screen. In fact, it is not even necessary for a video card to be connected for this

procedure to work. The procedure can be monitored by listening to the speaker and looking at the floppy drive LED. When the system beeps and the floppy drive LED is lit, the system is copying the BIOS recovery code into the flash device.

3. As soon as the drive LED goes off, the recovery should be complete. Power the system off.
4. Change the flash recovery jumper back to the default position for normal operation.

Figure 5.5 Typical Intel motherboard BIOS recovery jumper.

When you power the system back on, the new BIOS should be installed and functional. However, you might want to leave the BIOS upgrade floppy in drive A: and check to see that the proper BIOS version was installed.

Note

Note that this BIOS recovery procedure is often the fastest way to update a large number of machines, especially if you are performing other upgrades at the same time. This is how it is normally done in a system assembly or production environment.

Using IML System Partition BIOS

IBM and Compaq used a scheme similar to a flash ROM, called Initial Microcode Load (IML), in some of their older Pentium and 486 systems. IML is a technique in which the BIOS code is installed on the hard disk in a special hidden-system partition and is loaded every time the system is powered up. Of course, the system still has a core BIOS on the motherboard, but all that BIOS does is locate and load updated BIOS code from the system partition. This technique enabled Compaq and IBM to distribute ROM updates on disk for installation in the system partition. The IML BIOS is loaded every time the system is reset or powered on.

Along with the system BIOS code, the system partition contains a complete copy of the Setup and Diagnostics or Reference Disk, which provides the option of running the setup and system-configuration software at any time during a reboot operation. This option eliminates the need to boot from this disk to reconfigure the system and gives the impression that the entire Setup and Diagnostics or Reference Disk is contained in ROM.

One drawback to this technique is that the BIOS code is installed on the hard disk; the system cannot function properly without the correctly set-up hard disk connected. You always can boot from the Reference Disk floppy should the hard disk fail or become disconnected, but you cannot boot from a standard floppy disk.

Caution

This scheme makes hard drive updates problematic and causes all kinds of support nightmares. I recommend avoiding any system with an IML BIOS, especially if you are buying it used, because support for these types of configurations is hard to come by and not many people know how to deal with them.

Motherboard CMOS RAM Addresses

In the original AT system, a Motorola 146818 chip was used as the RTC (real-time clock) and CMOS (complementary metal-oxide semiconductor) RAM chip. This is a special chip that had a simple digital clock that used 10 bytes of RAM and an additional 54 more bytes of leftover RAM in which you could store anything you wanted. The designers of the IBM AT used these extra 54 bytes to store the system configuration.

Modern PC systems don't use the Motorola chip; instead, they incorporate the functions of this chip into the motherboard chipset (South Bridge) or Super I/O chip, or they use a special battery and NVRAM (nonvolatile RAM) module from companies such as Dallas or Benchmarq.

Table 5.6 shows the standard format of the information stored in the 64-byte standard CMOS RAM module. This information controls the configuration of the system and is read and written by the system setup program.

Table 5.6 AT CMOS RAM Addresses

Offset Hex	Offset Dec	Field Size	Function
00h	0	1 byte	Current second in binary coded decimal (BCD)
01h	1	1 byte	Alarm second in BCD
02h	2	1 byte	Current minute in BCD
03h	3	1 byte	Alarm minute in BCD
04h	4	1 byte	Current hour in BCD
05h	5	1 byte	Alarm hour in BCD
06h	6	1 byte	Current day of week in BCD
07h	7	1 byte	Current day in BCD
08h	8	1 byte	Current month in BCD
09h	9	1 byte	Current year in BCD
0Ah	10	1 byte	Status register A Bit 7 = Update in progress 0 = Date and time can be read 1 = Time update in progress Bits 6-4 = Time frequency divider 010 = 32.768KHz Bits 3-0 = Rate selection frequency 0110 = 1.024KHz square wave frequency

15h	21	1 byte	Base memory low-order byte
16h	22	1 byte	Base memory high-order byte
17h	23	1 byte	Extended memory low-order byte
18h	24	1 byte	Extended memory high-order byte
19h	25	1 byte	Hard Disk 0 Extended Type (0-255)
1Ah	26	1 byte	Hard Disk 1 Extended Type (0-255)
1Bh	27	9 bytes	Reserved
2Eh	46	1 byte	CMOS checksum high-order byte
2Fh	47	1 byte	CMOS checksum low-order byte
30h	48	1 byte	Actual extended memory low-order byte
31h	49	1 byte	Actual extended memory high-order byte
32h	50	1 byte	Date century in BCD

(continues)

Table 5.6 Continued

Offset Hex	Offset Dec	Field Size	Function
33h	51	1 byte	POST information flag Bit 7 = Top 128KB base memory status 0 = Top 128KB base memory not installed 1 = Top 128KB base memory installed Bit 6 = Setup program flag 0 = Normal (default) 1 = Put out first user message Bits 5-0 = Reserved
34h	52	2 bytes	Reserved

Note that many newer systems have more than 64 bytes of CMOS RAM; in fact, in some systems they may have 2KB or 4KB. The extra room is used to store the Plug-and-Play information detailing the configuration of adapter cards and other options in the system. As such, no 100% standard exists for how CMOS information is stored in all systems. Table 5.6 shows only how the original systems did it; newer BIOS versions and motherboard designs can do things differently. You should consult the BIOS manufacturer for more information if you want the full details of how CMOS is stored as the CMOS configuration and the setup program is normally a part of the BIOS. This is another example of how close the relationship is between the BIOS and the motherboard hardware.

Backup programs and utilities are in the public domain for CMOS RAM information, which can be useful for saving and later restoring a configuration. Unfortunately, these programs are BIOS specific and would only function on a BIOS for which they are designed. As such, I don't normally rely on these programs because they are too motherboard- and BIOS-specific and will not work seamlessly on all my systems.

Table 5.7 shows the values that may be stored by your system BIOS in a special CMOS byte called the diagnostics status byte. By examining this location with a diagnostics program, you can determine whether your system has set trouble codes, which indicate that a problem previously has occurred.

Table 5.7 CMOS RAM Diagnostic Status Byte Codes

Bit Number	7	6	5	4	3	2	1	0	Hex	Function
1	•	•	•	•	•	•	•	•	80	Real-time clock (RTC) chip lost power
•	1	•	•	•	•	•	•	•	40	CMOS RAM checksum is bad
•	•	1	•	•	•	•	•	•	20	Invalid configuration information found at POST
•	•	•	1	•	•	•	•	•	10	Memory size compare error at POST
•	•	•	•	1	•	•	•	•	08	Fixed disk or adapter failed initialization
•	•	•	•	•	1	•	•	•	04	Real-time clock (RTC) time found invalid
•	•	•	•	•	•	•	1	•	02	Adapters do not match configuration
•	•	•	•	•	•	•	•	1	01	Time-out reading an adapter ID
•	•	•	•	•	•	•	•	•	00	No errors found (Normal)

If the Diagnostic status byte is any value other than zero, you will normally get a CMOS configuration error on bootup. These types of errors can be cleared by rerunning the setup program.

Replacing a BIOS ROM

Systems dating from 1995 or earlier usually won't have a flash ROM and instead will use an EPROM. To upgrade the BIOS in one of these systems is to replace the EPROM chip with a new one preloaded with the new BIOS. As with a flash ROM upgrade, you must get this from your motherboard manufacturer. There is usually a fee for this because they will have to custom burn a chip just for you and mail it out. Most boards older than 1995 are probably not worth upgrading the BIOS on, so weigh this option carefully! It doesn't make sense to spend \$50 on a new BIOS for an ancient board when a new Pentium or Pentium II board can be had for \$75, and that new board will include a flash BIOS and many other new features.

To replace the BIOS chip, follow these steps:

1. Back up the CMOS RAM settings.
2. Power the system down and unplug the power cord.
3. Remove the cover and any other components in the way of the BIOS EPROM chip. Remember to use caution with respect to static discharges; it is a good idea to wear an anti-static wrist strap for this procedure, or ground yourself to the chassis before touching any internal components.
4. Using a chip puller or a thin flat-blade screwdriver, gently pry the chip out of its socket.
5. Remove the new EPROM from the anti-static packing material it came in.
6. Install the new EPROM chip into the socket.
7. Reinstall anything you removed to gain access to the chip.
8. Put the cover back on, plug the system in, and power on.
9. Enter the BIOS setup information you saved earlier.
10. Reboot and enjoy the new BIOS!

As you can see, things are much easier with a modern motherboard with a flash ROM because normally you don't even have to remove the lid.

CMOS Setting Specifications

Running or Accessing the CMOS Setup Program

If you want to run the BIOS Setup program, you usually have to reboot and press a particular key or key combination during the POST. The major vendors have standardized the following key-strokes to enter the BIOS Setup:

- *AMI BIOS*. Press Delete during POST.
- *Phoenix BIOS*. Press F2 during POST.
- *Award BIOS*. Press Delete or Ctrl+Alt+Esc during POST.
- *Microid Research BIOS*. Press Esc during POST.

If your system will not respond to one of these common keystroke settings, you may have to contact the manufacturer or read the system documentation to find the correct keystrokes.

Some unique ones are as follows:

- *IBM Aptiva/Valuepoint*. Press F1 during POST.
- *Older Phoenix BIOS*. Boot to a safe mode DOS command prompt, and then press Ctrl+Alt+Esc or Ctrl+Alt+S.
- *Compaq*. Press F10 during POST.

After you are in the BIOS Setup main screen, you'll usually find a main menu allowing access to other menus and submenus of different sections or screens. Using the Intel SE440BX-2 motherboard as an example (one of the most popular motherboards in the world) we will go through all the menus and submenus of this typical motherboard. Although other motherboards may feature slightly different settings, most will be very similar.

BIOS Setup Menus

Most modern BIOSes offer a menu bar at the top of the screen when you're in the BIOS Setup that controls navigation through the various primary menus. A typical menu bar offers the choices shown in Table 5.8.

Note

Because most common BIOSes use similar settings, I've chosen the Phoenix BIOS—used by all modern Intel motherboards—to use as an example in the following tables. If your machine uses another BIOS—AMI, Award, or a proprietary BIOS—these settings will be different. These settings will, however, help you get a general idea of the type of settings to expect and how the BIOS Setup settings affect your computer.

Table 5.8 Typical BIOS Setup Menus*

Setup Menu Screen	Description
Maintenance	Specifies the processor speed and clears the setup passwords. This menu is only available in Configure mode, set by a jumper on the board.
Main	Allocates resources for hardware components.
Advanced	Specifies advanced features available through the chipset.
Security	Specifies passwords and security features.
Power	Specifies power management features.
Boot	Specifies boot options and power supply controls.
Exit	Saves or discards changes to the setup program options.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Choosing each of these selections takes you to another menu with more choices. We'll examine all the choices available in a typical motherboard, such as the Intel SE440BX-2.

Maintenance Menu

The Maintenance menu is a special menu for setting the processor speed and clearing the setup passwords. Older motherboards used jumpers to configure the processor bus speed (motherboard speed) and processor multiplier. Most newer boards from Intel and others now offer this control via the BIOS Setup rather than moving jumpers. In the case of Intel, one jumper still remains on the board called the configuration jumper, which must be set to Configure mode for the Maintenance menu to be available.

Setup displays this menu only if the system is set in Configure mode. To set Configure mode, power the system off and move the configuration jumper on the motherboard from *Normal* to *Configure* (see Figure 5.5 earlier in this chapter). Because this is the only jumper on a modern Intel board, it is pretty easy to find. When the system is powered back on, the BIOS Setup automatically runs, and you will be able to select the Maintenance menu shown in Table 5.9. After making changes and saving, power the system off and reset the jumper to Normal mode for normal operation.

Table 5.9 Typical Maintenance Menu Settings*

Feature	Options	Description
Processor Speed	233	Specifies the processor speed in megahertz. This setup screen shows only speeds up to and including the maximum speed of the processor installed on the motherboard.
	266	
	300	
	333	
	350	
	400	
	450	
	500	
	550	
Clear All Passwords	No options	Clears the user and supervisor passwords.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Note that most newer Intel processors are designed to allow operation only at or below their rated speed, whereas others allow higher-than-rated speeds to be selected.

If users forget their password, all they have to do is set the configuration jumper, enter the Maintenance menu in BIOS Setup, and use the option provided to clear the password. This function will not tell the user what the password was; it will simply clear it, allowing a new one to be set if desired. This means the security is only as good as the lock on the system case because anybody who can get to the configuration jumper can clear the password and access the system. This is why most better cases come equipped with locks.

Main Menu

The standard CMOS Setup menu dates back to the 286 days, when the complete BIOS Setup consisted of only one menu. In the standard menu you can set the system clock, record hard disk and floppy drive parameters and the basic video type. Newer BIOSes have more complicated setups with more menus and submenus, so the main menu often is fairly sparse compared to older systems.

The main menu in a modern system reports system information such as the BIOS version, the processor type and speed, the amount of memory, and whether the memory or cache is configured for ECC functionality. The main menu also can be used to set the system date and time.

Table 5.10 shows a typical main menu.

Table 5.10 Typical Main Menu Settings*

Feature	Options	Description
BIOS Version	No options	Displays the version of the BIOS.
Processor Type	No options	Displays the processor type.
Processor Speed	No options	Displays the processor speed.
System Memory	No options	Displays the total amount of RAM on the motherboard.
Memory Bank 0	No options	Displays size and type of DIMM installed in each memory bank.
Memory Bank 1		
Memory Bank 2		
Language	English (default) Italian Francais Deutch Espanol	Selects the default language used by the BIOS.
ECC Configuration	Non-ECC (default) ECC	Specifies ECC memory operation.
L2 cache ECC Support	Disabled (default) Enabled	Enabled allows error checking to occur on data accessed from L2 cache. This option will not appear when using processors that have L2 cache ECC permanently enabled.
System Time	Hour, minute, second	Specifies the current time.
System Date	Month, day, year	Specifies the current date.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

ECC stands for Error Correcting Code, which is the use of extra bits on the memory modules to detect and even correct memory errors on-the-fly. For ECC to be enabled, more expensive ECC DIMMs would have to be installed in the system. Note that all DIMMs would need to be ECC versions for this to work; if only one is non-ECC, then ECC cannot be enabled. I highly recommend purchasing ECC memory and enabling this function because it makes the system much more fault tolerant and will prevent corrupted data due to soft errors in memory. Random memory errors will occur at the rate of 1 bit error per month for every 64 to 256 megabytes installed. ECC ensures that these errors will not creep into your data files, corrupt the system, or cause it to crash.

▶▶ See “ECC (Error Correcting Code),” p. 464.

Most older BIOSes report memory as base and extended memory instead of as a single value. Base memory is typically 640KB and is sometimes called conventional memory. Extended memory is that which is beyond the first megabyte in the system.

Note that you cannot change any values in the memory fields; they are only for your information because they are automatically counted up by the system. If the memory count doesn't match what you have installed, a problem has likely occurred with some of the memory; it is defective, not fully seated or properly installed, or it is a type that is incompatible with your system.

Advanced Menu

The Advanced menu is for setting advanced features that are available through the motherboard chipset. This part of your BIOS setup is specific to the particular chipset the motherboard uses. Many different chipsets are available on the market today, and each has unique features. The chipset setup is designed to allow the user to customize these features and control some of the chipset settings. Right now, one of the most popular chipsets is the Intel 440BX chipset. Table 5.11 shows the typical BIOS chipset settings for a board with a 440BX chipset.

Table 5.11 Typical Advanced Menu Settings*

Feature	Options	Description
Plug-and-Play O/S	No (default) Yes	Specifies whether a plug-and-play operating system is being used. No—lets the BIOS configure all devices. Yes—lets the operating system configure Plug-and-Play devices. Not required with a Plug-and-Play operating system.
Reset Configuration Data	No (default) Yes	Clears the Plug-and-Play BIOS configuration data on the next boot.
Numlock	Auto (default) On Off	Specifies the power-on state of the Num Lock feature on the numeric keypad of the keyboard.
Peripheral Configuration	No options	Configures peripheral ports and devices. When selected, displays the Peripheral Configuration submenu.
IDE Configuration	No options	Specifies type of connected IDE device.
Floppy Configuration	No options	When selected, displays the Floppy Options submenu.
DMI Events Logging	No options	Configures DMI Events Logging. When selected, displays the DMI Events Logging submenu.
Video Configuration	No options	Configures video features. When selected, displays the Video Configuration submenu.
Resource Configuration	No options	Configures memory blocks and IRQs for legacy ISA devices. When selected, displays the Resource Configuration submenu.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

The Plug-and-Play OS setting is important mainly if you are not using a plug-and-play operating system, such as Windows NT. In that case, you should set that function to No, which will allow the Plug-and-Play BIOS to configure the devices.

Even if this function is set to No, if a Plug-and-Play operating system such as Windows 95/98 or Windows 2000 is used, the operating system will override and reconfigure any settings configured by the BIOS. To speed system boot time, if a Plug-and-Play operating system is being used, you can set this function to Yes, which eliminates the BIOS configuration step.

The Reset Configuration Data setting is a one-time setting that causes the ESCD (Enhanced System Configuration Data) plug-and-play data stored in CMOS RAM to be wiped out at the next boot time. The setting defaults back to No after the next boot. This is useful if the settings in CMOS don't match those stored in the cards themselves, which can happen, for example, if a previously configured card is moved from one system to another, or even from one slot to another in the same system. This can cause the plug-and-play BIOS to become confused; resetting the plug-and-play data in CMOS will help clear up this type of problem.

Additional Advanced Features

Many boards differ in the advanced chipset menus. In most cases, unless you know exactly which chipset and what type of memory and other items are found in your system, it is best to leave these settings on Auto. In that case, the modern boards will use the configuration ROM found on the DIMM memory modules to properly configure the memory settings. In fact, most newer boards no longer allow these settings to be manually adjusted because, in most cases, all it will do is lead to trouble in the form of an unstable or failing system. If you do want to play with these settings, I recommend first finding out exactly what memory modules and chipset you have and contacting the manufacturers of them to get their databooks. The databooks have all the technical information related to those devices.

Table 5.12 lists some additional settings you may find on some boards.

Table 5.12 Additional Advanced Features Settings*

Auto Configuration	Selects predetermined optimal values of chipset parameters. When Disabled, chipset parameters revert to setup information stored in CMOS. Many fields in this screen are not available when Auto Configuration is Enabled.
EDO DRAM Speed Selection	The value in this field must correspond to the speed of the EDO DRAM installed in your system. This value is access speed, so a lower value means a faster system.
SDRAM RAS-to-CAS Delay	This field lets you control the number of cycles between a Row Activate command and a read or write command.
SDRAM RAS Precharge Time	The precharge time is the number of cycles it takes for the RAS to accumulate its charge before DRAM refresh. If insufficient time is allowed, refresh may be incomplete, and the DRAM may fail to retain data.
SDRAM CAS Latency Time	When synchronous DRAM is installed, you can control the number of cycles between when the SDRAMs sample a read command and when the controller samples read data from the SDRAMs.
SDRAM Precharge Control	When Enabled, all CPU cycles to SDRAM result in an All Banks Precharge Command on the SDRAM interface.
DRAM Data Integrity Mode	Select Non-ECC or ECC (error-correcting code) according to the type of installed DRAM. ECC allows for single-bit error correction and multibit error detection at a slight speed penalty to the system.
System BIOS Cacheable	Allows caching of the system BIOS ROM at F0000h-FFFFFh, resulting in better system performance. If any program writes to this memory area, a system error may result.
Video BIOS Cacheable	Allows caching of the video BIOS ROM at C0000h to C7FFFh, resulting in better video performance. If any program writes to this memory area, a system error may result.

Video RAM Cacheable	Selecting Enabled allows caching of the video memory (RAM) at A0000h to AFFFFh, resulting in better video performance. If any program writes to this memory area, a memory access error may result.
8/16 Bit I/O Recovery Time	The I/O recovery mechanism adds bus clock cycles between PCI-originated I/O cycles to the ISA bus. This delay takes place because the PCI bus is so much faster than the ISA bus.
Memory Hole at 15M-16M	Places a 1MB empty RAM area between 15MB and 16MB. Older software sometimes would not run with 16MB or more memory in the system; enabling this provides a workaround. This is normally not used.
Passive Release	When Enabled, CPU to PCI bus accesses are allowed during passive release. Otherwise, the arbiter only accepts another PCI master access to local DRAM.
Delayed Transaction	The chipset has an embedded 32-bit posted write buffer to support delay transactions cycles. Select Enabled to support compliance with PCI specification version 2.1.
AGP Aperture Size (MB)	Select the size of the Accelerated Graphics Port (AGP) aperture. The aperture is a portion of the PCI memory address range dedicated for graphics memory address space. Host cycles that hit the aperture range are forwarded to the AGP without any translation.
CPU Warning Temperature	Select the combination of lower and upper limits for the CPU temperature if your computer contains an environmental monitoring system. If the CPU temperature extends beyond either limit, any warning mechanism programmed into your system is activated.
Current CPU Temperature	This field displays the current CPU temperature if your computer contains an environmental monitoring system.
Shutdown Temperature	Select the combination of lower and upper limits for the system shutdown temperature if your computer contains an environmental monitoring system. If the temperature extends beyond either limit, the system shuts down.
CPUFAN Turn On IN Win98	If you are running Windows 98, which supports ACPI, selecting Enabled gives the user a cooling choice at runtime. The user can run with the CPU fan turned on or off, depending on deciding factors such as CPU activity, battery power consumption, and noise tolerance.
Current System Temperature	This field displays the current system temperature if your computer contains a monitoring system.
Current CPUFAN 1/2/3 Speed	These fields display the current speed of up to three CPU fans if your computer contains a monitoring system.
IN0-IN6(V)	These fields display the current voltage of up to seven voltage input lines if your computer contains a monitoring system.
Spread Spectrum	When the system clock generator pulses, the extreme values of the pulse generate excess EMI. Enabling pulse spectrum spread modulation changes the extreme values from spikes to flat curves, thus reducing EMI. This benefit may in some cases be outweighed by problems with timing-critical devices, such as a clock-sensitive SCSI device.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Peripheral Configuration

The Peripheral Configuration menu is used to configure the devices built into the motherboard, such as serial ports, parallel ports, and built-in audio and USB ports.

Table 5.13 shows a typical Peripheral Configuration menu and choices.

Table 5.13 Typical Peripheral Configuration Menu*

Feature	Options	Description
Serial port A	Disabled Enabled Auto (default)	Configures serial port A. Auto-assigns the first free COM port, normally COM 1, the address 3F8h, and the interrupt IRQ4. An asterisk (*) displayed next to an address indicates a conflict with another device.
Base I/O address	3F8 (default) 2F8 3E8 2E8	Specifies the base I/O address for serial port A.
Interrupt	IRQ 3 IRQ 4 (default)	Specifies the interrupt for serial port A.
Serial port B	Disabled Enabled Auto (default)	Configures serial port B. Auto-assigns the first free COM port, normally COM 2, the address 2F8h, and the interrupt IRQ3. An asterisk (*) displayed next to an address indicates a conflict with another device. If either serial port address is set, that address will not appear in the list of options for the other serial port. If an ATI mach32 or an ATI mach64 video controller is active as an add-in card, the COM4, 2E8h address will not appear in the list of options for either serial port.
Mode	Normal IrDA (default)	Specifies the mode for serial port B for normal (COM 2) or infrared applications.
Base I/O address	3F8 2F8 (default) 3E8 2E8	Specifies the base I/O address for serial port B.
Interrupt	IRQ 3 IRQ 4 (default)	Specifies the interrupt for serial port B.
Parallel port	Disabled Enabled Auto (default)	Configures the parallel port. Auto assigns LPT1 the address 378h and the interrupt IRQ7. An asterisk (*) displayed next to an address indicates a conflict with another device.
Mode	Output Only Bidirectional (default) EPP ECP	Selects the mode for the parallel port. Output Only operates in AT-compatible mode. Bidirectional operates in bidirectional PS/2-compatible mode. EPP is Extended Parallel Port mode, a high-speed bidirectional mode. ECP is Enhanced Capabilities Port mode, a high-speed bidirectional mode.
Base I/O address	378 (default) 278 228	Specifies the base I/O address for the parallel port.
Interrupt	IRQ 5 IRQ 7 (default)	Specifies the interrupt for the parallel port.
Audio	Disabled Enabled (default)	Enables or disables the onboard audio subsystem.
Legacy USB Support	Disabled (default) Enabled	Enables or disables USB legacy support. USB legacy support allows support for USB keyboards and mice even though no operating system drivers have been loaded.

*Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.

I recommend disabling serial and parallel ports if they are not being used because this will free up those resources (especially interrupts that are in high demand) for other devices.

Legacy USB support means support for USB keyboards and mice. If you are using USB keyboards and mice, you will find that the keyboard will not be functional until a USB-aware operating system is loaded. This can be a problem when running DOS, diagnostics software, or other applications that run outside of USB-aware operating systems such as Windows 98 and Windows 2000. In that case, you should enable the USB legacy support via this menu.

Even with legacy support disabled, the system will still recognize a USB keyboard and enable it to work during the POST and BIOS Setup. With USB legacy support in the default (disabled) mode, the system will operate as follows:

1. When you power up the computer, USB legacy support is disabled.
2. POST begins.
3. USB legacy support is temporarily enabled by the BIOS. This allows you to use a USB keyboard to enter the setup program or the Maintenance mode.
4. POST completes and disables USB legacy support (unless it was set to Enabled while in Setup).
5. The operating system loads. While the operating system is loading, USB keyboards and mice are not recognized. After the operating system loads the USB drivers, the USB devices are recognized.

To install an operating system that supports USB, enable USB legacy support in BIOS Setup and follow the operating system's installation instructions. After the operating system is installed and the USB drivers are configured, USB legacy support is no longer used, and the operating system USB drives will take over. However, I recommend that you leave legacy support enabled so the USB keyboard will function in DOS while running self-booting or DOS based diagnostics, or when running other non-USB-aware operating systems.

Note that if USB legacy support is enabled, you shouldn't mix USB and PS/2 port keyboards and mice. For example, don't use a PS/2 keyboard with a USB mouse or a USB keyboard and a PS/2 mouse. Also remember that this legacy support is for keyboards and mice only; it will not work for USB hubs or other USB devices. For devices other than keyboards or mice to work, you will need a USB-aware operating system with the appropriate USB drivers.

IDE Configuration Menu

The IDE Configuration menu is for configuring IDE devices such as hard drives, CD-ROM drives, LS-120 (SuperDisk) drives, tape drives, and so on. Table 5.14 shows the IDE configuration menu and options for a typical modern motherboard.

Table 5.14 Typical IDE Configuration Menu Settings*

Feature	Options	Description
IDE Controller	Disabled Primary Secondary Both (default)	Specifies the integrated IDE controller. Primary enables only the Primary IDE Controller. Secondary enables only the Secondary IDE Controller. Both enables both IDE controllers.
Hard Disk Pre-Delay	Disabled (default) 3 Seconds 6 Seconds 9 Seconds 12 Seconds 15 Seconds 21 Seconds 30 Seconds	Specifies the hard disk drive pre-delay.
Primary IDE Master	No options	Reports type of connected IDE device. When selected, displays the Primary IDE Master submenu.
Primary IDE Slave	No options	Reports type of connected IDE device. When selected, displays the Primary IDE Slave submenu.
Secondary IDE Master	No options	Reports type of connected IDE device. When selected, displays the Secondary IDE Master submenu.
Secondary IDE Slave	No options	Reports type of connected IDE device. When selected, displays the Secondary IDE Slave submenu.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

The hard disk pre-delay function is to delay accessing drives that are slow to spin up. Some drives aren't ready when the system begins to look for them during boot, causing the system to display Fixed Disk Failure messages and fail to boot. By setting this delay, it allows time for the drive to become ready before continuing the boot. Of course, this slows down the boot process, so if your drives don't need this delay, it should be disabled.

IDE Configuration Submenus

These submenus are for configuring each IDE device, including primary and secondary masters and slaves.

Of all the BIOS Setup menus, the hard disk settings are by far the most important. In fact, they are the most important of all the BIOS settings. Most modern motherboards incorporate two IDE controllers that support up to four drives. Most modern BIOSes have an autodetect feature that allows for automatic configuration of the drives. If this is available, in most cases you should use it because it will prevent confusion in the future. With the auto setting, the BIOS sends a special Identify Drive command to the drive, which responds with information about the correct settings. From this, the BIOS can automatically detect the specifications and optimal operating mode of almost all IDE hard drives. When you select type AUTO for a hard drive, the BIOS redetects the drive specifications during POST, every time the system boots. You could swap drives with the power off, and the system would automatically detect the new drive the next time it was turned on.

In addition to the Auto setting, most older BIOSes offered a standard table of up to 47 drive types with specifically prerecorded parameters. Each defined drive type has a specified number of cylinders, number of heads, write precompensation factor, landing zone, and number of sectors. This was often used many years ago, but it is rarely used today because virtually no drives will conform to the parameters on these drive type lists.

Another option is to select a setting called User or User Defined, which is where you can enter the specific drive CHS (Cylinder, Head, and Sector) parameters into the proper fields. These parameters are saved in the CMOS RAM and reloaded every time the system is powered up.

Most BIOSes today offer control over the drive translation settings if the type is set to User and not Auto. Normally, two translation settings are available, called Standard and LBA. Standard or LBA-disabled is used only for drives of 528MB or less, where the maximum number of cylinders, heads, and sectors are 1,024, 16, and 63, respectively. Because most drives today are larger, this setting is rarely used.

LBA (Logical Block Addressing) is used for virtually all drives that are larger than 528MB. Note that systems dating from 1997 and earlier are usually limited to a maximum drive size of 8.4GB unless they have a BIOS upgrade. Systems from 1998 and later will usually support drives up to 136.9GB. During drive accesses, the IDE controller transforms the data address described by sector, head, and cylinder number into a physical block address, significantly improving data transfer rates.

Table 5.15 shows the IDE drive settings found in a typical modern motherboard BIOS.

Table 5.15 Typical IDE Drive Settings*

Feature	Options	Description
Type	None ATAPI Removable Other ATAPI CD-ROM User IDE Removable Auto (default)	Specifies the IDE Configuration mode for IDE devices. Auto automatically fills in the transfer mode values. Other options are device dependent.
Maximum Capacity	No options	Reports the maximum capacity for the hard disk.
Multi-Sector Transfers	Disabled 2 Sectors 4 Sectors 8 Sectors 16 Sectors	Specifies number of sectors per block for transfers from the hard drive to memory. Check the hard drive's specifications for optimum setting.
LBA Mode Control	Disabled Enabled	Enables or disables the LBA mode control.
Transfer Mode	Standard Fast PIO 1 Fast PIO 2 Fast PIO 3 Fast PIO 4 FPIO 3/DMA 1 FPIO 4/DMA 2	Specifies the method for moving data to/from the drive.

(continues)

Table 5.15 Continued

Feature	Options	Description
Ultra DMA	Disabled Mode 0 Mode 1 Mode 2	Specifies the Ultra DMA mode for the drive.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Setting the drive type to Auto causes the other values to be automatically configured correctly. I recommend this for virtually all standard system configurations. When set to Auto, the BIOS sends an Identify command to the drive, causing it to report back all the options and features found on that drive. Using this information, the BIOS then automatically configures all the settings on this menu for maximum performance with that drive, including selecting the fastest possible transfer modes and other features.

For hard drives, the only option available other than Auto is User. When set to User, the other choices are made available and are not automatically set. This can be useful for somebody who wishes to “play” with these settings, but in most cases, all you will get by doing so is lower performance and possibly even trouble in the form of corrupted data or a nonfunctional drive.

Floppy Options

The Floppy Options submenu is for configuring the floppy drive and interface. Table 5.16 shows the options in a typical BIOS Setup.

Table 5.16 Typical Floppy Drive and Interface Settings*

Feature	Options	Description
Floppy Disk Controller	Disabled Enabled (default) Auto	Disables or enables the integrated floppy disk drive controller.
Diskette A:	Disabled 360KB, 5 1/4-inch 1.2MB, 5 1/4-inch 720KB, 3 1/2-inch 1.44MB, 3 1/2-inch (default) 2.88MB, 3 1/2-inch	Specifies the capacity and physical size of floppy disk drive A:.
Floppy Write Protect	Disabled (default) Enabled	Disables or enables write protect for floppy disk drive A:.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

By enabling the write-protect feature, you can disallow writing to floppy disks. This can help prevent the theft of data as well as helping to prevent infecting disks with viruses should they be on the system.

DMI Event Logging

The DMI menu is for configuring the DMI event logging features. DMI stands for Desktop Management Interface, a special protocol that software can use to communicate with the motherboard.

Using DMI, a system administrator can remotely obtain information about a system. Applications such as the Intel LANDesk Client Manager can use DMI to report the following DMI information:

- BIOS data, such as the BIOS revision level
- System data, such as installed peripherals, serial numbers, and asset tags
- Resource data, such as memory size, cache size, and processor speed
- Dynamic data, such as event detection including chassis intrusion detection and ECC error logging

Table 5.17 shows a typical DMI menu in BIOS Setup.

Table 5.17 Typical DMI Menu*

Feature	Options	Description
Event log capacity	No options	Indicates whether space is available in the event log.
Event log validity	No options	Indicates whether contents of the event log are valid.
View DMI event log	No options	Enables viewing of DMI event log.
Clear all DMI event logs	No (default) Yes	Clears the DMI event log after rebooting.
Event Logging	Disabled Enabled (default)	Enables logging of DMI events.
ECC Event Logging	Disabled Enabled (default)	Enables logging of ECC events.
Mark DMI events as read	No options	Marks all DMI events as read.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

I find DMI particularly useful for tracking errors such as ECC errors. Using the View Log feature, you can see whether any errors have been detected (and corrected) by the system.

Video Configuration

The Video Configuration menu is for configuring video features. Table 5.18 shows the functions of this menu in a typical modern motherboard BIOS.

Table 5.18 Typical Video Configuration Menu*

Feature	Options	Description
Palette Snooping	Disabled (default) Enabled	Controls the capability of a primary PCI graphics controller to share a common palette with an ISA add-in video card.
AGP Aperture Size	64MB (default) 256MB	Specifies the aperture size for the AGP video controller.
Default Primary Video Adapter	PCI AGP (default)	Selects the type of video card used for the boot display device.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

The most common use of this menu is to change the primary video device. This is useful under Windows 98 and Windows 2000, which support dual monitor configurations. Using this feature, you can set either the AGP or PCI video card to be the primary boot device.

Resource Configuration

The Resource Configuration menu is used for configuring the memory and interrupt usage of non-plug-and-play (legacy) ISA bus-based devices. Table 5.19 shows the functions and options found in a typical modern BIOS.

Table 5.19 Typical Resource Configuration Menu*

Feature	Options	Description
Memory Reservation	C800 CBFF Available (default) Reserved CC00 CFFF Available (default) Reserved D000 D3FF Available (default) Reserved D400 D7FF Available (default) Reserved D800 DBFF Available (default) Reserved DC00 DFFF Available (default) Reserved	Reserves specific upper memory blocks for use by legacy ISA devices.
IRQ Reservation	IRQ3 Available (default) Reserved IRQ4 Available (default) Reserved IRQ5 Available (default) Reserved IRQ7 Available (default) Reserved IRQ10 Available (default) Reserved IRQ11 Available (default) Reserved	Reserves specific IRQs for use by legacy ISA devices. An asterisk (*) displayed next to an IRQ indicates an IRQ conflict.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Note that these settings are only for legacy (non–plug-and-play) ISA devices. For all Plug-and-Play ISA devices as well as PCI devices (which are Plug and Play by default), these resources are instead configured by the operating system or by software that comes with the cards.

Setting these resources here does not actually control the legacy ISA device; that usually must be done by moving jumpers on the card. By setting the resource as reserved here, you are telling the Plug-and-Play operating system that the reserved resources are off-limits, so it won't accidentally set a Plug-and-Play device to use the same resource as a legacy ISA device. Reserving resources in this manner is sometimes required because the Plug-and-Play software cannot detect all legacy ISA devices and therefore won't know what settings the device may be using.

In a system with no legacy devices, it is not necessary to reserve any resources via this menu.

Some boards have additional configuration options for the Plug and Play (PnP) BIOS features as well as the PCI bus. These features are largely chipset dependent, but some common examples are shown in Table 5.20.

Table 5.20 Typical PnP and PCI Options*

DMA n Assigned to	When resources are controlled manually, assign each system DMA channel as one of the following types, depending on the type of device using the interrupt: <ul style="list-style-type: none"> ■ Legacy ISA devices compliant with the original PC AT bus specification, requiring a specific DMA channel ■ PCI/ISA PnP devices compliant with the Plug-and-Play standard, whether designed for PCI or ISA bus architecture.
PCI IRQ Activated by	Leave the IRQ trigger set at Level unless the PCI device assigned to the interrupt specifies edge-triggered interrupts.
PCI IDE IRQ Map to	This field enables you to select PCI IDE IRQ mapping or PC AT (ISA) interrupts. If your system does not have one or two PCI IDE connectors on the system board, select values according to the type of IDE interface(s) installed in your system (PCI or ISA). Standard ISA interrupts for IDE channels are IRQ14 for primary and IRQ15 for secondary.
Primary/Secondary IDE INT#	Each PCI peripheral connection is capable of activating up to four interrupts: INT# A, INT# B, INT# C and INT# D. By default, a PCI connection is assigned INT# A. Assigning INT# B has no meaning unless the peripheral device requires two interrupt services rather than just one. Because the PCI IDE interface in the chipset has two channels, it requires two interrupt services. The primary and secondary IDE INT# fields default to values appropriate for two PCI IDE channels, with the primary PCI IDE channel having a lower interrupt than the secondary. Note that all single-function PCI cards normally use INT# A, and each of these must be assigned to a different and unique ISA interrupt request (IRQ).
Used Mem base addr	Select a base address for the memory area used by any peripheral that requires high memory.
Used Mem Length	Select a length for the memory area specified in the previous field. This field does not appear if no base address is specified.
Assign IRQ for USB	Select Enabled if your system has a USB controller and you have one or more USB devices connected. If you are not using your system's USB controller, select Disabled to free the IRQ resource.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Security Menu

Most BIOSes include two passwords for security, called the Supervisor and User passwords. These passwords help control who is allowed to access the BIOS Setup program and who is allowed to boot the computer. The supervisor password is also called a setup password because it controls access to the setup program. The user password is also called a system password because it controls access to the entire system.

If a supervisor password is set, a password prompt is displayed when an attempt is made to enter the BIOS Setup menus. When entered correctly, the supervisor password gives unrestricted access to view and change all the Setup options in the Setup program. If the supervisor password is not entered or is entered incorrectly, access to view and change Setup options in the Setup program will be restricted.

If the user password is set, the password prompt is displayed before the computer boots up. The password must be entered correctly before the system is allowed to boot. Note that if only the supervisor password is set, the computer boots without asking for a password because the supervisor password controls access only to the BIOS Setup menus. If both passwords are set, the password prompt is displayed at boot time, and either the user or the supervisor password can be entered to boot the computer. In most systems, the password can be up to seven or eight characters in length.

If you forget the password, most systems have a jumper on the board which allows all passwords to be cleared. This means that for most systems, the password security also requires that the system case be locked to prevent users from opening the cover and accessing the password-clear jumper. This jumper is often not labeled on the board for security reasons, but it can be found in the motherboard or system documentation.

Note that provided you know the password and can get into the BIOS Setup, a password can also be cleared by entering the BIOS Setup and selecting the Clear Password function. If there is no Clear function, you can still clear the password by selecting the Set Password function and pressing Enter (for no password) at the prompts.

Table 5.21 shows the security functions in a typical BIOS Setup.

Table 5.21 Typical Security Settings*

Feature	Options	Description
User Password Is	No options	Reports if there is a user password set.
Supervisor Password Is	No options	Reports if there is a supervisor password set.
Set User Password	Password can be up to seven alphanumeric characters.	Specifies the user password.
Set Supervisor Password	Password can be up to seven alphanumeric characters.	Specifies the supervisor password.
Clear User Password	No Options	Clears the user password.

Feature	Options	Description
User Setup Access	None View Only Limited Access Full Access (default)	Controls the user's capability to run the BIOS Setup program.
Unattended Start	Disabled (default) Enabled	Enables the unattended start feature. When enabled, the computer boots, but the key board is locked. The user must enter a password to unlock the computer or boot from a diskette.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

To clear passwords if the password is forgotten, most motherboards will have a password-clear jumper or switch. Intel motherboards require that you set the configuration jumper, enter the Maintenance menu in BIOS Setup, and select the Clear Password feature there. If you can't find the documentation for your board and aren't sure how to clear the passwords, you can try removing the battery for 15 minutes or so, which will clear the CMOS RAM. It can take that long for the CMOS RAM to clear on some systems because they have capacitors in the circuit that retain a charge. Note that this will also erase all other BIOS settings, including the hard disk settings, so they should be recorded beforehand.

Power Management Menu

Power management is defined as the capability of the system to automatically enter power-conserving modes during periods of inactivity. There are two main classes of power management; the original standard was called APM (Advanced Power Management) and had been supported by most systems since the 386 and 486 processors. More recently, a new type of power management called ACPI (Advanced Configuration and Power Interface) has been developed and began appearing in systems during 1998. Most systems sold in '98 or later support the more advanced ACPI type of power management. In APM, the hardware does the actual power management, and the operating system or other software had little control. With ACPI, the power management is now done by the operating system and BIOS, and not the hardware. This makes the control more centralized and easier to access and allows applications to work with the power management.

Table 5.22 shows the typical power settings found in most motherboard BIOSes.

Table 5.22 Typical Power Settings*

Feature	Options	Description
Power Management	Disabled Enabled (default)	Enables or disables the BIOS power-management feature.
Inactivity Timer	Off (default) 1 Minute 5 Minutes 10 Minutes 20 Minutes 30 Minutes 60 Minutes 120 Minutes	Specifies the amount of time before the computer enters Standby mode.
Hard Drive	Disabled Enabled (default)	Enables power management for hard disks during Standby and Suspend modes.
VESA Video Power Down	Disabled Standby (default) Suspend Sleep	Specifies power management for video during Standby and Suspend modes.
Fan Always On	No (default) Yes	Select Yes to force the fan to remain on when the system is in a power-managed state.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

When in Standby mode, the BIOS reduces power consumption by spinning down hard drives and reducing power to or turning off VESA (Video Electronics Standards Organization) DPMS (Display Power Management Signaling)-compliant monitors. While in Standby mode, the system can still respond to external interrupts, such as those from keyboards, mice, fax/modems or network adapters. For example, any keyboard or mouse activity brings the system out of Standby mode and immediately restores power to the monitor.

In most systems, the operating system takes over most of the power-management settings, and in some cases, it can even override the BIOS settings. This is definitely true if the operating system and the motherboard both support ACPI.

Some systems feature additional power management settings in their BIOS. Some of the more common ones are shown in Table 5.23.

Table 5.23 Typical Power Management Settings*

ACPI Function	Select Enabled only if your computer's operating system supports the Advanced Configuration and Power Interface (ACPI) specification. Currently, Windows 98 and Windows 2000 support ACPI.
Power Management	This option enables you to select the type (or degree) of power saving for Doze, Standby, and Suspend modes. Following are the individual mode settings: Max Saving—Maximum power savings. Inactivity period is 1 minute in each mode. User Define—Set each mode individually. Select timeout periods in the section for each mode. Min Saving—Minimum power savings. Inactivity period is 1 hour in each mode (except the hard drive).

PM Control by APM	If Advanced Power Management (APM) is installed on your system, selecting Yes gives better power savings.
Video Off Method V/H SYNC+Blank	Determines the manner in which the monitor is blanked. System turns off vertical and horizontal synchronization ports and writes blanks to the video buffer.
DPMS Support	Select this option if your monitor supports the Display Power Management Signaling (DPMS) standard of the Video Electronics Standards Association (VESA). Use the software supplied for your video subsystem to select video power-management values.
Blank Screen	System writes only blanks to the video buffer.
Video Off After	As the system moves from lesser to greater power-saving modes, select the mode in which you want the monitor to blank.
MODEM Use IRQ	Name the interrupt request (IRQ) line assigned to the modem (if any) on your system. Activity of the selected IRQ always awakens the system.
Doze Mode	After the selected period of system inactivity, the CPU clock throttles to a small percentage of its duty cycle: between 10 percent and 25 percent for most chipsets. All other devices still operate at full speed.
Standby Mode	After the selected period of system inactivity, the CPU clock stops, the hard drive enters an idle state, and the L2 cache enters a power-save mode. All other devices still operate at full speed.
Suspend Mode	After the selected period of system inactivity, the chipset enters a hardware suspend mode, stopping the CPU clock and possibly causing other system devices to enter power-management modes.
HDD Power Down	After the selected period of drive inactivity, any system IDE devices compatible with the ATA-2 specification or later power manage themselves, putting themselves into an idle state after the specified timeout and then waking themselves up when accessed.
Throttle Duty Cycle	When the system enters Doze mode, the CPU clock runs only part of the time. You may select the percent of time that the clock runs.
VGA Active Monitor	When Enabled, any video activity restarts the global timer for Standby mode.
Soft-Off by PWR-BTTN	When you select Instant Off or Delay 4 Sec., turning the system off with the On/Off button places the system in a very low power-usage state, either immediately or after 4 seconds, with only enough circuitry receiving power to detect power button activity or Resume by Ring activity.
CPUFAN Off in Suspend Resume by Ring	When Enabled, the CPU fan turns off during Suspend mode. When Enabled, an input signal on the serial Ring Indicator (RI) line (in other words, an incoming call on the modem) awakens the system from a soft off state.
Resume by Alarm	When Enabled, you can set the date and time at which the RTC (real-time clock) alarm awakens the system from Suspend mode.
Date (of Month) Alarm	Select a date in the month when you want the alarm to go off.
Time (hh:mm:ss) Alarm	Set the time you want the alarm to go off.
Wake Up On LAN	When Enabled, an input signal from a local area network (LAN) awakens the system from a soft off state.
IRQ8 Break [Event From] Suspend	You can select Enabled or Disabled for monitoring of IRQ8 (the real-time clock) so it does not awaken the system from Suspend mode.

(continues)

Table 5.23 Continued

Reload Global Timer Events	When Enabled, an event occurring on each device listed below restarts the global timer for Standby mode. IRQ3-7, 9-15, NMI Primary IDE 0 Primary IDE 1 Secondary IDE 0 Secondary IDE 1 Floppy Disk Serial Port Parallel Port
----------------------------	--

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Boot Menu (Boot Sequence, Order)

The Boot menu is used for setting the boot features and the boot sequence. If your operating system includes a bootable CD—Windows 2000, for example—use this menu to change the boot drive order to check your CD before your hard drive. Table 5.24 shows the functions and settings available on a typical motherboard.

Table 5.24 Typical Boot Menu Settings*

Feature	Options	Description
Boottime Diagnostic Screen	Disabled (default) Enabled	Displays the diagnostics screen during boot.
Quick Boot Mode	Disabled Enabled (default)	Enables the computer to boot without running certain POST tests.
Scan User Flash Area	Disabled (default) Enabled	Enables the BIOS to scan the flash memory for user binary files that are executed at boot time.
After Power Failure	Power On Stay Off Last State (default)	Specifies the mode of operation if an AC/Power loss occurs. Power On restores power to the computer. Stay Off keeps the power off until the power button is pressed. Last State restores the previous power state before power loss occurred.
On Modem Ring	Stay Off Power On (default)	Specifies how the computer responds to an incoming call on an installed modem when the power is off.
On LAN	Stay Off Power On (default)	Specifies how the computer responds to a LAN wakeup event when the power is off.
First Boot Device Second Boot Device Third Boot Device Fourth Boot Device	Removable devices Hard Drive ATAPI CD-ROM Drive Network Boot	Specifies the boot sequence from the available devices.

Feature	Options	Description
		To specify boot sequence: <ol style="list-style-type: none"> 1. Select the boot device with <code>_</code> or <code>~</code>. 2. Press <code>+</code> to move the device up the list or <code>-</code> to move the device down the list. <p>The operating system assigns a drive letter to each boot device in the order listed. Changing the order of the devices changes the drive lettering.</p>
Hard Drive	No options	Lists available hard drives. When selected, displays the Hard Drive submenu.
Removable Devices	No options	Lists available removable devices. When selected, displays the Removable Devices submenu.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

Using this menu, you can configure which devices your system boots from and in which order the devices are sequenced. From this menu, you can also access Hard Drive and Removable Devices submenus, which allow you to configure the ordering of these devices in the boot sequence. For example, you can set hard drives to be the first boot choice, and then in the hard drive submenu, decide to boot from the secondary drive first and the primary drive second. Normally, the default with two drives would be the other way around.

Exit Menu

The Exit menu is for exiting the Setup program, saving changes, and for loading and saving defaults. Table 5.25 shows the typical selections found in most motherboard BIOSes.

Table 5.25 Typical Exit Menu Settings*

Feature	Description
Exit Saving Changes	Exits and saves the changes in CMOS RAM.
Exit Discarding Changes	Exits without saving any changes made in Setup.
Load Setup Defaults	Loads the factory default values for all the Setup options.
Load Custom Defaults	Loads the custom defaults for Setup options.
Save Custom Defaults	Saves the current values as custom defaults. Normally, the BIOS reads the Setup values from flash memory. If this memory is corrupted, the BIOS reads the custom defaults. If no custom defaults are set, the BIOS reads the factory defaults.
Discard Changes	Discards changes without exiting Setup. The option values present when the computer was turned on are used.

**Based on the Phoenix BIOS used by the Intel SE440BX-2 motherboard. Used by permission of Intel Corporation.*

After you have selected an optimum set of BIOS Setup settings, you can save these settings using the Save Custom Defaults option. This will enable you to quickly restore your settings if they are corrupted or lost. All BIOS settings are stored in the CMOS RAM memory, which is powered by a battery attached to the motherboard.

Additional BIOS Setup Features

Some systems have additional features in their BIOS Setup screens, which may not be found in all BIOSes. Some of the more common features you might see are shown in Table 5.26.

Table 5.26 Additional BIOS Setup Features*

Virus Warning	When enabled, you receive a warning message if a program attempts to write to the boot sector or the partition table of the hard disk drive. If you get this warning during normal operation, you should run an antivirus program to see whether an infection has occurred. This feature protects only the master boot sector, not the entire hard drive. Note that programs which usually write to the master boot sector, such as FDISK, can trigger the virus warning message.
CPU Internal Cache/ External Cache	This allows you to disable the L1 (internal) and L2 (external) CPU cache. This is often used when testing memory, in which case you don't want the cache functioning. For normal operation, both caches should be enabled.
Quick Power On Self Test	When enabled, this reduces the amount of time required to run the power on self test (POST). A quick POST skips certain steps such as the memory test. If you trust your system, you can enable the quick POST, but in most cases I recommend leaving it disabled so you get the full-length POST version.
Swap Floppy Drive	This field is functional only in systems with two floppy drives. Selecting Enabled assigns physical drive B: to logical drive A, and physical drive A: to logical drive B:.
Boot Up Floppy Seek	When Enabled, the BIOS tests (seeks) floppy drives to determine whether they have 40 or 80 tracks. Only 360KB floppy drives have 40 tracks; drives with 720KB, 1.2MB, and 1.44MB capacity all have 80 tracks. Because very few modern PCs have 40-track floppy drives, you can disable this function to save time.
Boot Up System Speed	Select High to boot at the default CPU speed; select Low to boot at a simulated 8MHz speed. The 8MHz option was often used in the past with certain copy-protected programs, which would fail the protection scheme if booted at full speed. This option is not used today.
Gate A20 Option	Gate A20 refers to the way the system addresses memory above 1MB (extended memory). When set to Fast, the system chipset controls Gate A20. When set to Normal, a pin in the keyboard controller controls Gate A20. Setting Gate A20 to Fast improves system speed, particularly with protected-mode operating systems such as Win9x and Win2000.
Typematic Rate Setting	When Disabled, the following two items (Typematic Rate and Typematic Delay) are irrelevant. Keystrokes repeat at a rate determined by the keyboard controller in your system. When Enabled, you can select a typematic rate and typematic delay.
Typematic Rate (Chars/Sec)	When the typematic rate setting is enabled, you can select a typematic rate (the rate at which characters repeat when you hold down a key) of 6, 8, 10, 12, 15, 20, 24, or 30 characters per second.
Typematic Delay (Msec)	When the typematic rate setting is Enabled, you can select a typematic delay (the delay before key strokes begin to repeat) of 250, 500, 750 or 1,000 milliseconds.
Security Option	If you have set a password, select whether the password is required every time the system boots, or only when you enter Setup.
PS/2 Mouse Function Control	If your system has a PS/2 (motherboard) mouse port and you install a serial pointing device, select Disabled.

PCI/VGA Palette Snoop	Allows multimedia boards to read data from video RAM. Normally set to Disabled unless specifically instructed when installing a multimedia board.
HDD S.M.A.R.T. capability	S.M.A.R.T. is an acronym for Self-Monitoring Analysis and Reporting Technology system. S.M.A.R.T. is a hard drive self-diagnostic feature available on some IDE hard drives.
Report No FDD For WIN 95	Select Yes to release IRQ6 when the system contains no floppy drive, for compatibility with Windows 95 logo certification. In the Integrated Peripherals screen, select Disabled for the Onboard FDC Controller field.
ROM Shadowing	ROM chips are typically very slow, around 150ns (nanoseconds), and operate only 8 bits at a time, whereas RAM runs 60ns or even 10ns or less and is either 32 bits or 64 bits wide in most systems. Shadowing is the copying of BIOS code from ROM into RAM, where the CPU can read the BIOS drivers at the higher speed of RAM.

Year 2000 BIOS Issues

Everybody is concerned about the year 2000 problem. In a nutshell, the problem stems from the fact that the clock in the PC was originally designed to automatically update the year digits only, and the century had to be manually updated. This meant that if the PC was off during the transition from 1999 to 2000, the clock would be reset to 1900 instead. Newer PCs have a redesigned clock that automatically updates the century digits as well as the year digits.

When the PC is running, the system BIOS receives the date and time from the RTC. The first time a non-year 2000 compliant PC is turned on after January 1, 2000, 12:00 a.m., the BIOS will be told by the RTC that the year is 1900. Some BIOSes will convert this to 1980 or some other more recent date. With most of these systems, the user can then manually set the year to 2000, and the BIOS will update the century digits in the RTC. At that point the problem won't reoccur until 2099.

When the operating system (OS) is loaded, it receives the time and date from the system BIOS. An application can request the date and time from the OS, the BIOS, or the RTC. Most applications get the date and time from the OS, some get it from the BIOS, and a few get it from the RTC. An application can be Y2K compliant but report a bad date if it is sent from either a non-year 2000 compliant BIOS or RTC.

To test your operating system for Y2K compatibility:

1. If you are using DOS, boot your system to a safe mode command prompt (no other drivers loaded).
2. Set the date to December 31, 1999 by typing the following command at the DOS prompt:
`DATE 12-31-1999 <enter>`
3. Then set the time to 11:59 p.m. by typing
`TIME 23:59 <enter>`
4. Verify that the date and time are set correctly by typing
`DATE <enter>`

and then

```
TIME <enter>
```

5. Observe the output. Now wait more than one minute, and then check the date by typing
DATE <enter>

If the date has changed to January 1, 2000, then your version of DOS does not have a Y2K problem.

1. If you are running Windows 9x, NT, or Windows 2000, boot to the operating system desktop.
2. Open the control panel by selecting Start, Settings, Control Panel.
3. Select the Date/Time icon and set the date to December 31, 1999 and set the time to 11:59 p.m. Watch for a minute to see what happens. If after a minute the date and time correctly change, you have a Y2K-compliant operating system.

Note

This test does not guarantee that your applications are Y2K compliant. This test only checks the operating system for Y2K compliance.

Now you can check your BIOS with the following procedure:

1. First enter your BIOS setup.

◀◀ See "Running or Accessing the CMOS Setup Program," p. 375

2. Then set the date to December 31, 1999.
3. Set the time to 11:59 p.m. Watch for a minute to see what happens. If after a minute the date and time correctly change, you have a Y2K-compliant BIOS.

Note

Again, this does not mean that you won't have any problems with applications; this checks only the BIOS. If the date and time do not correctly change, your BIOS is not Y2K compliant.

Finally, you can check your real-time clock (RTC) using the following procedure:

1. Enter your BIOS setup the same as in the previous example.
2. Set the date to December 31, 1999 and the time to 11:59 p.m.
3. Save and exit BIOS setup.
4. Power off the system.
5. Wait more than one minute, turn the system back on, and again enter the BIOS setup. If the date has correctly changed, you have a Y2K-compliant RTC. This verifies only the clock and does not affect applications. If the date and time did not correctly change, your clock is not Y2K compliant.

Note that many systems will not have compliant clocks, and some may not have compliant BIOSes; in that case, the simple workaround is either to ensure the system is running at midnight

on December 31, 1999, or if the system is off or the BIOS is the problem, the first time booting on or after January 1, 2000, run the BIOS Setup and enter the correct date.

Another solution is to purchase one of the Y2K adapter cards being sold today, which have an onboard BIOS that will correctly handle the date change. They can also help correct the problem of the clock by watching for 1900 from the BIOS, in which case they automatically correct the CMOS clock and pass the correct date on to the operating system.

Admittedly, these tests are fairly simple. For more serious testing, I recommend that you check out programs such as Y2000.EXE by the National Software Testing Laboratories (NSTL). This program can be downloaded for free from its Web site, and it will give an accurate picture of the compliance level of your PC. Most of the BIOS manufacturers also offer more comprehensive test programs free for the downloading.

The following sections examine some of the larger BIOS manufacturers and whether their BIOSes are Y2K compliant.

Award

Award states that its BIOS correctly handles the changeover from 1999 to 2000 and correctly reads and reports dates beyond Year 2000 from the system real-time clock, including leap year dates. This compliance depends on the release date:

If your Award BIOS was released before April 26, 1994, you need to reset your system clock only once after the change:

1. Turn the system off before midnight on December 31, 1999.
2. Turn it back on some time after midnight on January 1, 2000.
3. Then set the system date correctly in the BIOS setup.

If your Award BIOS was released between April 26, 1994 and May 31, 1995, you will need to obtain a BIOS upgrade or reset your system clock every day! BIOSes between these dates have a bug where they assume the century is fixed at 19.

If your Award BIOS was released after May 31, 1995, its calendar automatically rolls from 1999 to 2000 at midnight, even though it may fail the NSTL 2000.EXE test. Award Software has modified its BIOS source code to accommodate the requirements of 2000.EXE and other applications that invoke INT1Ah function 04h. Award BIOS source code issued later than November 18, 1996 passes the NSTL 2000.EXE test program.

In addition to BIOS upgrades through Unicore Software, Award is also offering a hardware/software solution called the Millennium/Pro BIOS upgrade card. This card is also available through Unicore Software (see the vendor list).

AMI

AMI states that BIOS products shipped by AMI before 1998 and with versions earlier than 6.31.01 may require updates.

Note

Note that some OEMs may have changed the version and must be consulted to determine the true AMI version number.

Detection of an AMI BIOS is performed with a power-on boot process, which will display the AMI logo and date of that BIOS version. For any AMIBIOS with a date older than 1998 and with a version less than 6.31.01, it recommends an upgrade to ensure Y2K readiness.

Phoenix

Phoenix states that, in general, many (but not all) machines equipped with PhoenixBIOS 4.0 Release 5 and later versions have support for automatic date update when the system is first switched on after December 31, 1999. (The change to support automatic updates was made available to manufacturers in mid 1995). I recommend that you test with a program such as Y2000.exe to be sure that the system is compliant. If not, upgrades should be available from your motherboard manufacturer or MicroFirmware (see the vendor list).

Plug-and-Play BIOS

Traditionally, installing and configuring devices in PCs has been a difficult process. During installation, the user is faced with the task of configuring the new card by selecting the IRQ, I/O ports, and DMA channel. In the past, users were required to move jumpers or set switches on the add-in cards to control these settings. They needed to know exactly what resources were already in use so they could find a set of resources that did not conflict with the devices already in the system. If a conflict exists, the system may not boot, the device may fail or cause the conflicting hardware to fail.

PnP is technology designed to prevent configuration problems and provide users with the capability to easily expand a PC. With PnP, the user simply plugs in the new card and the system configures it automatically for proper operation.

PnP is composed of three principal components:

- Plug-and-Play BIOS
- Extended System Configuration Data (ESCD)
- Plug-and-Play operating system

The PnP BIOS initiates the configuration of the PnP cards during the boot-up process. If the cards were previously installed, the BIOS reads the information from ESCD and initializes the cards, then boots the system. During the installation of new PnP cards, the BIOS consults the ESCD to determine what system resources are available and needed for the add-in card. If the BIOS is capable of finding sufficient available resources, it configures the card. However, if the BIOS is incapable of locating sufficient available resources, the Plug-and-Play routines in the operating system complete the configuration process. During the configuration process, the configuration registers (in flash BIOS) on the card as well as the ESCD are updated with the new configuration data.

PnP Device IDs

All Plug-and-Play devices must contain a Plug-and-Play device ID to allow the operating system to uniquely recognize the device so that it can load the appropriate driver software. Each device manufacturer is responsible for assigning the Plug-and-Play ID for each product and storing it in the hardware.

Plug-and-Play three-character Vendor ID followed by a four-digit product ID (for example, XYZ1234).

Each manufacturer of Plug-and-Play devices must be assigned an industry-unique, three-character Vendor ID. Then the device manufacturer is responsible for assigning a unique product ID to each individual product model. After an ID is assigned to a product model, it must not be assigned to any other product model manufactured by the same company (that is, one that uses the same Vendor ID).

Many devices have no standard ID, such as the interrupt controller or keyboard controller. In that case, Microsoft has reserved a prefix of PNP to identify various devices that do not have an existing ID, as well as defining compatibility devices. These IDs are shown in Table 5.27.

Table 5.27 PnP Device IDs

Device ID	Description
PNP0xxx	System Devices Interrupt Controllers
PNP0000	AT Interrupt Controller
PNP0001	EISA Interrupt Controller
PNP0002	MCA Interrupt Controller
PNP0003	APIC
PNP0004	Cyrix SliC MP interrupt controller Timers
PNP0100	AT Timer
PNP0101	EISA Timer
PNP0102	MCA Timer DMA
PNP0200	AT DMA Controller
PNP0201	EISA DMA Controller
PNP0202	MCA DMA Controller Keyboards
PNP0300	IBM PC/XT keyboard controller (83-key)
PNP0301	IBM PC/AT keyboard controller (86-key)
PNP0302	IBM PC/XT keyboard controller (84-key)
PNP0303	IBM Enhanced (101/102-key, PS/2 mouse support)
PNP0304	Olivetti Keyboard (83-key)
PNP0305	Olivetti Keyboard (102-key)
PNP0306	Olivetti Keyboard (86-key)
PNP0307	Microsoft Windows(R) Keyboard
PNP0308	General Input Device Emulation Interface (GIDEI) legacy

Initializing a PnP Device

One responsibility of a Plug-and-Play BIOS during POST is to isolate and initialize all Plug and Play cards and assign them with a valid Card Select Number (CSN). After a CSN is assigned, the system BIOS can then designate resources to the cards. The BIOS is responsible only for the configuration of boot devices; all the remaining Plug and Play devices may be configured dynamically by the operating system software.

The following steps outline a typical flow of a Plug-and-Play BIOS during the POST:

1. Disable all configurable devices.
2. Identify all Plug-and-Play devices.
3. Construct a resource map of resources that are statically allocated to devices in the system.
4. Enable input and output devices.
5. Perform ISA ROM scan.
6. Configure the boot device.

7. Enable Plug-and-Play ISA and other configurable devices.
8. Start the bootstrap loader.

If the loaded operating system is Plug-and-Play compliant, it will take over management of the system resources. Any unconfigured Plug-and-Play devices will be configured by the appropriate system software or the Plug-and-Play-operating system.

At this point, the operating system is loaded and takes control over Plug-and-Play system resources. Using the Device Manager in the operating system such as Windows, the user can now control any Plug-and-Play devices.

BIOS Error Messages

When a PC system is first powered on, the system runs a power on self test (POST). If errors are encountered during the POST, in most cases you will see a text error message displayed on the screen. Errors that occur very early in the POST may happen before the video card is initialized. These types of errors cannot be displayed, so the system uses two other alternatives for communicating the error message. One is beeping; that is, the system will beep the speaker in a specific pattern that indicates which error has occurred.

The other alternative is to send a hexadecimal error code to I/O port address 80h, which can be read by a special card in one of the bus slots. When the ROM BIOS is performing the POST, in most systems the results of these tests are continuously sent to I/O Port 80h so they can be monitored by special diagnostics cards called POST cards. These tests sometimes are called manufacturing tests because they were designed into the system for testing systems on the assembly line without a video display attached.

The POST-code cards have a two-digit hexadecimal display used to report the number of the currently executing test routine. Before executing each test, a hexadecimal numeric code is sent to the port, and then the test is run. If the test fails and locks up the machine, the hexadecimal code of the last test being executed remains on the card's display.

Many tests are executed in a system before the video display card is enabled, especially if the display is EGA or VGA. Therefore, many errors can occur that would lock up the system before the system could possibly display an error code through the video system. Because not all these errors generate beep codes, to most normal troubleshooting procedures, a system with this type of problem (such as a memory failure in Bank 0) would appear completely "dead." By using one of the commercially available POST-code cards, however, you can often diagnose the problem.

These codes are completely BIOS dependent because the card does nothing but display the codes sent to it. Some BIOSes have more detailed POST procedures and therefore send more informative codes. POST cards can be purchased from JDR Microdevices or other sources.

For simple but otherwise fatal errors that cannot be displayed on the screen, most of the BIOS versions also send audio codes that can be used to help diagnose such problems. The audio codes are similar to POST codes, but they are read by listening to the speaker beep rather than by using a special card.

The following sections detail the text, beep, and I/O port 80h error codes for all the popular BIOS versions.

Note

The CD accompanying this book contains an exhaustive listing of BIOS error codes, error messages, and beep codes for BIOSes from Phoenix, AMI, Award, Microid Research, and IBM.

General BIOS Boot Text Error Messages

The ROM maps of most PCs are similar to the original IBM systems with which they are compatible—with the exception of the Cassette BASIC portion (also called ROM BASIC). It may come as a surprise to some PC users, but the original IBM PC actually had a jack on the rear of the system for connecting a cassette tape recorder. This was to be used for loading programs and data to or from a cassette tape. Tapes were used at the time because floppy drives were very costly, and hard disks were not even an option yet. Floppy drives came down in price quickly at the time, and the cassette port never appeared on any subsequent IBM systems. The cassette port also never appeared on any compatible system.

The original PC came standard with only 16KB of memory in the base configuration. No floppy drives were included, so you could not load or save files from disks. Most computer users at the time would either write their own programs in the BASIC (Beginner's All-Purpose Symbolic Instruction Code) language or run programs written by others. A BASIC language interpreter was built into the ROM BIOS of these early IBMs and was designed to access the cassette port on the back of the system.

What is really strange is that IBM kept this ROM BASIC relationship all the way into the early 1990s! I liken this to humans having an appendix. The ROM BASIC in those IBM systems is a sort of vestigial organ—a leftover that had some use in prehistoric ancestors but that has no function today.

You can catch a glimpse of this ROM BASIC on older IBM systems that have it by disabling all the disk drives in the system. In that case, with nothing to boot from, most IBM systems unceremoniously dump you into the strange (vintage 1981) ROM BASIC screen. When this occurs, the message looks like this:

```
The IBM Personal Computer Basic
Version C1.10 Copyright IBM Corp 1981
62940 Bytes free
Ok
```

Many people used to dread seeing this because it usually meant that your hard disk had failed to be recognized! Because no compatible systems ever had the Cassette BASIC interpreter in ROM, they had to come up with different messages to display for the same situations in which an IBM system would invoke this BASIC. Compatibles that have an AMI BIOS in fact display a confusing message, as follows:

```
NO ROM BASIC - SYSTEM HALTED
```

This message is a BIOS error message that is displayed by the AMI BIOS when the same situations occur that would cause an IBM system to dump into Cassette BASIC, which, of course, is not present in an AMI BIOS (or any other compatible BIOS, for that matter). Other BIOS versions display different messages. For example, under the same circumstances, a Compaq BIOS displays the following:

```
Non-System disk or disk error
replace and strike any key when ready
```

This is somewhat confusing on Compaq's part because this very same (or similar) error message is contained in the DOS Boot Sector and would normally be displayed if the system files were missing or corrupted.

In the same situations in which you would see Cassette BASIC on an IBM system, a system with an Award BIOS would display the following:

```
DISK BOOT FAILURE, INSERT SYSTEM DISK AND PRESS ENTER
```

Phoenix BIOS systems will display either

```
No boot device available -
strike F1 to retry boot, F2 for setup utility
```

or

```
No boot sector on fixed disk -
strike F1 to retry boot, F2 for setup utility
```

The first or second Phoenix message displays depending on which error actually occurred.

Although the message displayed varies from BIOS to BIOS, the cause is the same for all of them. Two things can generally cause any of these messages to be displayed, and they both relate to specific bytes in the Master Boot Record, which is the first sector of a hard disk at the physical location Cylinder 0, Head 0, Sector 1.

The first problem relates to a disk that has either never been partitioned or that has had the Master Boot Sector corrupted. During the boot process, the BIOS checks the last two bytes in the Master Boot Record (the first sector of the drive) for a "signature" value of 55AAh. If the last two bytes are not 55AAh, an Interrupt 18h is invoked. This calls the subroutine that displays the message you received, and the others indicated, or on an IBM system invokes Cassette (ROM) BASIC.

The Master Boot Sector (including the signature bytes) is written to the hard disk by the DOS FDISK program. Immediately after you low-level format a hard disk, all the sectors are initialized with a pattern of bytes, and the first sector does not contain the 55AAh signature. In other words, these ROM error messages are exactly what you see if you attempt to boot from a hard disk that has been low-level formatted but has not yet been partitioned.

Now consider the second situation that can cause these messages. If the signature bytes are correct, the BIOS executes the Master Partition Boot Record code, which performs a test of the Boot Indicator Bytes in each of the four partition table entries. These bytes are at offset 446 (1BEh), 462 (1CEh), 478 (1DEh), and 494 (1EEh), respectively. They are used to indicate which of the four possible partition table entries contains an active (bootable) partition. A value of 80h in any of

these byte offsets indicates that table contains the active partition, whereas all other values must be 00h. If more than one of these bytes is 80h (indicating multiple active partitions), or any of the byte values is anything other than 80h or 00h, you see the following error message:

Invalid partition table

If all these four Boot Indicator Bytes are 00h, indicating no active (bootable) partitions, then you also see Cassette BASIC on an IBM system or the other messages indicated earlier, depending on which BIOS you have. This is exactly what occurs if you were to remove the existing partitions from a drive using FDISK but had not created new partitions on the drive, or had failed to make one of the partitions Active (bootable) with FDISK before rebooting your system.

Unfortunately, no easy way exists to clear out the partition table on a system where it is damaged. You can try to use FDISK to remove damaged partitions, but FDISK will not always allow it. In that case, you have to resort to something more powerful, such as the DISKEDIT command found in the Norton Utilities package by Symantec.

Memory

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Memory Basics

ROM

DRAM

Cache Memory: SRAM

RAM Memory Speeds

Future DRAM Memory Technologies

Physical RAM Memory

Installing RAM Upgrades

Troubleshooting Memory

The System Logical Memory Layout

Memory Basics

This chapter looks at memory from both a physical and logical point of view. First, you will look at what memory is, where it fits into the PC architecture, and how it works. Then I'll discuss the different types of memory, speeds, and packaging of the chips and memory modules you can buy and install.

This chapter also covers the logical layout of memory, defining the different areas and their uses from the system's point of view. Because the logical layout and uses are within the "mind" of the processor, memory mapping and logical layout remain perhaps the most difficult subjects to grasp in the PC universe. This chapter contains useful information that removes the mysteries associated with memory and enables you to get the most out of your system.

Memory is the workspace for the computer's processor. It is a temporary storage area where the programs and data being operated on by the processor must reside. Memory storage is considered temporary because the data and programs remain there only as long as the computer has electrical power or is not reset. Before being shut down or reset, any data that has been changed should be saved to a more permanent storage device of some type (usually a hard disk) so it can be reloaded into memory again in the future.

We often call memory *RAM*, for *random access memory*. Main memory is called RAM because you can randomly (and quickly) access any location in memory. This designation is somewhat misleading and often misinterpreted. Read-only memory (ROM), for example, is also randomly accessible, yet is normally differentiated from the system RAM because it cannot normally be written to. Also, disk memory is randomly accessible too, but we don't consider that RAM either.

Over the years, the definition of RAM has changed from a simple acronym to become something that means the primary memory workspace used by the processor to run programs, which usually is constructed of a type of chip called DRAM (Dynamic RAM). One of the characteristics of DRAM chips (and therefore RAM in general) is that they store data dynamically, which means information can be written to RAM over and over again at any time. An important characteristic of RAM is that data is stored only as long as the memory has electrical power.

Therefore, when we talk about a computer's memory, we usually mean the RAM or physical memory in the system, which is primarily the memory chips or modules used by the processor to store primary active programs and data. This is often confused with the term "*storage*," which should be used when referring to things such as disk and tape drives (although they can be used as a form of RAM called virtual memory).

RAM can refer to both the physical chips that make up the memory in the system and the logical mapping and layout of that memory. Logical mapping and layout refer to how the memory addresses are mapped to actual chips and what address locations contain which types of system information.

People new to computers often confuse main memory with disk storage because both have capacities that are expressed in similar megabyte or gigabyte terms. The best analogy to explain the relationship between memory and disk storage I've found is to think of a small office with a desk and a file cabinet.

In this popular analogy, the file cabinet represents the system's hard disk, where both programs and data are stored for long-term safekeeping. The desktop represents the system's main memory, which allows the person working at the desk (acting as the processor) direct access to any files placed on it. Files represent the programs and documents you can "load" into the memory. To work on a particular file, it must first be retrieved from the cabinet and placed on the desktop. If the desktop is large enough, you might be able to have several files open on it at one time; likewise, if your system has more memory, you can run more or larger programs and work on more or larger documents.

Adding hard disk space to a system is like putting a bigger file cabinet in the office; more files can be permanently stored. Adding more memory to a system is like getting a bigger desk; you can work on more programs and data at the same time.

One difference between this analogy and the way things really work in a computer is that when a file is loaded into memory, it is a copy of the file that is actually loaded; the original still resides on the hard disk. Note that because of the temporary nature of memory, any files that have been changed after being loaded into memory must then be saved back to the hard disk before the system is powered off and the memory subsequently cleared. If the changed file is not saved, then the original copy of the file on the hard disk remains unaltered. This is like saying that any changes made to files left on the desktop are discarded when the office is closed, although the original files themselves are still in the cabinet.

Memory temporarily stores programs when they are running, along with the data being used by those programs. RAM chips are sometimes termed *volatile storage* because when you turn off your computer or an electrical outage occurs, whatever is stored in RAM is lost unless you saved it to your hard drive. Because of the volatile nature of RAM, many computer users make it a habit to save their work frequently. (Some software applications can do timed backups automatically.)

Launching a computer program brings files into RAM, and as long as they are running, computer programs reside in RAM. The CPU executes programmed instructions in RAM, and also stores results in RAM. RAM stores your keystrokes when you use a word processor and also stores numbers used in calculations. Telling a program to save your data instructs the program to store RAM contents on your hard drive as a file.

Physically, the *main memory* in a system is a collection of chips or modules containing chips that are normally plugged into the motherboard. These chips or modules vary in their electrical and physical design and must be compatible with the system into which they are being installed to function properly. In this chapter, I'll discuss the different types of chips and modules that can be installed in different systems.

Next to the processor, memory can be one of the more expensive components in a modern PC, although the total amount spent on memory for a typical system has declined over the past few years. Even after the price drops, you should still be spending more on the memory for your system than for your motherboard—in fact, up to twice as much. Before the memory price crash in mid-'96, memory had maintained a fairly consistent price for many years of about \$40 per megabyte. A typical configuration back then of 16MB cost more than \$600. In fact, memory was

so expensive at that time, it was worth more than its weight in gold. These high prices caught the attention of criminals as memory module manufacturers were robbed at gunpoint in several large heists. These robberies were partially induced by the fact that memory was so valuable, the demand was high, and stolen chips or modules were virtually impossible to trace. After the rash of armed robberies and other thefts, memory module manufacturers began posting armed guards and implementing beefed-up security procedures.

By the end of 1996, memory prices had cooled considerably to about \$4 a megabyte, a tenfold price drop in less than a year. Prices continued to fall after the major crash and recently have reached about a dollar per megabyte, or about \$125 for 128MB, a typical configuration today. This means that of all the money spent on a PC system today, we are now installing about four times more memory in a system compared to a few years ago and, at the same time, are spending about 1/6 of its previous cost.

Memory costs less now than a few years ago, but its useful life has become much shorter. New types of memory are being adopted more quickly than before, and any new systems you purchase now most likely will not accept the same memory as your existing ones. In an upgrade or repair situation, that means you often have to change the memory if you change the motherboard. The chance that you can reuse the memory in an existing motherboard when upgrading to a new one is slim. This is likely to continue in the future, meaning that the system or upgrade motherboard you buy next year most likely can't use the memory in your current systems.

Because of this, you should understand all the different types of memory on the market today, so you can best determine which types are required by which systems, and thus more easily plan for future upgrades and repairs.

To better understand physical memory in a system, you should see where and how it fits into the system. There are three main types of physical memory used in modern PCs:

- *ROM*. Read-only memory
- *DRAM*. Dynamic random access memory
- *SRAM*. Static RAM

ROM

Read-only memory, or ROM, is a type of memory that can permanently or semipermanently hold data. It is called read-only because it is either impossible or difficult to write to. ROM is also often referred to as *nonvolatile memory* because any data stored in ROM remains there, even if the power is turned off. As such, ROM is an ideal place to put the PC's startup instructions—that is, the software that boots the system.

Note that ROM and RAM are not opposites, as some people seem to believe. In fact, ROM is technically a subset of the system's RAM. In other words, a portion of the system's Random Access Memory address space is mapped into one or more ROM chips. This is necessary to contain the software that enables the PC to boot up; otherwise, the processor would have no program in memory to execute when it was powered on.

▶▶ See “The Boot Process,” p. 1351.

For example, when a PC is turned on, the processor automatically jumps to address FFFF0h, expecting to find instructions to tell the processor what to do. This location is exactly 16 bytes from the end of the first megabyte of RAM space and the end of the ROM. If this location were mapped into regular memory chips, any data stored there would have disappeared when the power was turned off previously, and the processor would subsequently find no instructions to run the next time power was turned on. By placing a ROM chip at this address, a system startup program can be permanently loaded into the ROM and is available every time the system is turned on.

◀◀ For more information about Dynamic RAM, see “DRAM,” p. 418.

Normally, the system ROM starts at address F0000h, which is 64KB prior to the end of the first megabyte. Because the ROM chip is normally 64KB, the ROM programs occupy the entire last 64KB of the first megabyte, including the critical FFFF0h startup instruction address.

Some think it strange that the PC would start executing instructions 16 bytes from the end of the ROM, but this design was intentional. All the ROM programmer has to do is place a JMP (jump) instruction at that address, which instructs the processor to jump to the actual beginning of the ROM—in most cases close to F0000h, which is about 64KB earlier in the memory map. It's kind of like deciding to read every book starting 16 pages from the end, and then having all book publishers agree to place an instruction there to jump back the necessary number of pages to get to page 1. By setting the startup location in this way, Intel allowed the ROM to grow to be any size, all the while keeping it at the upper end of addresses in the first megabyte of the memory address space.

The main ROM BIOS is contained in a ROM chip on the motherboard, but there are also adapter cards with ROMs on them as well. ROMs on adapter cards contain auxiliary BIOS routines and drivers needed by the particular card, especially for those cards that must be active early in the boot process, such as video cards. Cards that don't need drivers active at boot time normally do not have a ROM because those drivers can be loaded from the hard disk later in the boot process.

The motherboard ROM normally contains four main programs, including the following in most systems:

- *POST (power on self test)*. A series of test routines that ensure the system components are operating properly.
- *CMOS Setup*. A menu-driven application that allows the user to set system configuration parameters, options, security settings, and preferences.
- *Bootstrap Loader*. The routine that first scans the floppy drive and then the hard disk, looking for an operating system to load.
- *BIOS (basic input/output system)*. A series of device driver programs designed to present a standard interface to the basic system hardware, especially hardware that must be active during the boot process.

Because the BIOS is the main portion of the code stored in ROM, we often call the ROM the *ROM BIOS*. In older PCs, the motherboard ROM BIOS could consist of up to five or six total chips, but

most PCs have required only a single chip for many years now. For more information on the motherboard ROM, see Chapter 4, “Motherboards and Buses,” and Chapter 5 “BIOS.”

Adapter cards that require startup drivers also have ROMs on them. This includes cards such as video cards, most SCSI (Small Computer Systems Interface) cards, Enhanced IDE controller cards, and some network cards. The ROM chip on these cards contains drivers and startup programs that are executed by the motherboard ROM at boot time.

This, for example, is how a video card can be recognized and initialized, even though your motherboard ROM does not contain specific drivers for it. You wouldn't want to load the initial VGA mode drivers from disk because the screen would remain dark until those drivers were loaded. What happens is the motherboard ROM scans a special adapter ROM area of RAM (addresses C0000–DFFFFh), looking for a 55AAh signature byte pair that indicates the start of a ROM. The motherboard BIOS automatically runs the programs in any adapter ROMs it finds during the scan. You see this in most systems when you turn your system on, and during the POST you see the video card BIOS initialize and announce its presence.

There are four different types of ROM chips:

- *ROM*. Read-only memory
- *PROM*. Programmable ROM
- *EPROM*. Erasable PROM
- *EEPROM*. Electrically Erasable PROM, also called flash ROM

No matter which type of ROM you use, the data stored in a ROM chip is non-volatile and remains indefinitely unless intentionally erased or overwritten.

For more information on these types of chips, see Chapter 5.

DRAM

Dynamic RAM (DRAM) is the type of memory chip used for most of the main memory in a modern PC. The main advantages of DRAM are that it is very dense, meaning you can pack a lot of bits into a very small chip, and it is inexpensive, which makes it affordable for large amounts of memory.

The memory cells in a DRAM chip are tiny capacitors that retain a charge to indicate a bit. The problem with DRAM is that it is dynamic, and because of the design it must be constantly refreshed or the electrical charges in the individual memory capacitors will drain and the data will be lost. Refresh occurs when the system memory controller takes a tiny break and accesses all the rows of data in the memory chips. Most systems have a memory controller (normally built into the North Bridge portion of the motherboard chipset), which is set for an industry-standard refresh rate of 15 μ s (microseconds). The memory is accessed in such a way that all rows of data will be accessed after exactly 128 of these special refresh cycles. This means that every 1.92ms (milliseconds or 128 \times 15 μ sec), all the rows in the memory are read to refresh the data.

Refreshing the memory unfortunately takes processor time away from other tasks because each refresh cycle takes several CPU cycles to complete. In older systems, the refresh cycling could take up to 10 percent or more of the total CPU time, but with modern systems running in the hundreds of megahertz, refresh overhead is now on the order of 1 percent or less of the total CPU time. Some systems allow you to alter the refresh timing parameters via the CMOS Setup, but be aware that increasing the time between refresh cycles to speed up your system can allow some of the memory cells to begin draining, which can cause random soft memory errors to appear. A *soft error* is a data error that is not caused by a defective chip. It is usually safer to stick with the recommended or default refresh timing. Because refresh consumes less than 1 percent of modern system overall bandwidth, altering the refresh rate has little effect on performance.

DRAMs use only one transistor and capacitor pair per bit, which makes them very dense, offering more memory capacity per chip than other types of memory. There are currently DRAM chips available with densities of up to 256Mbits or more. This means that there are DRAM chips with 256 million or more transistors! Compare this to a Pentium II, which has 7.5 million transistors, and it makes the processor look wimpy by comparison. The difference is that in a memory chip, the transistors and capacitors are all consistently arranged in a (normally square) grid of simple repetitive structures, unlike the processor, which is a much more complex circuit of different structures and elements interconnected in a highly irregular fashion. At least one manufacturer is working on chips, intended for the 2001–2002 timeframe, with 256-gigabit densities using circuit line widths of 0.05 micron, indicating that memory densities will continue to rise as they have for years.

The transistor for each DRAM bit cell reads the charge state of the adjacent capacitor. If the capacitor is charged, the cell is read to contain a 1; no charge indicates a 0. The charge in the tiny capacitors is constantly draining, which is why the memory must be refreshed constantly. Even a momentary power interruption, or anything that interferes with the refresh cycles, can cause a DRAM memory cell to lose the charge and therefore the data.

DRAM is used in PC systems because it is inexpensive and the chips can be densely packed, meaning that a lot of memory capacity can fit in a small space. Unfortunately, DRAM is also slow, normally much slower than the processor. For this reason, there have been many different types of DRAM architectures developed to improve performance.

Cache Memory: SRAM

There is another distinctly different type of memory that is significantly faster than most types of DRAM. SRAM stands for *Static RAM*, which is so named because it does not need the periodic refresh rates like DRAM (Dynamic RAM). Because of SRAM's design, not only are refresh rates unnecessary, but SRAM is much faster than DRAM and fully able to keep pace with modern processors.

SRAM memory is available in access times of 2ns or less, which means it can keep pace with processors running 500MHz or faster! This is because of the SRAM design, which calls for a cluster of six transistors for each bit of storage. The use of transistors but no capacitors means that refresh rates are not necessary because there are no capacitors to lose their charges over time. As

long as there is power, SRAM remembers what is stored. With these attributes, why don't we use SRAM for all system memory? The answers are simple:

Type	Speed	Density	Cost
DRAM	Slow	High	Low
SRAM	Fast	Low	High

Compared to DRAM, SRAM is much faster, but also much lower in density and much more expensive. The lower density means that SRAM chips are physically larger and store many fewer bits overall. The high number of transistors and the clustered design means that SRAM chips are both physically larger and much more expensive to produce than DRAM chips. For example, a DRAM module might contain 64MB of RAM or more, while SRAM modules of the same approximate physical size would have room for only 2MB or so of data and would cost the same as the 64MB DRAM module. Basically, SRAM is up to 30 times larger physically and up to 30 times more expensive than DRAM. The high cost and physical constraints have prevented SRAM from being used as the main memory for PC systems.

Even though SRAM is too expensive for PC use as main memory, PC designers have found a way to use SRAM to dramatically improve PC performance. Rather than spend the money for all RAM to be SRAM memory, which can run fast enough to match the CPU, it is much more cost-effective to design in a small amount of high-speed SRAM memory, called *cache memory*. The cache runs at speeds close to or even equal to the processor and is the memory from which the processor normally directly reads from and writes to. During read operations, the data in the high-speed cache memory is resupplied from the lower-speed main memory or DRAM in advance. Up until recently, DRAM was limited to about 60ns (16MHz) in speed. To convert access time in nanoseconds to MHz, use the following formula:

$$1 / \text{nanoseconds} \times 1000 = \text{MHz}$$

Likewise to convert from MHz to nanoseconds, use the following inverse formula:

$$1 / \text{MHz} \times 1000 = \text{nanoseconds}$$

When PC systems were running 16MHz and less, it was possible for the DRAM to fully keep pace with the motherboard and system processor, and there was no need for cache. However, as soon as processors crossed the 16MHz barrier, it was no longer possible for DRAM to keep pace, and that is exactly when SRAM began to enter PC system designs. This occurred back in 1986–1987 with the debut of systems with the 386 processor running at 16MHz and 20MHz. These were among the first PC systems to employ what's called *cache memory*, a high-speed buffer made up of SRAM that directly feeds the processor. Because the cache can run at the speed of the processor, the system is designed so that the cache controller will anticipate the processor's memory needs and preload the high-speed cache memory with that data. Then, as the processor calls for a memory address, the data can be retrieved from the high-speed cache rather than the much lower speed main memory.

Cache effectiveness is expressed as a hit ratio. This is the ratio of cache hits to total memory accesses. A *hit* happens when the data the processor needs has been preloaded into the cache from the main memory, meaning that the processor can read it from the cache. A *cache miss* is when the cache controller did not anticipate the need for a specific address; the desired data was not preloaded into the cache; therefore, the processor must retrieve the data from the slower main memory, instead of the faster cache. Anytime the processor reads data from main memory, the processor must wait because the main memory cycles at a much slower rate than the processor. If the processor is running at 233MHz, then it is cycling at nearly 4ns, while the main memory might be 60ns, which means it is running at only 16MHz. Therefore, every time the processor reads from main memory, it would effectively slow down to 16MHz! The slowdown is accomplished by having the processor execute what are called *wait states*, which are cycles in which nothing is done; the processor essentially cools its heels while waiting for the slower main memory to return the desired data. Obviously, we don't want our processors slowing down, so cache function and design become important as system speeds increase.

To minimize the processor being forced to read data from the slow main memory, there are normally two stages of cache in a modern system, called Level 1 (L1) and Level 2 (L2). The L1 cache is also called *integral* or *internal cache* because it is directly built into the processor and is actually a part of the processor die (raw chip). Because of this, L1 cache always runs at the full speed of the processor core and is the fastest cache in any system. All 486 and higher processors incorporate integral L1 cache, making them significantly faster than their predecessors. L2 cache is also called *external cache* because it is external to the processor chip. Originally, this meant it was installed on the motherboard, as was the case with all 386, 486, and Pentium systems. In those systems, the L2 cache runs at motherboard speed because it is installed on the motherboard. You can normally find the L2 cache directly next to the processor socket in Pentium and earlier systems.

In the interest of improved performance, later processor designs from Intel, including the Pentium Pro and Pentium II/III, have included the L2 cache as a part of the processor. It is still external to the actual CPU die and is instead a separate die or chip mounted inside the processor package or module. As such, Pentium Pro or Pentium II systems will not have any cache on the motherboard; it is all contained in the processor module, instead.

The key to understanding both cache and main memory is to see where they fit in the overall system architecture.

Figure 6.1 shows a typical Pentium MMX system with the Intel 430TX chipset.

See Figure 4.35 in Chapter 4 for a diagram showing a typical Pentium III system with integrated L2 cache.

Table 6.1 illustrates the need for and function of L1 (internal) and L2 (external) cache in modern systems.

Figure 6.1 System architecture, Pentium MMX system with an Intel 430TX chipset.

Table 6.1 The Relationship Between L1 (Internal) and L2 (External) Cache in Modern Systems

CPU Type	486 DX4	Pentium	Pentium Pro	Pentium II (1997)	Pentium II (1998)
Typical CPU speed	100MHz	233MHz	200MHz	300MHz	400MHz
L1 cache speed	10ns	4.3ns	5.0ns	3.3ns	2.5ns
L2 cache speed	(100MHz)	(233MHz)	(200MHz)	(300MHz)	(400MHz)
Motherboard speed	33MHz	66MHz	66MHz	66MHz	100MHz
SIMM/DIMM speed	60ns (16MHz)	60ns (16MHz)	60ns (16MHz)	15ns (66MHz)	10ns (100MHz)

Cache designs were originally *asynchronous*, meaning they ran at a clock speed that was not identical or in sync with the processor bus. Starting with the 430FX chipset released in early 1995, a new type of synchronous cache design was supported. It required that the chips now run in sync or at the same identical clock timing as the processor bus, further improving speed and performance. Also added at that time was a feature called *pipeline burst mode*, which reduced overall cache latency (wait states) by allowing single-cycle accesses for multiple transfers after the first one. Because both synchronous and pipeline burst capability came at the same time in new modules, usually specifying one implies the other. Overall synchronous pipeline burst cache allowed for about a 20 percent improvement in overall system performance, which was a significant jump.

The cache controller for a modern system is contained in either the North Bridge of the chipset, as with Pentium and lesser systems, or within the processor, as with the Pentium Pro/II and newer systems. The capabilities of the cache controller dictate the cache's performance and capabilities. One important thing to note is that most cache controllers have a limitation on the amount of memory that can be cached. Often, this limit can be quite low, as with the 430TX chipset-based Pentium systems. The 430TX chipset can cache data only within the first 64MB of system RAM. If you have more memory than that, you will see a noticeable slowdown in system performance because all data outside the first 64MB is never cached, and is always accessed with all the wait states required by the slower DRAM. Depending on what software you use and where data is stored in memory, this can be significant. For example, 32-bit operating systems, such as Windows 9x and NT, load from the top down, so if you had 96MB of RAM, the operating system and applications would load directly into the upper 32MB (past 64MB), which is not cached. This results in a dramatic slowdown in overall system use. Removing the additional memory to bring the system total down to the cacheable limit of 64MB is the solution. In short, it is unwise to install more main RAM memory than your system (chipset) can cache. Consult your system documentation or the chipset section in Chapter 4 for more information.

AMD K6-2	AMD K6-3	Celeron	Pentium III	Pentium III Xeon
475MHz	450MHz	466MHz	550MHz	550MHz
2.1ns	2.2ns	2.1ns	1.8ns	1.8ns
(475MHz)	(450MHz)	(466MHz)	(550MHz)	(550MHz)
10ns	2.2ns	2.1ns	3.6ns	1.8ns
(100MHz)	(450MHz)	(466MHz)	(275MHz)	(550MHz)
95MHz	100MHz	66MHz	100MHz	100MHz
10.5ns (95MHz)	10ns (100MHz)	15ns (66MHz)	10ns (100MHz)	10ns (100MHz)

RAM Memory Speeds

The speed and performance issue with memory is confusing to some because memory speed is usually expressed in ns (nanoseconds), and processor speed has always been expressed in MHz (megahertz). Recently, however, some newer and faster types of memory have speeds expressed in MHz, adding to the confusion. Let's see if we can come up with a way to translate one to the other.

A *nanosecond* is defined as one billionth of a second—a very short time indeed. To put some perspective on that, the speed of light is 186,282 miles (299,792 kilometers) per second in a vacuum. In one billionth of a second, a beam of light travels a mere 11.80 inches or 29.98 centimeters, less than the length of a typical ruler!

Chip and system speed has been expressed in megahertz (MHz), which is millions of cycles per second. There are systems today with processors running 600MHz or faster, and we should see gigahertz (GHz, or billions of cycles per second) speeds within a few years.

Because it is confusing to speak in these different terms for speeds, I thought it would be interesting to see how they compare. Table 6.2 shows the relationship between nanoseconds (ns) and megahertz (MHz) for the speeds associated with PCs from yesterday to today and tomorrow.

Table 6.2 The Relationship Between Megahertz (MHz) and Cycle Times in Nanoseconds (ns)

Clock Speed	Cycle Time	Clock Speed	Cycle Time	Clock Speed	Cycle Time
4.77MHz	210ns	120MHz	8.3ns	433MHz	2.3ns
6MHz	167ns	133MHz	7.5ns	450MHz	2.2ns
8MHz	125ns	150MHz	6.7ns	466MHz	2.1ns
10MHz	100ns	166MHz	6.0ns	500MHz	2.0ns
12MHz	83ns	180MHz	5.6ns	533MHz	1.9ns
16MHz	63ns	200MHz	5.0ns	550MHz	1.8ns
20MHz	50ns	225MHz	4.4ns	600MHz	1.7ns
25MHz	40ns	233MHz	4.3ns	650MHz	1.5ns
33MHz	30ns	250MHz	4.0ns	700MHz	1.4ns
40MHz	25ns	266MHz	3.8ns	750MHz	1.3ns
50MHz	20ns	300MHz	3.3ns	800MHz	1.3ns
60MHz	17ns	333MHz	3.0ns	850MHz	1.2ns
66MHz	15ns	350MHz	2.9ns	900MHz	1.1ns
75MHz	13ns	366MHz	2.7ns	950MHz	1.1ns
80MHz	13ns	400MHz	2.5ns	1000MHz	1.0ns
100MHz	10ns				

As you can see from this table, as clock speeds increase, cycle time decreases proportionately.

If you examine this table, you can clearly see that the 60ns DRAM memory used in the typical PC for many years is totally inadequate when compared to processor speeds of 400MHz and higher. Up until 1998, most DRAM memory used in PCs has been rated at an access time of 60ns or higher, which works out to be 16.7MHz or slower! This super-slow 16MHz memory has been installed in systems running up to 300MHz or faster, and you can see what a mismatch there has been between processor and main memory performance. More recently we have 100MHz and even 133MHz memory, called PC100 and PC133 respectively.

System memory timing is a little more involved than simply converting nanoseconds to megahertz. The transistors for each bit in a memory chip are most efficiently arranged in a grid, using a row and column scheme to access each transistor. All memory accesses involve selecting a row address and then a column address, and then transferring the data. The initial setup for a memory transfer where the row and column addresses are selected is a necessary overhead normally referred to as *latency*. The access time for memory is the cycle time plus latency for selecting the row and column addresses. For example, memory rated at 60ns normally has a latency of about 25ns (to select the row and column address) and a cycle time of about 35ns to actually transfer the data. Therefore, the true memory clock rate in a system with 60ns memory would be on the order of 28.5MHz (35ns = 28.5MHz). Even so, a single memory transfer still requires a full 60ns, so consecutive transfers happen at a rate of only 16.7MHz (60ns) because of the added latency.

What happens when a 300MHz processor is trying to read multiple bytes of data from 16MHz memory? A lot of wait states! A wait state is an additional “do nothing” cycle that the processor must execute while waiting for the data to become ready. With memory cycling every 60ns (16MHz) and a processor cycling every 3ns (300MHz), the processor has to execute approximately 19 wait states before the data is ready on the twentieth cycle. Adding wait states in this fashion effectively slows the processing speed to that of the memory, or 16MHz in this example. To reduce the number of wait states required, several types of faster memory and cache are available, all of which are discussed in this chapter.

Over the development life of the PC, memory has had a difficult time keeping up with the processor, requiring several levels of high-speed cache memory to intercept processor requests for the slower main memory. Table 6.3 shows the progress and relationship between system board (motherboard) speeds in PCs and the different types and speeds of main memory or RAM used.

Table 6.3 Relationship of Motherboard Speeds to RAM Speeds

Motherboard Speeds	Processor Speeds	RAM Type	RAM Speeds	Timeframe
5MHz–66MHz	5MHz–200MHz	FPM/EDO	5MHz–16MHz	1981–1996
66MHz–100MHz	200MHz–450MHz	SDRAM	66MHz or 100MHz	1997–1998
100MHz+	500MHz+	RDRAM	600MHz or 800MHz	1999+

FPM = Fast Page Mode

EDO = Extended Data Out

SDRAM = Synchronous Dynamic RAM

RDRAM = Rambus DRAM

As you can see from this table, memory development was very slow for the first 15 years of PC history, with speeds accelerating from 200ns (5MHz) to 60ns (16MHz). By 1996, PC processor speeds had increased from 5MHz to 200MHz, but main memory had increased from 5MHz to only 16MHz in that same timeframe! More recently, main memory has caught up to the processor speed with the introduction of the RDRAM (Rambus DRAM) in new systems for 1999 and beyond.

Fast Page Mode (FPM) DRAM

Standard DRAM is accessed through a technique called *paging*. Normal memory access requires that a row and column address be selected, which takes time. Paging allows faster access to all the data within a given row of memory by keeping the row address the same and changing only the column. Memory that uses this technique is called *Page Mode* or *Fast Page Mode* memory. Other variations on Page Mode were called *Static Column* or *Nibble Mode* memory.

Paged memory is a simple scheme for improving memory performance that divides memory into pages ranging from 512 bytes to a few kilobytes long. The paging circuitry then enables memory locations in a page to be accessed with fewer wait states. If the desired memory location is outside the current page, one or more wait states are added while the system selects the new page.

To improve further on memory access speeds, systems have evolved to allow faster access to DRAM. One important change was the implementation of burst mode access in the 486 and later processors. Burst mode cycling takes advantage of the consecutive nature of most memory accesses. After setting up the row and column addresses for a given access, using burst mode, you can then access the next three adjacent addresses with no additional latency or wait states. A burst access is normally limited to four total accesses. To describe this, we often refer to the timing in the number of cycles for each access. A typical burst mode access of standard DRAM is expressed as $x\text{-}y\text{-}y\text{-}y$; x is the time for the first access (latency plus cycle time), and y represents the number of cycles required for each consecutive access.

Standard 60ns DRAM normally runs 5-3-3-3 burst mode timing. This means the first access takes a total of five cycles (on a 66MHz system bus, this is about 75ns total or $5 \times 15\text{ns}$ cycles), and the consecutive cycles take three cycles each ($3 \times 15\text{ns} = 45\text{ns}$). As you can see, the actual system timing is somewhat less than the memory is technically rated for. Without the bursting technique, memory access would be 5-5-5-5 because the full latency is needed for each memory transfer.

DRAM memory that supports paging and this bursting technique is called *Fast Page Mode (FPM)* memory. The term comes from the ability of memory accesses to data on the same page to be done with less latency. Most 486 and Pentium systems from 1995 and earlier use FPM memory.

Another technique for speeding up FPM memory was a technique called *interleaving*. In this design, two separate banks of memory are used together, alternating access from one to the other as even and odd bytes. While one is being accessed, the other is being precharged, when the row and column addresses are being selected. Then, by the time the first bank in the pair is finished returning data, the second bank in the pair is finished with the latency part of the cycle and is now ready to return data. While the second bank is returning data, the first bank is being

precharged, selecting the row and column address of the next access. This overlapping of accesses in two banks reduces the effect of the latency or precharge cycles and allows for faster overall data retrieval. The only problem is that to use interleaving, you must install identical pairs of banks together, doubling the amount of SIMMs or DIMMs required. This method was popular on 32-bit wide memory systems on 486 processors, but fell out of favor on Pentiums because of their 64-bit wide memory width. To do interleaving on a Pentium machine, you would need to install memory 128 bits at a time, meaning four 72-pin SIMMs or two DIMMs at a time.

EDO (Extended Data Out) RAM

A new type of memory called *EDO (Extended Data Out)* RAM became available for Pentium systems in 1995. EDO, a modified form of FPM memory, is also referred to as *Hyper Page Mode*. EDO was invented and patented by Micron Technology, although it has licensed production to many other memory manufacturers. EDO memory consists of specially manufactured chips that allow a timing overlap between successive accesses. The name *Extended Data Out* refers specifically to the fact that unlike FPM, the data output drivers on the chip are not turned off when the memory controller removes the column address to begin the next cycle. This allows the next cycle to overlap the previous one, saving approximately 10ns per cycle.

The effect of EDO is that cycle times are improved by allowing the memory controller to begin a new column address instruction while it is reading data at the current address. This is almost identical to what was achieved in older systems by interleaving banks of memory, but unlike interleaving, you don't need to install two identical banks of memory in the system at a time.

EDO RAM allows for burst mode cycling of 5-2-2-2, compared to the 5-3-3-3 of standard Fast Page Mode memory. To do four memory transfers, then, EDO would require 11 total system cycles, compared to 14 total cycles for FPM. This is a 22 percent improvement in overall cycling time, but in actual testing EDO normally increases overall system benchmark speed by about 5 percent. Even though the overall system improvement might seem small, the important thing about EDO is that it uses the same basic DRAM chip design as FPM, meaning that there is practically no additional cost over FPM. As such, EDO costs about the same as FPM and offers higher performance.

To actually use EDO memory, your motherboard chipset must support it. Most motherboard chipsets since the Intel 430FX (Triton), which debuted in 1995, have offered support for EDO. Because EDO memory chips cost the same to manufacture as standard chips, combined with Intel's support of EDO in all their chipsets, the PC market jumped on the EDO bandwagon full force.

- ◀◀ See "Fifth-Generation (P5 Pentium Class) Chipsets," p. 129, and "Sixth-Generation (P6 Pentium Pro/Pentium II/III Class) Chipsets," p. 151.

EDO RAM is ideal for systems with bus speeds of up to 66MHz, which fit perfectly with the PC market up through 1997. However, since 1998, the market for EDO has rapidly declined as the newer and faster SDRAM (Synchronous DRAM) architecture has become the standard for new PC system memory.

Burst EDO

A variation of EDO is *Burst Extended-Data-Out Dynamic Random Access Memory (BEDO DRAM)*. BEDO is basically EDO memory with special burst features for even speedier data transfers than standard EDO. Unfortunately, only one chipset (Intel 440FX Natoma) supported it, and it was quickly overshadowed by SDRAM, which seemed to be favored among PC system chipset and system designers. As such, you won't see BEDO being used in systems today, and it is no longer in production.

SDRAM

SDRAM stands for *Synchronous DRAM*, a type of DRAM that runs in synchronization with the memory bus. SDRAM delivers information in very high-speed bursts using a high-speed, clocked interface. SDRAM removes most of the latency involved in asynchronous DRAM because the signals are already in synchronization with the motherboard clock.

Like EDO RAM, your chipset must support this type of memory for it to be usable in your system. Starting in 1997 with the 430VX and 430TX, most of Intel's subsequent chipsets support SDRAM, making it the most popular type of memory for new systems. SDRAM is especially suited to the Pentium II/III architecture and the high-performance motherboards that run them.

SDRAM's performance is dramatically improved over FPM or EDO RAM. Because SDRAM is still a type of DRAM, the initial latency is the same, but overall cycle times are much faster than with FPM or EDO. SDRAM timing for a burst access would be 5-1-1-1, meaning that four memory reads would complete in only eight system bus cycles, compared to 11 cycles for EDO and 14 cycles for FPM.

Besides being able to work in fewer cycles, SDRAM is also capable of supporting 100MHz (10ns) or faster system bus cycling, which since 1998 has become the new standard for system speed. As such, almost all new PC systems sold in 1998 and for probably three years thereafter will include SDRAM memory. Recently SDRAM was updated to a revised PC133 specification, where the memory runs at up to 133MHz. This will be used in lower cost systems in lieu of faster RDRAM.

In the near future, this figure will probably be pushed to 200MHz to keep up with faster systems of the future.

SDRAM is sold in DIMM form and is often rated by megahertz speed rather than nanosecond cycling time, so you see SDRAM sold as 66MHz or 15ns, 83MHz or 12ns, or 100MHz or 10ns. Because of the extreme timing at the 100MHz level, Intel has created a PC/100 standard that defines the performance criteria a 100MHz memory module must meet to be reliable in a 100MHz system. To meet the criteria with enough overhead to spare, most PC/100-certified memory will be 8ns, or 125MHz. Even though they are technically capable of 125MHz, they will be PC/100 or 100MHz "certified." Although 10ns memory might work, Intel feels that it will not be reliable enough because the margins are too close.

Although SDRAM is much faster than previous types of memory, prices are not appreciably higher, which has made SDRAM's acceptance even more rapid.

Future DRAM Memory Technologies

RDRAM

The *RDRAM*, or *Rambus DRAM*, is a radical new memory design found in high-end PC systems starting in 1999. It is endorsed by Intel and is supported in most of their new PC motherboard chipsets for 1999 and beyond.

Rambus developed what is essentially a chip-to-chip memory bus, with specialized devices that communicate at very high rates of speed. What may be interesting to some is that this technology was first developed for game systems and first made popular by the Nintendo 64 game system!

Conventional memory systems that use FPM/EDO or SDRAM are known as *wide channel systems*. They have memory channels as wide as the processor's data bus, which for the Pentium and up is 64 bits. The DIMM (Dual Inline Memory Module) is a 64-bit wide device, meaning data can be transferred to it 64 bits (or 8 bytes) at a time. The fastest DIMMs are the SDRAM type, which run at 100MHz, meaning the overall throughput is 100×8 , or 800MB/sec. Most SDRAM controllers (built into the motherboard chipset North Bridge component) can handle only a single channel of memory with up to three or four banks total.

RDRAMs, on the other hand, are a narrow channel device. They transfer data only 16 bits (2 bytes) at a time (plus 2 optional parity bits), but at much faster speeds. They normally run 800MHz, meaning the overall throughput is 800×2 , or 1.6GB per second, twice that of SDRAM. Also, there is far less latency between transfers because they all run synchronously in a looped system and in only one direction, meaning that the actual overall throughput of an RDRAM bus is nearly triple that of standard 100MHz SDRAM. For further increases in speed, it is possible to use two or four RDRAM channels simultaneously, increasing memory throughput to 3.2GB/sec or 6.4GB/sec if necessary.

A single Rambus memory channel can support up to 32 individual RDRAM devices (the RDRAM chips), more if buffers are used. Each individual chip is serially connected to the next on a package called a *RIMM* (*Rambus Inline Memory Module*), but all memory transfers are done between the memory controller and a single device, not between devices. The individual RDRAM chips are contained on RIMMs, and a single channel normally has three RIMM sockets. The RDRAM memory bus is a continuous path through each device and module on the bus, with each module having input and output pins on opposite ends. Therefore, any RIMM sockets not containing a RIMM must then be filled with a continuity module to ensure that the path is completed. The signals that reach the end of the bus are terminated on the motherboard.

Each RDRAM on a RIMM essentially operates as a standalone module sitting on the 16-bit data bus. Internally, each RDRAM chip has a core that operates on a 128-bit wide bus split into eight 16-bit banks running at 100MHz. In other words, every 10ns (100MHz), each RDRAM chip can transfer 16 bytes to and from the core. This internally wide, yet externally narrow, high-speed interface is the key to RDRAM. Because of this design, the same type of silicon chip technology

can be used to increase speeds dramatically, while maintaining the same overall cost as the SDRAM type memory that preceded it. In other words, RDRAM, which is three times faster than SDRAM overall, costs about the same and is easy to manufacture.

Other improvements to the design include separating control and data signals on the bus. There are independent control and address buses split into two groups of pins for row and column commands, while data is transferred across the 2-byte wide data bus. The actual memory bus clock runs at 400MHz; however, data is transferred on both the falling and rising edge of the clock signal, or twice per clock pulse. The falling edge is called an *even cycle* and the rising edge is called an *odd cycle*. Complete memory bus synchronization is achieved by sending packets of data beginning on an even cycle interval. The overall wait before a memory transfer can begin (latency) is only one cycle, or 2.5ns maximum.

Figure 6.2 shows the relationship between clock and data cycles; you can see 5 total clock cycles (each with a falling and rising edge) and 10 data cycles in the same time. An RDRAM data packet always begins on an even (falling) transition for synchronization purposes.

Figure 6.2 RDRAM clock and data cycle relationship.

The architecture also supports multiple, simultaneous interleaved transactions in multiple separate time domains. This means that before a transfer has even completed, another can begin.

Another important feature of RDRAM is that it is a low-power memory system. The RIMMs themselves as well as the RDRAM devices run on only 2.5 volts and use low voltage signal swings from 1.0v to 1.8v, a swing of only 0.8v total. Combine this with RDRAMs also having four power-down modes and automatically transitioning into standby at the end of a transaction, and you can see why total module power is slightly lower than an SDRAM's at the desktop and similar to EDO for mobile systems.

RDRAM chips will be installed in modules called RIMMs. A RIMM (shown in Figure 6.3) is similar in size and physical form to current DIMMs, but they are not interchangeable. RIMMs are available in 32MB, 64MB, 128MB, and soon 256MB and larger capacities. They can be added to a system one at a time because each individual RIMM represents multiple banks to a system.

Figure 6.3 A 168-pin RIMM module.

An RDRAM memory controller with a single Rambus channel supports up to three RIMM modules, which at the 64Mbit-chip density level supports 256MB per RIMM. Future RIMM versions will be available in higher capacities, up to 1GB or more, and it will be possible to develop chipsets (with integral Rambus memory controllers) that can support more Rambus channels, allowing more RIMM sockets per board. There will also be a Small Outline (SO) version of the RIMM called an *SO-RIMM*, specifically designed to be used in notebook and portable computers.

RIMM modules and sockets are gold-plated and designed for 25 insertion/removal cycles. Each RIMM has 184 pins, split into two groups of 92 pins on opposite ends and sides of the module. The pinout of the RIMM is shown in Table 6.4.

RIMMs are keyed with two notches in the center. This prevents a backward insertion and prevents the wrong type (voltage) RIMM from being used in a system. Currently, all RIMMs run on 2.5v, but there might be new versions in the future that run on less. To allow for these new types of RIMMs, there are three possible keying options in the design (see Figure 6.4). The left key (indicated as “DATUM A” in the following figure) is fixed in position, but the center key can be in three different positions spaced 1 or 2mm to the right, indicating different types of RIMMs. The current default is option A, as shown in Figure 6.6 and Table 6.5, which corresponds to 2.5v operation.

Figure 6.4 RIMM keying options.

Table 6.5—Possible Keying Options for RIMMs

Option	Notch Separation	Description
A	11.5mm	2.5v RIMM
B	12.5mm	Reserved
C	13.5mm	Reserved

RIMMs incorporate a Serial Presence Detect (SPD) device, which is essentially a flash ROM on board. This ROM contains information about the RIMM's size and type, including detailed timing information for the memory controller. The memory controller automatically reads the data from the SPD ROM to configure the system to match the RIMMs installed.

Figure 6.5 shows a typical PC RIMM installation. The RDRAM controller and clock generator are typically in the motherboard chipset North Bridge component. As you can see, the Rambus memory channel flows from the memory controller through each of up to three RIMM modules in series. Each module contains 4, 8, 16, or more RDRAM devices (chips), also wired in series, with an onboard SPD ROM for system configuration. Any RIMM sockets without a RIMM installed must have a continuity module, shown in the last socket in this figure. This allows the memory bus to remain continuous from the controller through each module (and, therefore, each RDRAM device on the module) until the bus finally terminates on the motherboard. Note how the bus loops from one module to another. For timing purposes, the first RIMM socket must be 6 inches or less from the memory controller, and the entire length of the bus must not be more than it would take for a signal to go from one end to another in four data clocks, or about 5ns.

**Figure 6.5** Typical RDRAM bus layout, showing two RIMMs and one continuity module installed.

Interestingly, Rambus does not manufacture the RDRAM devices (the chips) or the RIMMs; that is left to other companies. Rambus is merely a design company, and it has no chip fabs or manufacturing facilities of its own. It licenses its technology to other companies who then manufacture

the devices and modules. There are currently at least 13 RDRAM licensees, including Fujitsu Ltd., Hitachi Ltd., Hyundai Electronics Industry Co. Ltd., IBM Microelectronics, LG Semiconductor Co. Ltd., Micron Technology Inc., Mitsubishi Electric Corp., NEC Corp., Oki Electric Industry Co. Ltd., Samsung Electronics Corp., Siemens AG, and Toshiba Corp. All these companies are manufacturing both the RDRAM devices and the RIMMs that contain them.

With Intel throwing its full weight behind the Rambus memory, and the outstanding performance of RDRAM combined with low cost, low power consumption, and small size, RDRAM is positioned to be the standard for PC memory into the next millennium and beyond.

DDR SDRAM

Double Data Rate (DDR) SDRAM memory is an evolutionary design of standard SDRAM in which data is transferred twice as fast. Instead of doubling the actual clock rate, DDR memory achieves the doubling in performance by transferring twice per transfer cycle, once at the leading (falling) and once at the trailing (rising) edge of the cycle (see Figure 6.2). This is similar to the way RDRAM operates and effectively doubles the transfer rate, even though the same overall clock and timing signals are used.

DDR is being proposed by processor companies, including AMD and Cyrix, and chipset manufacturers, including VIA Technologies, ALi (Acer Labs, Inc.), and SiS (Silicon Integrated Systems), as a low-cost license-free alternative to RDRAMs. Intel is officially supporting only RDRAMs for new high-end systems in 1999 and beyond, but DDR seems destined for the lower-end commodity PCs as an alternative. The DDR Consortium, an industry panel consisting of Fujitsu, Ltd., Hitachi, Ltd., Hyundai Electronics Industries Co., Mitsubishi Electric Corp., NEC Corp., Samsung Electronics Co., Texas Instruments, Inc., and Toshiba Corp. undertook official standardization of DDR.

Expect DDR SDRAM to make an appearance during late 1999, primarily in non-Intel processor-based systems.

Physical RAM Memory

The CPU and motherboard architecture (chipset) dictates a particular computer's physical memory capacity and the types and forms of memory that can be installed. Over the years, two main changes have occurred in computer memory—it has gradually become faster and wider! The CPU and the memory controller circuitry indicate the speed and width requirements. The memory controller in a modern PC resides in the motherboard chipset. Even though a system may physically support a given amount of memory, the type of software you run could dictate whether all the memory can be used.

The 8088 and 8086, with 20 address lines, can use as much as 1MB (1,024KB) of RAM. The 286 and 386SX CPUs have 24 address lines; they can keep track of as much as 16MB of memory. The 386DX, 486, Pentium, Pentium-MMX, and Pentium Pro CPUs have a full set of 32 address lines; they can keep track of 4GB of memory, and the Pentium II/III with 36 address lines can manage an impressive 64GB!

- ◀◀ See “Processor Specifications,” p. 39.

When the 286 and higher chips emulate the 8088 chip (as they do when running 16-bit software, such as DOS or Windows 3.x), they implement a hardware operating mode called *real mode*. Real mode is the only mode available on the 8086 and 8088 chips used in PC and XT systems. In real mode, all Intel processors—even the mighty Pentium—are restricted to using only 1MB of memory, just as their 8086 and 8088 ancestors were, and the system design reserves 384KB of that amount. Only in protected mode can the 286 or better chips use their maximum potential for memory addressing.

- ◀◀ See “Processor Modes,” p. 58.

Pentium-based systems can address as much as 4GB of memory, and P6 class (Pentium Pro/II/Celeron/III) systems can address 64GB. To put these memory-addressing capabilities into perspective, 64GB (65,536MB) of memory would cost about \$70,000! Even if you could afford all this memory, some of the largest memory modules available today are 168-pin DIMMs with 256MB capacity. To install 64GB of RAM would require 256 of the largest 256MB DIMMs available, and most systems today can support up to only four or maybe eight DIMM sockets.

Most Pentium II/Celeron/III motherboards have a maximum of only three to six DIMM sockets, which allows a maximum of .75–1.5GB if all the sockets are filled. These limitations are from the chipset, not the processor. Technically, a Pentium can address 4GB of memory and a Pentium II/Celeron/III can address 64GB, but there isn’t a chipset on the market that will allow that! Most of the Pentium II/III chipsets today are limited to 1GB of memory, some will handle up to 4GB.

Pentium systems have even more limitations. Pentium systems have been available since 1993, but only those built in 1997 or later use a motherboard chipset that supports SDRAM DIMMs. Even those using the newest 430TX chipset from Intel will not support more than 256MB of total memory and should not have more than 64MB actually installed because of memory-caching limitations. Don’t install more than 64MB of RAM in your Pentium system unless you are sure the motherboard and chipset will allow the L2 cache to function with the additional memory.

Note

See the “Chipsets” section in Chapter 4 for the maximum cacheable limits on all the Intel and other motherboard chipsets.

Older 386 and 486 motherboards could have problems addressing memory past 16MB because of DMA (Direct Memory Access) controller problems. If you install an ISA adapter that uses a DMA channel (such as a busmaster SCSI adapter) and you have more than 16MB of memory, you have the potential for problems because the ISA bus allows only DMA access to 16MB. Attempted transfers beyond 16MB cause the system to crash. This should not be an issue with newer 32-bit operating systems and 32-bit slots such as PCI. The 32-bit operating systems automatically remap ISA bus DMA transfers beyond 16MB properly, and PCI simply doesn’t have any such limitations.

SIMMs and DIMMs

Originally, systems had memory installed via individual chips. They are often referred to as *DIP* (*Dual Inline Package*) chips because of their design. The original IBM XT and AT had 36 sockets on the motherboard for these individual chips, and then more of them were installed on the memory cards plugged into the bus slots. I remember spending hours populating boards with these chips, which was a tedious job.

Besides being a time-consuming and labor-intensive way to deal with memory, DIP chips had one notorious problem—they crept out of their sockets over time as the system went through thermal cycles. Every day, when you powered the system on and off, the system heated and cooled, and the chips gradually walked their way out of the sockets. Eventually, good contact was lost and memory errors resulted. Fortunately, reseating all the chips back in their sockets usually rectified the problem, but that method was labor intensive if you had a lot of systems to support.

The alternative to this at the time was to have the memory soldered into either the motherboard or an expansion card. This prevented the chips from creeping and made the connections more permanent, but that caused another problem. If a chip did go bad, you had to attempt desoldering and resoldering a new one or resort to scrapping the motherboard or memory card where the chip was installed. This was expensive and made memory troubleshooting difficult.

What was needed was a chip that was both soldered yet removable, and that is exactly what was found in the chip called a *SIMM*. For memory storage, most modern systems have adopted the Single Inline Memory Module (SIMM) or Dual Inline Memory Module (DIMM) as an alternative to individual memory chips. These small boards plug into special connectors on a motherboard or memory card. The individual memory chips are soldered to the SIMM/DIMM, so removing and replacing them is impossible. Instead, you must replace the entire module if any part of it fails. The SIMM/DIMM is treated as though it were one large memory chip.

PC systems use two main physical types of SIMMs—30-pin (8 bits plus 1 optional parity bit) and 72-pin (32 bits plus 4 optional parity bits)—with various capacities and other specifications. The 30-pin SIMMs are smaller than the 72-pin versions and may have chips on one or both sides. The 30-pin SIMMs are basically obsolete and are being followed rapidly by the 72-pin versions. This is true primarily because the 64-bit systems, which are now the industry standard, would require eight 30-pin SIMMs or two 72-pin SIMMs per bank.

DIMMs, which are popular on Pentium-MMX, Pentium Pro, and Pentium II–based systems, are 168-pin units with 64-bit (non-parity) or 72-bit (parity or ECC) data paths. A 168-pin DIMM is physically one inch longer than a 72-pin SIMM, and can be recognized by having a secondary keying notch, but the main physical difference is that DIMMs have different signal pins on each side of the module. That is why they are called Dual Inline Memory Modules, and why with only an inch of additional length, they have many more pins than a SIMM.

Figures 6.6, 6.7, and 6.8 show typical 30-pin (8-bit) and 72-pin (32-bit) SIMMs and a 168-pin (64-bit) DIMM, respectively. The pins are numbered from left to right and are connected through

to both sides of the module on the SIMMs. The pins on the DIMM are different on each side, but on a SIMM, each side is the same as the other, and the connections carry through. Note that all dimensions are in both inches and millimeters (in parentheses).

Figure 6.6 A typical 30-pin SIMM. The one shown here is 9-bit, although the dimensions would be the same for 8-bit.

Figure 6.7 A typical 72-pin SIMM, although the dimensions would be the same for 32 bit.

Single inline pinned packages, sometimes called *SIPPs*, really are SIMMs with pins, not contacts. The pins are designed to be installed in a long connector socket that is much cheaper than the standard SIMM socket. SIPPs are inferior to SIMMs because they lack the positive latching mechanism that retains the module, and the connector lacks the high-force wiping contacts that resist corrosion. SIPPs are rarely used today.

Note

You could convert a SIPP to a SIMM by cutting off the pins or convert a SIMM to a SIPP by soldering pins on. Also, some companies have made SIPP-to-SIMM converters that allow the SIPPs to be plugged into 30-pin SIMM sockets.

Figure 6.8 A typical 168-pin DIMM. The one shown here is 72-bit, although the dimensions would be the same for 64-bit.

These memory modules are extremely compact, considering the amount of memory they hold. SIMMs and DIMMs are available in several capacities and speeds. Table 6.6 lists the different capacities available for the 30-pin and 72-pin SIMMs and 168-pin DIMMs.

Table 6.6 SIMM and DIMM Capacities

30-Pin SIMM Capacities

Capacity	Parity SIMM	Non-Parity SIMM
256KB	256KB×9	256KB×8
1MB	1MB×9	1MB×8
4MB	4MB×9	4MB×8
16MB	16MB×9	16MB×8

72-Pin SIMM Capacities

Capacity	Parity SIMM	Non-Parity SIMM
1MB	256KB×36	256KB×32
2MB	512KB×36	512KB×32
4MB	1MB×36	1MB×32
8MB	2MB×36	2MB×32
16MB	4MB×36	4MB×32
32MB	8MB×36	8MB×32
64MB	16MB×36	16MB×32
128MB	32MB×36	32MB×32

168-Pin DIMM Capacities

Capacity	Parity DIMM	Non-Parity DIMM
8MB	1MBx72	1MBx64
16MB	2MBx72	2MBx64
32MB	4MBx72	4MBx64
64MB	8MBx72	8MBx64
128MB	16MBx72	16MBx64
256MB	32MBx72	32MBx64

Dynamic RAM (DRAM) SIMMs and DIMMs of each type and capacity are available in different speed ratings. SIMMs have been available in many different speed ratings, ranging from 120ns for some of the slowest, to 50ns for some of the fastest available. DIMMs are available in speeds from 60ns to 10ns or faster. Many of the first systems to use SIMMs used versions rated at 120ns. They were quickly replaced in the market by 100ns and even faster versions. Today, you generally purchase EDO SIMMs rated at 60ns and SDRAM DIMMs rated at 10ns. Both faster and slower ones are available, but they are not often required and are difficult to get.

If a system requires a specific speed, you can almost always substitute faster speeds if the one specified is not available. There are no problems in mixing SIMM speeds, as long as you use SIMMs equal to or faster than what the system requires. Because there's little price difference between the different speed versions, I usually buy faster SIMMs than are needed for a particular application. This may make them more usable in a future system that could require the faster speed.

Since DIMMs have an onboard ROM which reports their speed to the system, most systems will run the memory controller and memory bus at the speed matching the slowest DIMM installed.

Note

Most DIMMs are Synchronous DRAM (SDRAM) memory, which means they deliver data in very high-speed bursts using a clocked interface. SDRAM supports bus speeds of up to 133MHz, with data transfer rates of up to 200MHz or higher possible in the future.

Several variations on the 30-pin SIMMs can affect how they work (if at all) in a particular system. First, there are actually two variations on the pinout configurations. Most systems use a generic type of SIMM, which has an industry-standard pin configuration. Many older IBM systems used a slightly modified 30-pin SIMM, starting with the XT-286 introduced in 1986 through the PS/2 Model 25, 30, 50, and 60. These systems require a SIMM with different signals on five of the pins. They are known as IBM-style 30-pin SIMMs. You can modify a generic 30-pin SIMM to work in the IBM systems and vice versa, but purchasing a SIMM with the correct pinouts is much easier. Be sure you tell the SIMM vendor if you need the specific IBM-style versions.

Another issue for the 30-pin SIMMs is the chip count. The SIMM acts as though it were a single chip of 8 bits wide (with optional parity), and it really does not matter how this total is derived.

Older SIMMs were constructed with eight or nine individual 1-bit-wide chips to make up the module, but many newer SIMMs use two 4-bit-wide chips and optionally one 1-bit-wide chip for parity, making a total of two or three chips on the SIMM. Accessing the two- or three-chip SIMMs can require adjustments to the refresh timing circuits on the motherboard, and many older 386 and 486 motherboards could not cope. Most newer motherboards automatically handle the slightly different refresh timing of both the two- and three-chip or eight- and nine-chip SIMMs. The two- and three-chip versions are more reliable, use less power, and generally cost less. If you have an older system, most likely it will work with the two- and three-chip SIMMs, but some do not. Unfortunately, the only way to know is to try them. To avoid the added time of changing to the eight/nine-chip versions if the two- and three-chip versions don't work in an older system, it seems wise to stick with the eight- and nine-chip variety in any older system.

The 72-pin SIMMs do not have different pinouts and are differentiated only by capacity and speed. The number of chips on them does not affect these SIMMs. The 72-pin SIMMs are ideal for 32-bit systems, such as 486 machines, because they compose an entire bank of memory (32 data bits plus 4 parity bits). When you configure a 32-bit (486) system that uses 72-pin SIMMs, you can usually add or remove memory as single SIMM modules (except on systems that use interleaved memory schemes to reduce wait states). This is because a 32-bit chip such as a 486 reads and writes banks of memory 32 bits wide, and a 72-pin SIMM is exactly 32 bits wide (36 bits with optional parity).

In 64-bit systems—which includes any Pentium or newer processor—72-pin SIMMs must be used in pairs to fill a single bank. A few motherboard manufacturers offer “SIMM-saver” motherboards that are designed for newer Pentium processors, but have both 72- and 30-pin SIMM sockets. Although this is not the most desirable arrangement, it allows users on a budget to reuse their old 30-pin SIMMs. In this situation, eight 30-pin SIMMs can be used at a time to fill one bank. Alternatively, you could pair four 30-pin SIMMs with one 72-pin SIMM to create one bank. This setup, however, really is not very because it consumes large amounts of space on the motherboard.

Other options available are SIMM stackers and converters. These items allow you to use 30-pin SIMMs in 72-pin sockets, thereby saving you the expense of having to scrap all those old 30-pin SIMMs you have lying around. Again, such adapters can cause problems—especially if overhead clearance is tight—so investigate carefully before you buy. With the falling prices of SIMMs today, you are probably better off staying with 72-pin SIMMs and 168-pin DIMMs.

Remember that some older high-performance 486 systems use interleaved memory to reduce wait states. This requires a multiple of two 72-pin 36-bit (32-bit) SIMMs because interleaved memory access is alternated between the SIMMs to improve performance. Thus, a 32-bit processor ends up using two 32-bit banks together in an alternating fashion.

If a Pentium system using 72-pin SIMMs were to use interleaving, you would have to install four 72-pin (32-bit) SIMMs at a time because it takes two of them to make up a single bank. Similarly, with DIMMs, you would have to install two at a time because normally a single DIMM represents

a bank on a Pentium, but interleaving requires that two banks be installed at a time and that they be identical. Most Pentium and higher systems don't use interleaving, as first EDO and then SDRAM eliminated the advantages it would offer.

Note

A bank is the smallest amount of memory that can be addressed by the processor at one time and usually corresponds to the data bus width of the processor. If the memory is interleaved, a virtual bank may be twice the absolute data bus width of the processor.

You cannot always replace a SIMM with a higher capacity unit and expect it to work. Systems might have specific design limitations for the maximum capacity of SIMM they can take. A larger capacity SIMM works only if the motherboard is designed to accept it in the first place. Consult your system documentation to determine the correct capacity and speed to use.

All systems on the market today use SIMMs, and many use DIMMs. The SIMM/DIMM is not a proprietary memory system, but an industry-standard device. As mentioned, some SIMMs have slightly different pinouts and specifications other than speed and capacity, so be sure you get the correct SIMMs for your system.

SIMM Pinouts

Tables 6.7 and 6.8 show the interface connector pinouts for 30-pin SIMM varieties and the standard 72-pin version. They also include a special presence detect table that shows the configuration of the presence detect pins on various 72-pin SIMMs. The presence detect pins are used by the motherboard to detect exactly what size and speed SIMM is installed. Industry-standard 30-pin SIMMs do not have a presence detect feature, but IBM did add this capability to their modified 30-pin configuration. Note that all SIMMs have the same pins on both sides of the module.

Table 6.7 Industry-Standard and IBM 30-Pin SIMM Pinouts

Pin	Standard SIMM Signal Names	IBM SIMM Signal Names
1	+5 Vdc	+5 Vdc
2	Column Address Strobe	Column Address Strobe
3	Data Bit 0	Data Bit 0
4	Address Bit 0	Address Bit 0

54	Data Bit 26	70	Presence Detect 4
55	Data Bit 11	71	Reserved
56	Data Bit 27	72	Ground

Notice that the 72-pin SIMMs use a set of four or five pins to indicate the type of SIMM to the motherboard. These presence detect pins are either grounded or not connected to indicate the type of SIMM to the motherboard. Presence detect outputs must be tied to the ground through a zero-ohm resistor or jumper on the SIMM—to generate a high logic level when the pin is open or low logic level when the pin is grounded by the motherboard. This produces signals that can be decoded by the memory interface logic. If the motherboard uses presence detect signals, then a POST procedure can determine the size and speed of the installed SIMMs and adjust control and addressing signals automatically. This allows the memory size and speed to be autodetected.

Note

In many ways, the presence detect pin function is similar to the industry-standard DX coding used on modern 35mm film rolls to indicate the ASA (speed) rating of the film to the camera. When you drop the film into the camera, electrical contacts can read the film's speed rating via an industry standard configuration.

Table 6.9 shows the JEDEC industry standard presence detect configuration listing for the 72-pin SIMM family. JEDEC is the Joint Electronic Devices Engineering Council, an organization of the U.S. semiconductor manufacturers and users that sets package outline dimension and other standards for chip and module packages.

Table 6.9 Presence Detect Pin Configurations for 72-Pin SIMMs

Size	Speed	Pin 67	Pin 68	Pin 69	Pin 70	Pin 11
1MB	100ns	Gnd	—	Gnd	Gnd	—

— = No Connection (open)

Gnd = Ground

Pin 67 = Presence detect 1

Pin 68 = Presence detect 2

Pin 69 = Presence detect 3

Pin 70 = Presence detect 4

Pin 11 = Presence detect 5

Unfortunately, unlike the film industry, not everybody in the computer industry follows established standards. As such, presence detect signaling is not a standard throughout the PC industry. Different system manufacturers sometimes use different configurations for what is expected on these four pins. Compaq, IBM (mainly PS/2 systems), and Hewlett-Packard are notorious for this type of behavior. Many of the systems from these vendors require special SIMMs that are basically the same as standard 72-pin SIMMs, except for special presence detect requirements. Table 6.10 shows how IBM defines these pins.

Table 6.10 72-Pin SIMM Presence Detect Pins

67	68	69	70	SIMM Type	IBM Part Number
—	—	—	—	Not a valid SIMM	n/a

Gnd = Ground

The DIMM uses a completely different type of presence detect called *serial presence detect*. It consists of a small EEPROM (Electrically Erasable Programmable Read Only Memory) or flash memory chip on the DIMM that contains specially formatted data indicating the DIMM's features. This serial data can be read via the serial data pins on the DIMM, and it allows the motherboard to autoconfigure to the exact type of DIMM installed.

Physical RAM Capacity and Organization

Several types of memory chips have been used in PC system motherboards. Most of these chips are single-bit-wide chips, available in several capacities. The following table lists available RAM chips and their capacities:

RAM Chip	Capacity
16KB by 1 bit	These devices were used in the original IBM PC with a Type 1 motherboard.
64KB by 1 bit	These chips were used in the standard IBM PC Type 2 motherboard and in the XT Type 1 and 2 motherboards. Many memory adapters of the era, such as the popular vintage AST six-pack boards, also used these chips.
128KB by 1 bit	These chips, used in the IBM AT Type 1 motherboard, often were a strange physical combination of two 64KB chips stacked one on top of the other and soldered together. Single-chip versions were also used for storing the parity bits in the IBM XT 286.
256KB by 1 bit (or 64KB by 4 bits)	These chips were once very popular in motherboards and memory cards. The IBM XT Type 2 and IBM AT Type 2 motherboards, and most compatible systems of that era, used these chips.
1MB by 1 bit (or 256KB by 4 bits)	1MB chips were very popular for a number of years and were most often used in 256KB to 8MB SIMMs.
4MB by 1 bit (or 1MB by 4 bits)	4MB chips are used primarily in SIMMs from 1MB to 16MB in capacity. They are used primarily in 4MB and 8MB SIMMs and generally are not sold as individual chips.
16MB by 1 bit (or 4MB by 4 bits)	16MB chips are often used in 72-pin SIMMs of 16MB to 32MB capacity.
64MB by 1 bit (or 16MB by 4 bits)	64MB chips are popular in high-capacity 16MB or larger memory modules, especially for notebook systems.

RAM Chip

256MB by 1 bit
(or 64MB by 4 bits)

Capacity

256MB chips are the most recent on the market. These chips allow enormous SIMM capacities of 128MB or larger! Because of the high expense and limited availability of these chips, you see them only in the most expensive and highest capacity modules on the market.

Note that chip capacity normally goes up by factors of 4 because the die that make up the chips are square. When they increase capacity, this normally results in four times more transistors and four times more capacity. Most modern SIMMs and DIMMs use 16Mbit to 256Mbit chips onboard.

Figure 6.9 shows the markings on a typical older memory chip. Many memory manufacturers use similar schemes for numbering their chips; however, if you are really trying to identify a particular chip, it is best to consult the manufacturer catalog for more information.

Figure 6.9 The markings on a typical older memory chip.

The -10 on the chip corresponds to its speed in nanoseconds (a 100-nanosecond rating). MB81256 is the chip's part number, which usually contains a clue about the chip's capacity. The key digits are 1256, which indicate that this chip is 1 bit wide and has a depth of 256KB. The 1 means that to make a full byte with parity, you need nine of these single-bit-wide chips. A chip with a part number of KM4164B-10 indicates a 64KB by 1-bit chip at a speed of 100 nanoseconds. The following list matches common chips with their industry-standard part numbers:

Part Number	Chip
4164	64KB by 1 bit
4464	64KB by 4 bits
41128	128KB by 1 bit
44128	128KB by 4 bits
41256	256KB by 1 bit
44256	256KB by 4 bits
41000	1MB by 1 bit
44000	1MB by 4 bits

Chips wider than 1 bit are used to construct banks of less than 9, 18, or 36 chips (depending on the system architecture). For example, a 32-bit SIMM can be constructed of only eight 4-bit-wide chips.

In Figure 6.9, the “F” symbol centered between two lines is the manufacturer’s logo for Fujitsu Microelectronics. The 8609 indicates the date of manufacture (ninth week of 1986). Some manufacturers, however, use a Julian date code. To further decode the chip, contact the manufacturer or chip vendor.

SIMMs and DIMMs also have part numbers that can be difficult to decode. Unfortunately, there is no industry standard for numbering these modules, so you have to contact the manufacturer if you want to decode the numbers. Figure 6.10 shows how Micron Technology (also Crucial Technology) SIMMs are encoded.

Figure 6.10 Typical SIMM part numbers for Micron (Crucial Technology) SIMMs.

Memory Banks

Memory chips (DIPs, SIMMs, SIPPs, and DIMMs) are organized in banks on motherboards and memory cards. You should know the memory bank layout and position on the motherboard and memory cards.

You need to know the bank layout when adding memory to the system. In addition, memory diagnostics report error locations by byte and bit addresses, and you must use these numbers to locate which bank in your system contains the problem.

The banks usually correspond to the data bus capacity of the system’s microprocessor. Table 6.12 shows the widths of individual banks based on the type of PC.

Table 6.12 Memory Bank Widths on Different Systems

Processor	Data Bus	Memory Bank Size (No Parity)	Memory Bank Size (Parity)	30-pin SIMMs per Bank	72-pin SIMMs per Bank	168-pin DIMMs per Bank
8088	8-bit	8 bits	9 bits	1	n/a	n/a
8086	16-bit	16 bits	18 bits	2	n/a	n/a
286	16-bit	16 bits	18 bits	2	n/a	n/a
386SX, SL, SLC	16-bit	16 bits	18 bits	2	n/a	n/a
486SLC, SLC2	16-bit	16 bits	18 bits	2	n/a	n/a
386DX	32-bit	32 bits	36 bits	4	1	n/a
486SX, DX, DX2, DX4, 5x86	32-bit	32 bits	36 bits	4	1	n/a
Pentium, K6	64-bit	64 bits	72 bits	8	2	1
Pentium Pro, II, Celeron, III	64-bit	64 bits	72 bits	8	2	1

The number of bits for each bank can be made up of single chips, SIMMs, or DIMMs. Modern systems don't use individual chips; instead, they use only SIMMs or DIMMs. If the system has a 16-bit processor such as a 386SX, it would probably use 30-pin SIMMs and have two SIMMs per bank. All the SIMMs in a single bank must be the same size and type.

A 486 system requires four 30-pin SIMMs or one 72-pin SIMM to make up a bank. A single 72-pin SIMM is 32 bits wide or 36 bits wide if it supports parity. You can often tell whether a SIMM supports parity by counting its chips. To make a 32-bit SIMM, you could use 32 individual 1-bit-wide chips, or you could use eight individual 4-bit-wide chips to make up the data bits. If the system used parity, then four extra bits are required (36 bits total), so you would see one more 4-bit-wide or four individual 1-bit-wide chips added to the bank for the parity bits.

As you might imagine, 30-pin SIMMs are less than ideal for 32-bit or 64-bit systems (that is, 486 or Pentium) because you must use them in increments of four or eight per bank! Because these SIMMs are available in 1MB, 4MB, and 16MB capacities today, this means that a single bank of 30-pin SIMMs in a 486 system would be 4MB, 16MB, or 64MB; for a Pentium system, this would be 8MB, 32MB, or 128MB of memory, with no in-between amounts. Using 30-pin SIMMs in 32- and 64-bit systems artificially constrains memory configurations and such systems are not recommended. If a 32-bit system (such as any PC with a 486 processor) uses 72-pin SIMMs, each SIMM represents a separate bank, and the SIMMs can be added or removed on an individual basis rather than in groups of four, as would be required with 30-pin SIMMs. This makes memory configuration much easier and more flexible. In modern 64-bit systems that use SIMMs, two 72-pin SIMMs are required per bank.

DIMMs are ideal for Pentium and higher systems, as the 64-bit width of the DIMM exactly matches the 64-bit width of the Pentium processor data bus. This means that each DIMM represents an individual bank, and they can be added or removed one at a time.

The physical orientation and numbering of the SIMMs or DIMMs used on a motherboard is arbitrary and determined by the board's designers, so documentation covering your system or card comes in handy. You can determine the layout of a motherboard or adapter card through testing, but that takes time and might be difficult, particularly after you have a problem with a system.

RAM Chip Speed

PC memory speeds vary from about 10ns to 200ns. When you replace a failed memory module, you must install a module of the same type and speed as the failed module. You can substitute a chip with a different speed only if the replacement chip's speed is equal to or faster than that of the failed chip.

Some people have had problems when "mixing" chips because they used a chip that did not meet the minimum required specifications (for example, refresh timing specifications) or was incompatible in pinout, depth, width, or design. Chip access time can always be less (that is, faster) as long as your chip is the correct type and meets all other specifications.

Substituting faster memory usually doesn't cause improved performance because the system still operates the memory at the same speed. In systems not engineered with a great deal of "forgiveness" in the timing between memory and system, however, substituting faster memory chips might improve reliability.

To place more emphasis on timing and reliability, Intel has created standards for the new high-speed 100MHz and 133MHz memory supported by their newer chipsets. Called the PC/100 and PC/133 standards, these are standards for certifying that memory modules perform within Intel's timing and performance guidelines. At 100MHz or higher, there is not much "forgiveness" or slop allowed in memory timing.

The same common symptoms result when the system memory has failed or is simply not fast enough for the system's timing. The usual symptoms are frequent parity check errors or a system that does not operate at all. The POST might report errors, too. If you're unsure of what chips to buy for your system, contact the system manufacturer or a reputable chip supplier.

▶▶ See "Parity Checking," p. 459.

Gold Versus Tin

Many people don't understand the importance of the SIMM and DIMM electrical contacts in a computer system. Both SIMMs and DIMMs are available in gold- or tin-plated contact form. I initially thought that gold contact SIMMs or DIMMs were the best way to go for reliability in all situations, but that is not true. To have the most reliable system, you must install SIMMs or DIMMs with gold-plated contacts into gold-plated sockets and SIMMs or DIMMs with tin-plated contacts into only tin-plated sockets.

If you don't heed this warning and install memory with gold-plated contacts into tin sockets or vice versa, you will get memory errors. In my experiences, they occur six months to one year after installation. I have encountered this problem several times in my own systems and in

several systems I have serviced. I have even been asked to assist one customer in a lawsuit. The customer had bought several hundred machines from a vendor, and severe memory failures began appearing in most of the machines approximately a year after delivery. The cause was traced to dissimilar metals between the memory modules and sockets (gold SIMMs in tin sockets, in this case). The vendor refused to replace the SIMMs with tin-plated versions, hence the lawsuit.

Most Intel Pentium and 486 motherboards that were designed to accept 72-pin SIMMs have tin-plated sockets, so they must have tin-plated memory. Intel now specifically recommends not mixing dissimilar metals in a system's memory. Studies done by the connector manufacturers show that a type of corrosion called *fretting* occurs when tin comes in pressure contact with gold or any other metal. With fretting corrosion, tin oxide transfers to the gold surface and hardens, eventually causing a high-resistance connection. This happens when gold comes into contact with tin, no matter how thick or thin the gold coating. Over time, depending on the environment fretting, corrosion can and will cause high resistance at the contact point and thus cause memory errors.

You would think tin makes a poor connector material because it readily oxidizes. Even so, electrical contact is easily made between two tin surfaces under pressure because the oxides on both soft surfaces bend and break, ensuring contact. This is especially true in SIMMs or DIMMs where a lot of pressure is placed on the contacts.

When tin and gold come into contact, because one surface is hard, the oxidation builds up and does not break easily under pressure. Increased contact resistance ultimately results in memory failures. The bottom line is that you should place only gold SIMMs into gold sockets and only tin SIMMs into tin sockets.

The connector manufacturer AMP has published several documents from the AMP Contact Physics Research Department that discuss this issue, but two are the most applicable. One is titled *Golden Rules: Guidelines for the Use of Gold on Connector Contacts*, and the other is called *The Tin Commandments: Guidelines for the Use of Tin on Connector Contacts*. Both can be downloaded in .PDF form from the AMP Web site. Here is an excerpt from the Tin Commandments, specifically commandment Number Seven, which states "7. Mating of tin-coated contacts to gold-coated contacts is not recommended." For further technical details, you can contact Intel or AMP at the sites I have recommended.

Certainly, the best type of setup is gold to gold, as in having gold-plated SIMMs or DIMMs and gold-plated sockets on the motherboard. Most high-end file servers or other high-reliability systems are designed this way. In fact, most systems that require SDRAM DIMMs use gold-plated sockets and therefore require SDRAM DIMMs with gold-plated contacts.

If you have mixed metals in your memory now, the correct solution is to replace the memory modules with the appropriate contact type to match the socket. Another much less desirable solution is to wait until problems appear (about six months to a year, in my experience), and then remove the modules, clean the contacts, reinstall, and repeat the cycle. This is probably fine if you are an individual with one or two systems, but it is not fine if you are maintaining hundreds of systems. If your system does not feature parity or ECC memory (most systems sold today

do not), when the problems do occur, you might not be able to immediately identify them as memory related (General Protection Faults, crashes, file and data corruption, and so on).

One problem with cleaning is that the hard tin oxide deposits that form on the gold surface are difficult to remove and often require abrasive cleaning (by using an eraser or crocus cloth, for example). This should never be done dry because it generates static discharges that can damage the chips. Instead, use a contact cleaner to lubricate the contacts; wet contacts minimize the potential for static discharge damage when rubbing the eraser or other abrasive on the surface.

To further prevent this problem from occurring, I highly recommend using a liquid contact enhancer and lubricant called Stabilant 22 from DW Electrochemicals when installing SIMMs or DIMMs. Its Web site has a detailed application note on this subject if you are interested in more technical details, see the Vendor List on the CD-ROM.

Some people have accused me of being too picky by insisting that the memory match the socket. On several occasions, I have returned either memory or motherboards because the vendor putting them together did not have a clue that this is a problem. When I tell some people about it, they tell me they have a lot of PCs with mixed metal contacts that run fine and have been doing so for many years.

Of course, that is certainly a poor argument against doing the right thing. Many people are running SCSI buses that are way too long, with improper termination, and they say it runs "fine." Parallel port cables are by the spec limited to 10 feet, yet I see many have longer cables, which they claim work "fine." The IDE cable limit is 18 inches; that spec is violated and people get away with it, saying their drive runs just "fine." I see cheap, crummy power supplies that put out noise, hash, and loosely regulated voltages, and I have even measured up to 69 volts AC of ground leakage, and yet the systems were running "fine." I have encountered numerous systems without proper CPU heat sinks, or where the active heat sink (fan) was stalled, and the system ran "fine." This reminds me of when Johnny Carson would interview 100-year-old people and often got them to admit that they drank heavily and smoked cigarettes every day, as if those are good practices that ensure longevity!

The truth is I am often amazed at how poorly designed or implemented some systems are, and yet they do seem to work... for the most part. The occasional lockup or crash is just written off by the user as "that's the way they all are." All except my systems, of course. In my systems, I adhere to proper design and engineering practices. In fact, I am often guilty of engineering or specifying overkill into things. Although it adds to the cost, they do seem to run better because of it.

In other words, what one individual can "get away" with does not change the laws of physics. It does not change the fact that for those supporting many systems or selling systems where the maximum in reliability and service life is desired, the gold/tin issue does matter.

Another issue that was brought to my attention was the thickness of the gold on the contacts; people are afraid that it is so thin, it will wear off after one or two insertions. Certainly, the choice of gold coating thickness depends on the durability required by the application; because of gold's high cost, it is prudent to keep the gold coating thickness as low as is appropriate for the durability requirements.

To improve durability, a small amount of cobalt or nickel added to the gold usually hardens the gold coatings. Such coatings are defined as “hard gold” and produce coatings with a low coefficient of friction and excellent durability characteristics. Hard gold-coated contacts can generally withstand hundreds to thousands of durability cycles without failing. Using an underlayer with a hardness value greater than that of gold alone that provides additional mechanical support can enhance the durability of hard gold coatings. Nickel is generally recommended as an underlayer for this purpose. Lubricants are also effective at increasing the durability of gold coatings. Generally, lubrication can increase the durability of a gold contact by an order of magnitude.

Increasing the thickness of a hard gold coating increases durability. The following laboratory results were obtained by AMP for the wear-through of a hard gold coating to the 1.3 micron (50 microinch) thick nickel underplate. The following data is for a 0.635cm. (0.250 in.) diameter ball wiped a distance of 1.27cm. (0.500 in.) under a normal force of 100 grams for each cycle.

Thickness Microns	Thickness Microinch	Cycles to Failure
0.4	15	200
0.8	30	1000
1.3	50	2000

As you can see from this table, an 0.8 micron (30 microinches) coating of hard gold results in durability that is more than adequate for most connector applications, as it allows 1,000 insertion and removal cycles before wearing through. I studied the specification sheets for DIMM and SIMM sockets produced by AMP and found that their gold-plated sockets come mostly as .000030 (30 microinches) thick gold over .000050 (50 microinches) thick nickel in the contact area. As far as I can determine, the coating on virtually all SIMM and DIMM contacts would be similar in thickness, allowing for the same durability.

AMP also has a few gold-plated sockets with specifications of .001020 (1,020 microinches)-thick gold over .001270 (1,270 microinches)-thick nickel. I’d guess that the latter sockets were for devices such as SIMM testers, where many insertions were expected over the life of the equipment. They could also be used in high-vibration or high-humidity environments.

For reference, all their tin-contact SIMM and DIMM sockets have the following connector plating specifications: .000030 (30 microinches) minimum thick tin on mating edge over .000050 (50 microinches) minimum thick nickel on entire contact.

The bottom line is that the thickness of the coating in current SIMM and DIMM sockets and modules is not an issue for the expected use of these devices. The thickness of the plating used in current SIMM and DIMM systems is also not relevant to the tin versus gold matability issue. The only drawback to a thinner gold plating is that it will wear after fewer insertion/removal cycles, exposing the nickel underneath and allowing the onset of fretting corrosion.

In my opinion, this tin/gold issue will be even more important for those using DIMMs, for two reasons. With SIMMs, you really have two connections for each pin (one on each side of the module), so if one of them goes high resistance, it will not matter; there is a built-in redundancy.

With DIMMs, you have many, many more connections (168 versus 72) and no redundant connections. The chance for failure is much greater. Also, most DIMM applications will be SDRAM, where the timing is down in the 15–10ns range for 66MHz and 100MHz boards, respectively. At these speeds, the slightest additional resistance in the connection causes problems.

Because of these issues, for the future I would specify only motherboards that have gold-plated SDRAM DIMM connectors, and then, of course, use only SDRAMs with gold-plated contacts. I noted that, for example, Micron produces only SDRAM DIMMs with gold-plated contacts, and all the DIMM sockets I've seen so far are gold plated, too. I would not currently recommend any motherboards using tin-lead SDRAM DIMM connectors, nor would I recommend purchasing tin-lead SDRAM DIMMs.

Parity and ECC

Part of the nature of memory is that it inevitably fails. These failures are usually classified as two basic types: hard fails and soft errors.

The most well understood are *hard fails*, in which the chip is working and then, because of some flaw, physical damage, or other event, becomes damaged and experiences a permanent failure. Fixing this type of failure normally requires replacing some part of the memory hardware, such as the chip, SIMM, or DIMM. Hard error rates are known as *HERs*.

The other more insidious type of failure is the *soft error*, which is a nonpermanent failure that might never reoccur or could occur only at infrequent intervals. (Soft fails are effectively “fixed” by powering the system off and back on.) Soft error rates are known as *SERs*.

About 20 years ago, Intel made a discovery about soft errors that shook the memory industry. It found that alpha-particles were causing an unacceptably high rate of soft errors or Single Event Upsets (*SEUs*, as they are sometimes called) in the 16KB DRAMs that were available at the time. Because alpha-particles are low-energy particles that can be stopped by something as thin and light as a sheet of paper, it became clear that for alpha-particles to cause a DRAM soft error, they would have to be coming from within the semiconductor material. Testing showed trace elements of thorium and uranium in the plastic and ceramic chip packaging materials used at the time. This discovery forced all the memory manufacturers to evaluate their manufacturing process to produce materials free from contamination.

Today, memory manufacturers have all but totally eliminated the alpha-particle source of soft errors. Many people believed that was justification for the industry trend to drop parity checking. The argument is that, for example, a 16MB memory subsystem built with 4MB technology would experience a soft error caused by alpha-particles only about once every 16 years! The real problem with this thinking is that it is seriously flawed, and many system manufacturers and vendors were coddled into removing parity and other memory fault-tolerant techniques from their systems even though soft errors continue to be an ongoing problem. More recent discoveries prove that alpha-particles are now only a small fraction of the cause of DRAM soft errors!

As it turns out, the biggest cause of soft errors today are cosmic rays. IBM researchers began investigating the potential of terrestrial cosmic rays in causing soft errors similar to alpha-particles.

The difference is that cosmic rays are very high-energy particles and cannot be stopped by sheets of paper or other more powerful types of shielding. The leader in this line of investigation was Dr. J.F. Ziegler of the IBM Watson Research Center in Yorktown Heights, New York. He has produced landmark research into understanding cosmic rays and their influence on soft errors in memory.

One example of the magnitude of the cosmic ray soft-error phenomenon demonstrated that with a certain sample of non-IBM DRAMs, the Soft Error Rate (SER) at sea level was measured at 5950 FIT (Failures in Time, which is measured at 1 billion hours) per chip. This was measured under real-life conditions with the benefit of millions of device hours of testing. In an average system with 36 memory chips among the SIMMs, this would result in a soft error occurring every six months! In power user or server systems with a larger amount of memory, it could mean an error per month or more. When the exact same test setup and DRAMs were moved to an underground vault shielded by over 50 feet of rock, thus eliminating all cosmic rays, absolutely no soft errors were recorded! This not only demonstrates how troublesome cosmic rays can be, but it also proves that the packaging contamination and alpha-particle problem has indeed been solved.

Cosmic ray-induced errors are even more of a problem in SRAMs than DRAMs because the amount of charge required to flip a bit in an SRAM cell is less than is required to flip a DRAM cell capacitor. Cosmic rays are also more of a problem for higher-density memory. As chip density increases, it becomes easier for a stray particle to flip a bit. It has been predicted by some that the Soft Error Rate of a 64MB DRAM will be double that of a 16MB chip, and a 256MB DRAM will have a rate four times higher.

Unfortunately, the PC industry has largely failed to recognize this new cause of memory errors. Electrostatic discharge, power surges, or unstable software can much more easily explain away the random and intermittent nature of a soft error, especially right after a new release of an operating system or major application.

Studies have shown that the soft-error rate for ECC systems is on the order of 30 times greater than the hard-error rate. This is not surprising to those familiar with the full effects of cosmic ray-generated soft errors. There is now data suggesting that some 16MB DRAM chip designs will actually experience soft errors numbering in the 24,000 FIT range. This would result in a soft error about once a month for most systems today!

Although cosmic rays and other radiation events are the biggest cause of soft errors, others can be caused by the following:

- *Power glitches or noise on the line.* This can be caused by a defective power supply in the system or by defective power at the outlet.
- *Incorrect type or speed rating.* The memory must be the correct type for the chipset, and match the system access speed.
- *RF (Radio Frequency) interference.* Caused by radio transmitters in close proximity to the system, which can generate electrical signals in system wiring and circuits.
- *Static discharges.* Causes momentary power spikes, which alters data.

- *Timing glitches.* Data doesn't arrive at the proper place at the proper time, causing errors. Often caused by improper settings in the BIOS setup, by memory that is rated slower than the system requires, or by overclocked processors and other system components.

Most of these problems don't cause chips to permanently fail (although bad power or static can damage chips permanently), but they can cause momentary problems with data.

How can you deal with these errors? Just ignoring them is certainly not the best way to deal with them, but unfortunately that is what many system manufacturers and vendors are doing today. The best way to deal with this problem is to increase the system's fault tolerance. This means implementing ways of detecting and possibly correcting errors in PC systems. There are basically three levels and techniques for fault tolerance used in modern PCs:

- Non-parity
- Parity
- ECC (Error Correcting Code)

Non-parity systems have no fault tolerance at all. The only reason they are used is because they have the lowest inherent cost. No additional memory is necessary, as is the case with parity or ECC techniques. Because a parity-type data byte has 9 bits versus 8 for non-parity, memory cost is 12.5 percent higher. Also, the non-parity memory controller is simplified because it does not need the logic gates to calculate parity or ECC check bits. Portable systems that place a premium on minimizing power might benefit from the reduction in memory power resulting from fewer DRAM chips. Finally, the memory system data bus is narrower, which reduces the amount of data buffers. The statistical probability of memory failures in a modern office desktop computer is now estimated at about one error every few months. Errors will be more or less frequent depending on how much memory you have.

This error rate might be tolerable for low-end systems that are not used for mission-critical applications. In this case, their extreme market cost sensitivity probably can't justify the extra cost of parity or ECC memory, and such errors then have to be tolerated.

At any rate, having no fault tolerance in a system is simply gambling that memory errors are unlikely. You further gamble that if they do occur, memory errors will result in an inherent cost less than the additional hardware necessary for error detection. However, the risk is that these memory errors can lead to serious problems. A memory error in a calculation could cause the wrong value to go into a bank check. In a server, a memory error could force a system hang and bring down all LAN-resident client systems with subsequent loss of productivity. Finally, with a non-parity or non-ECC memory system, tracing the problem is difficult, which is not the case with parity or ECC. These techniques at least isolate a memory source as the culprit, thus reducing both the time and cost of resolving the problem.

Parity Checking

One standard IBM set for the industry is that the memory chips in a bank of nine each handle 1 bit of data: 8 bits per character plus 1 extra bit called the *parity bit*. The parity bit enables memory-control circuitry to keep tabs on the other 8 bits—a built-in cross-check for the integrity of

each byte in the system. If the circuitry detects an error, the computer stops and displays a message informing you of the malfunction. If you are running a GUI operating system such as Windows or OS/2, a parity error generally manifests itself as a locked system. When you reboot, the BIOS should detect the error and display the appropriate error message.

SIMMs and DIMMs are available both with and without parity bits. Originally, all PC systems used parity-checked memory to ensure accuracy. Starting in 1994, a disturbing trend developed in the PC-compatible marketplace. Most vendors began shipping systems without parity checking or any other means of detecting or correcting errors! These systems can use cheaper non-parity SIMMs, which saves about 10–15 percent on memory costs for a system. Parity memory results in increased initial system cost, primarily because of the additional memory bits involved. Parity cannot correct system errors, but because parity can detect errors, it can make the user aware of memory errors when they happen. This has two basic benefits:

- Parity guards against the consequences of faulty calculations based on incorrect data.
- Parity pinpoints the source of errors, which helps with problem resolution, thus improving system serviceability.

PC systems can easily be designed to function using either parity or non-parity memory. The cost of implementing parity as an option on a motherboard is virtually nothing; the only cost is in actually purchasing the parity SIMMs or DIMMs, which are about 10–15 percent more expensive than non-parity versions. This enables a system manufacturer to offer its system purchasers the choice of parity if they feel the additional cost is justified for their particular application.

Unfortunately, several of the big names began selling systems without parity to reduce their prices, and they did not make it well known that the lower cost meant parity memory was no longer included as standard. This began happening mostly in 1994–1995, and has continued until recently, with few people understanding the full implications. After one or two major vendors did this, most of the others were forced to follow to remain price-competitive.

Because nobody wanted to announce this information, it remained sort of a dirty little secret within the industry. Originally, when this happened, you could still specify parity memory when you ordered a system, even though the default configurations no longer included it. There was a 10–15 percent surcharge on the memory, but those who wanted reliable, trustworthy systems could at least get them, provided they knew to ask, of course. Then a major bomb hit the industry, in the form of the Intel Triton 430FX Pentium chipset, which was the first major chipset on the market that did not support parity checking at all! It also became the most popular chipset of its time and was found in practically all Pentium motherboards sold in the 1995 timeframe. This set a disturbing trend for the next few years. All but one of Intel's Pentium processor chipsets after the 430FX did not support parity-checked memory; the only one that did was the 430HX Triton II. The good news is that this trend now seems to be over, and the system manufacturers and users are finally coming around to the importance of fault-tolerant memory. As such, all the Pentium Pro and Pentium II chipsets currently available do support parity and ECC, and more and more people are realizing that this type of memory is worthwhile. I do expect new low-end chipsets even for the Pentium II to emerge that do not support parity, but they are designed for the sub-\$1,000 market, where price, not system integrity, is the most important concern.

Let's look at how parity checking works, and then examine in more detail the successor to parity checking, called ECC (Error Correcting Code), which can not only detect but correct memory errors on-the-fly.

IBM originally established the odd parity standard for error checking. The following explanation may help you understand what is meant by odd parity. As the 8 individual bits in a byte are stored in memory, a parity generator/checker, which is either part of the CPU or located in a special chip on the motherboard, evaluates the data bits by adding up the number of 1s in the byte. If an even number of 1s is found, the parity generator/checker then creates a 1 and stores it as the ninth bit (parity bit) in the parity memory chip. That makes the sum for all 9 bits (including the parity bit) an odd number. If the original sum of the 8 data bits were an odd number, then the parity bit created would be a 0, keeping the sum for all 9 bits an odd number. The basic rule is that the value of the parity bit is always chosen so that the sum of all 9 bits (8 data bits plus 1 parity bit) is stored as an odd number. If the system used even parity, then the example would be the same except the parity bit would be created to ensure an even sum. It doesn't matter whether even or odd parity is used; the system will use one or the other, and it is completely transparent to the memory chips involved. Remember that the 8 data bits in a byte are numbered 0 1 2 3 4 5 6 7. The following examples might make it easier to understand:

Data bit number:	0 1 2 3 4 5 6 7	Parity bit
Data bit value:	1 0 1 1 0 0 1 1	0

In this example, because the total number of data bits with a value of 1 is an odd number (5), the parity bit must have a value of 0 to ensure an odd sum for all nine bits.

Here is another example:

Data bit number:	0 1 2 3 4 5 6 7	Parity bit
Data bit value:	1 1 1 1 0 0 1 1	1

In this example, because the total number of data bits with a value of 1 is an even number (6), the parity bit must have a value of 1 to create an odd sum for all 9 bits.

When the system reads memory back from storage, it checks the parity information. If a (9-bit) byte has an even number of bits with a parity bit value of 1, that byte must have an error. The system cannot tell which bit has changed or if only a single bit has changed. If 3 bits changed, for example, the byte still flags a parity-check error; if 2 bits changed, however, the bad byte could pass unnoticed. Because multiple bit errors (in a single byte) are rare, this scheme gives you a reasonable and inexpensive ongoing indication that memory is good or bad.

The following examples show parity-check messages for three types of older systems:

For the IBM PC:	PARITY CHECK x	
For the IBM XT:	PARITY CHECK x	yyyyy (z)
For the IBM AT and late model XT:	PARITY CHECK x	yyyyy

Where x is 1 or 2:

1 = Error occurred on the motherboard

2 = Error occurred in an expansion slot

In this example, *yyyyy* represents a number from 00000 through FFFFF that indicates, in hexadecimal notation, the byte in which the error has occurred.

Where (z) is (S) or (E):

(S) = Parity error occurred in the system unit

(E) = Parity error occurred in an optional expansion chassis

Note

An expansion chassis was an option IBM sold for the original PC and XT systems to add more expansion slots. This unit consisted of a backplane motherboard with eight slots; one slot contained a special extender/receiver card cabled to a similar extender/receiver card placed in the main system. Because of the extender/receiver cards in the main system and the expansion chassis, the net gain was six slots. Although the IBM version has long since been discontinued, other companies have since produced 8-bit and 16-bit ISA expansion chassis, allowing more ISA slots to be added to a system.

When a parity-check error is detected, the motherboard parity-checking circuits generate a *non-maskable interrupt (NMI)*, which halts processing and diverts the system's attention to the error. The NMI causes a routine in the ROM to be executed. The routine clears the screen and then displays a message in the screen's upper-left corner. The message differs depending on the type of computer system. On some older IBM systems, the ROM parity-check routine halts the CPU. In such a case, the system locks up, and you must perform a hardware reset or a power-off/power-on cycle to restart the system. Unfortunately, all unsaved work is lost in the process.

Most systems do not halt the CPU when a parity error is detected; instead, they offer you the choice of rebooting the system or continuing as though nothing happened. Additionally, these systems may display the parity error message in a different format from IBM, although the information presented is basically the same. For example, most systems with a Phoenix BIOS display one of these messages:

```
Memory parity interrupt at xxxx:xxxx
Type (S)hut off NMI, Type (R)eboot, other keys to continue
```

or

```
I/O card parity interrupt at xxxx:xxxx
Type (S)hut off NMI, Type (R)eboot, other keys to continue
```

The first of these two messages indicates a motherboard parity error (Parity Check 1), and the second indicates an expansion-slot parity error (Parity Check 2). Notice that the address given in the form *xxxx:xxxx* for the memory error is in a segment:offset form rather than a straight linear address, such as with IBM's error messages. The segment:offset address form still gives you the location of the error to a resolution of a single byte.

You have three ways to proceed after viewing this error message:

- You can press S, which shuts off parity checking and resumes system operation at the point where the parity check first occurred.

- Pressing R forces the system to reboot, losing any unsaved work.
- Pressing any other key causes the system to resume operation with parity checking still enabled.

If the problem occurs, it is likely to cause another parity-check interruption. It's usually prudent to press S, which disables the parity checking so that you can then save your work. In this case, it's best to save your work to a floppy disk to prevent the possible corruption of the hard disk. You should also avoid overwriting any previous (still good) versions of whatever file you are saving, because you could be saving a bad file caused by the memory corruption. Because parity checking is now disabled, your save operations will not be interrupted. Then you should power the system off, restart it, and run whatever memory diagnostics software you have to try to track down the error. In some cases, the POST finds the error on the next restart, but you usually need to run a more sophisticated diagnostics program, perhaps in a continuous mode, to locate the error.

Systems with an AMI BIOS displays the parity error messages in the following forms:

```
ON BOARD PARITY ERROR ADDR (HEX) = (xxxxx)
```

or

```
OFF BOARD PARITY ERROR ADDR (HEX) = (xxxxx)
```

These messages indicate that an error in memory has occurred during the POST, and the failure is located at the address indicated. The first one indicates that the error occurred on the motherboard, and the second message indicates an error in an expansion slot adapter card. The AMI BIOS can also display memory errors in the following manner:

```
Memory Parity Error at xxxxx
```

or

```
I/O Card Parity Error at xxxxx
```

These messages indicate that an error in memory has occurred at the indicated address during normal operation. The first one indicates a motherboard memory error, and the second indicates an expansion slot adapter memory error.

Although many systems enable you to continue processing after a parity error and even allow disabling further parity checking, continuing to use your system after a parity error is detected can be dangerous. The idea behind letting you continue using either method is to give you time to save any unsaved work before you diagnose and service the computer, but be careful how you do this.

Caution

When you are notified of a memory parity error, remember the parity check is telling you that memory has been corrupted. Do you want to save potentially corrupted data over the good file from the last time you saved? Definitely not! Make sure you save your work with a different filename. In addition, after a parity error, save only to a floppy disk if possible and avoid writing to the hard disk; there is a slight chance that the hard drive could become corrupted if you save the contents of corrupted memory.

After saving your work, determine the cause of the parity error and repair the system. You might be tempted to use an option to shut off further parity checking and simply continue using the system as though nothing were wrong. Doing so is like unscrewing the oil pressure warning indicator bulb on a car with an oil leak so that the oil pressure light won't bother you anymore!

A few years ago, when memory was more expensive, there were a few companies marketing SIMMs with bogus parity chips. Instead of actually having the extra memory chips needed to store the parity bits, these "logic parity" or parity "emulation" SIMMs used an onboard parity generator chip. This chip ignored any parity the system was trying to store on the SIMM, but when data was retrieved, it always ensured that the correct parity was returned, thus making the system believe all was well even though there might be a problem.

These bogus parity modules were used because memory was much more expensive, and a company could offer a "parity" SIMM for only a few dollars more with the fake chip. Unfortunately, identifying them can be difficult. The bogus parity generator doesn't look like a memory chip, and has different markings from the other memory chips on the SIMM. Most of them had a "GSM" logo, which indicated the original manufacturer of the parity logic device, not necessarily the SIMM itself.

One way to positively identify these bogus fake parity SIMMs is by using a hardware SIMM test machine, such as those by Darkhorse Systems or Aristo. Of course, I don't recommend using bogus parity SIMMs. Fortunately, the problem has mostly subsided because honest-to-gosh memory is much cheaper these days.

ECC (Error Correcting Code)

ECC goes a big step beyond simple parity error detection. Instead of just detecting an error, ECC allows a single bit error to be corrected, which means the system can continue without interruption and without corrupting data. ECC, as implemented in most PCs, can only detect, not correct, double-bit errors. Because studies have indicated that approximately 98% of memory errors are the single-bit variety, the most commonly used type of ECC is one in which the attendant memory controller detects and corrects single-bit errors in an accessed data word (double-bit errors can be detected, but not corrected). This type of ECC is known as *SEC-DED (Single-Bit Error Correction-Double-bit Error Detection)* and requires an additional 7 check bits over 32 bits in a 4-byte system and an additional 8 check bits over 64 bits in an 8-byte system. ECC in a 4-byte (32-bit, such as a 486) system obviously costs more than non-parity or parity, but in an 8-byte (64-bit, such as Pentium) system, ECC and parity costs are equal because the same number of extra bits (8) are required for either parity or ECC. Because of this, you can purchase parity SIMMs (36-bit) or DIMMs (72-bit) for Pentium systems and use them in an ECC mode if the chipset supports ECC functionality. If the Pentium system uses SIMMs, then two 36-bit (parity) SIMMs are added for each bank (for a total of 72-bits), and ECC is done at the bank level. If the Pentium system uses DIMMs, then a single parity/ECC 72-bit DIMM is used as a bank and provides the additional bits.

ECC entails the memory controller calculating the check bits on a memory-write operation, performing a compare between the read and calculated check-bits on a read operation, and, if necessary, correcting bad bits. The additional ECC logic in the memory controller is not very significant in this age of inexpensive, high-performance VLSI logic, but ECC actually affects memory performance on writes. This is because the operation must be timed to wait for the calculation of check bits and, when the system waits for corrected data, reads. On a partial-word write, the entire word must first be read, the affected byte(s) rewritten, and then new check bits calculated. This turns partial-word write operations into slower read-modify writes. Fortunately this performance hit is very small, on the order of a few percent at maximum, so the tradeoff for increased reliability is a good one.

Most memory errors are of a single-bit nature, which can be corrected by ECC. Incorporating this fault-tolerant technique provides high system reliability and attendant availability. An ECC-based system is a good choice for servers, workstations, or mission-critical applications in which the cost of a potential memory error outweighs the additional memory and system cost to correct it, along with ensuring that it does not detract from system reliability. If you value your data and use your system for important (to you) tasks, then you'll want ECC memory. No self-respecting manager would build or run a network server, even a lower end one, without ECC memory.

By designing a system that allows the user to make the choice of ECC, parity, or non-parity, users can choose the level of fault tolerance desired, as well as how much they want to gamble with their data.

Installing RAM Upgrades

Adding memory to a system is one of the most useful upgrades you can perform, and also one of the least expensive, especially when you consider the increased capabilities of Windows 9x, Windows NT, Windows 2000, and OS/2 when you give them access to more memory. In some cases, doubling the memory can practically double the speed of a computer.

The following sections discuss adding memory, including selecting memory chips, installing memory chips, and testing the installation.

Upgrade Options and Strategies

Adding memory can be an inexpensive solution; at this writing, the cost of memory has fallen to about \$1.50 per megabyte. A small dose can give your computer's performance a big boost.

How do you add memory to your PC? You have three options, listed in order of convenience and cost:

- Adding memory in vacant slots on your motherboard.
- Replacing your current motherboard's memory with higher-capacity memory.
- Purchasing a memory expansion card (not a cost-effective or performance-effective solution for any system currently on the market).

Adding expanded memory to PC- or XT-type systems is not a good idea, mainly because an expanded memory board with a couple of megabytes of expanded memory installed can cost more than the entire system is worth. Also, this memory does not function for Windows, and a PC- or XT-class system cannot run OS/2. Instead, purchase a more powerful system—for example, an inexpensive Pentium II 266—with greater expansion capabilities.

If you decide to upgrade to a more powerful computer system, you normally cannot salvage the memory from a PC or XT system. The 8-bit memory boards are useless in 16-bit systems, and the speed of the memory chips is usually inadequate for newer systems. All new systems use high-speed SIMM or DIMM modules rather than chips. A pile of 150ns (nanoseconds), 64KB, or 256KB chips is useless if your next system is a high-speed system that uses SIMMs, DIMMs or any memory devices faster than 70ns.

Be sure to carefully weigh your future needs for computing speed and for a multitasking operating system (OS/2, Windows 9x, Windows NT, Windows 2000, or Linux, for example) against the amount of money you spend to upgrade current equipment.

Before you add RAM to a system (or replace defective RAM chips), you must determine the memory chips required for your system. Your system documentation has this information.

If you need to replace a defective SIMM or DIMM and do not have the system documentation, you can determine the correct module for your system by inspecting the ones that are already installed. Each module has markings that indicate the module's capacity and speed. RAM capacity and speed are discussed in detail earlier in this chapter.

If you do not have the documentation for your system and the manufacturer does not offer technical support, open your system case and carefully write down the markings that appear on your memory chips. Then contact a local computer store or module vendor, such as Kingston, Micron (Crucial), PNY, or others, for help in determining the proper RAM chips for your system. Adding the wrong modules to a system can make it as unreliable as leaving a defective module installed and trying to use the system in that condition.

Note

Before upgrading a system beyond 64MB of RAM, be sure that your chipset supports caching more than 64MB. Adding RAM beyond the amount your system can cache slows performance rather than increases it. See the section "Cache Memory: SRAM" earlier in this chapter and the discussion of chipsets in Chapter 4 for a more complete explanation of this common system limitation. This limitation was mostly with Pentium (P5) class chipsets. Pentium II/III processors have the L2 cache controller integrated in the processor (not the chipset) which will support caching up to 1GB, or 4GB on most newer models.

Selecting and Installing Motherboard Memory with Chips, SIMMs, or DIMMs

If you are upgrading a motherboard by adding memory, follow the manufacturer's guidelines on which memory chips or modules to buy. As you learned earlier, memory comes in various form

factors, including individual chips known as DIP memory chips, SIMMs, and DIMMs. Your computer may use one or possibly a mixture of these form factors.

No matter what type of memory chips you have, the chips are installed in memory banks. A *memory bank* is a collection of memory chips that make up a block of memory. Your processor reads each bank of memory in one pass. A memory bank does not work unless it is filled with memory chips. (Banks are discussed in more detail earlier in this chapter in the section “Memory Banks.”)

Pentium and newer systems through the Pentium III normally have between two and four banks of memory, but each bank usually requires two 72-pin (32- or 36-bit) SIMMs or most likely one 168-pin DIMM.

Installing extra memory on your motherboard is an easy way to add memory to your computer. Most systems have at least one vacant memory bank where you can install extra memory at a later time and speed up your computer.

Replacing SIMMs and DIMMs with Higher Capacity

If all the SIMM or DIMM slots on your motherboard are occupied, your best option is to remove an existing bank of memory and replace it with higher-capacity memory. For example, if you have 16MB of RAM in a Pentium system with four SIMM slots filled with 4MB 72-pin SIMMs, you may be able to replace all four SIMMs with 8MB SIMMs and increase the system memory to 32MB. Alternatively, you could keep two of the existing 4MB SIMMs and replace two with 8MB SIMMs, increasing the total RAM to 24MB. Remember that just as when you install SIMMs, they need to be replaced in a full bank and all the SIMMs in the bank need to be the same capacity. The requirement for multiple modules is not an issue with DIMMs because in all current systems, a DIMM constitutes at least one full bank of memory.

However, just because there are higher-capacity SIMMs or DIMMs available that are the correct pin count to plug into your motherboard, don't automatically assume the higher-capacity memory will work. Your system's chipset and BIOS will set limits on the capacity of the memory you can use. Check your system or motherboard documentation to see what size SIMMs or DIMMs work with it before purchasing the new RAM. It is a good idea to make sure you have the latest BIOS when installing new memory.

Adding Adapter Boards

Memory expansion boards typically are a last-resort way to add memory. For many systems (such as older models from Compaq) with proprietary local bus memory-expansion connectors, you must purchase all memory-expansion boards from that company. Similarly, IBM used proprietary memory connectors in many of the PS/2 systems. For other industry-standard systems that use nonproprietary memory expansion, you can purchase from hundreds of vendors' memory-expansion boards that plug into the standard bus slots.

Unfortunately, any memory expansion that plugs into a standard bus slot runs at bus speed rather than at full-system speed. For this reason, most systems today provide standard SIMM or

DIMM connector sockets directly on the motherboard so that the memory can be plugged directly into the system's local bus. Using memory adapter cards in these systems only slows them down. Other systems use proprietary local bus connectors for memory-expansion adapters, which can cause additional problems and expense when you have to add or service memory. Upgrading a system by using a memory adapter card is no longer cost-effective, either. Because most systems and motherboards built on 486 or later processors can be upgraded with SIMMs or DIMMs, the only systems that would be upgraded with an adapter card are so old, it would be less expensive to replace the entire motherboard than to upgrade these old systems.

Installing Memory

This section discusses installing memory—specifically, new SIMM or DIMM modules. It also covers the problems you are most likely to encounter and how to avoid them. You will also get information on configuring your system to use new memory.

When you install or remove memory, you are most likely to encounter the following problems:

- Electrostatic discharge
- Broken or bent pins
- Incorrectly seated SIMMs and DIMMs
- Incorrect switch and jumper settings

To prevent electrostatic discharge (ESD) when you install sensitive memory chips or boards, do not wear synthetic-fiber clothing or leather-soled shoes. Remove any static charge you are carrying by touching the system chassis before you begin, or better yet, wear a good commercial grounding strap on your wrist. You can order one from an electronics parts store or mail-order house. A grounding strap consists of a conductive wristband grounded at the other end by a wire clipped to the system chassis. Leave the system unit plugged in—but turned off—to keep it grounded.

Caution

Be sure to use a properly designed commercial grounding strap; do not make one yourself. Commercial units have a one-meg ohm resistor that serves as protection if you accidentally touch live power. The resistor ensures that you do not become the path of least resistance to the ground and therefore become electrocuted. An improperly designed strap can cause the power to conduct through you to the ground, possibly killing you.

Broken or bent leads are another potential problems associated with installing individual memory chips (DIPs) or SIPP modules. Fortunately, this is not a problem you have when installing a SIMM or DIMM. Sometimes, the pins on new chips are bent into a V, making them difficult to align with the socket holes. If you notice this problem on a DIP chip, place the chip on its side on a table, and press gently to bend the pins so that they are at a 90-degree angle to the chip. For a SIPP module, you might want to use needle-nose pliers to carefully straighten the pins so that they protrude directly down from the edge of the module, with equal amounts of space between pins. Then you should install the chips in the sockets one at a time.

Caution

Straightening the pins on a DIP chip or SIPP module is not difficult work, but if you are not careful, you could easily break off one of the pins, rendering the chip or memory module useless. Use great care when you straighten the bent pins on any memory chip or module. You can use chip-insertion and pin-straightening devices to ensure that the pins are straight and aligned with the socket holes; these inexpensive tools can save you a great deal of time.

Each memory chip or module must be installed to point in a certain direction. Each device has a polarity marking on one end. This is normally a notch on SIMMs or DIMMs and could be a notch, circular indentation, or mark on any individual chip. The chip socket might have a corresponding notch. Otherwise, the motherboard may have a printed legend that indicates the chip's orientation. If the socket is not marked, you should use other chips as a guide. The orientation of the notch indicates the location of Pin 1 on the device. Aligning this notch correctly with the others on the board ensures that you do not install the chip backward. Gently set each chip into a socket, ensuring that every pin is properly aligned with the connector into which it fits. Then push the chip in firmly with both thumbs until it is fully seated.

SIMM memory is oriented by a notch on one side of the module that is not present on the other side, as shown in Figure 6.11. The socket has a protrusion that must fit into this notched area on one side of the module. This protrusion makes it impossible to install a SIMM backward unless you break the connector. Figure 6.11 shows a detailed blowup of the backside of the SIMM, showing the notch and the locking clip. Figure 6.12 shows a close-up of a SIMM (note that it, too, is keyed to ensure proper expansion socket installation).

Figure 6.11 The notch on this SIMM is shown on the left end. Insert the SIMM at an angle and then tilt it forward until the locking clips snap into place.

Similarly, DIMMs are keyed by notches along the bottom connector edge that are offset from center so that they can be inserted in only one direction, as shown in Figure 6.13. SIPP modules, however, do not plug into a keyed socket; you have to orient them properly. The system documentation can be helpful if the motherboard has no marks to guide you. You can also use existing SIPP modules as a guide.

The DIMM ejector tab locks into place in the notch on the side of the DIMM when it is fully inserted. Some DIMM sockets have ejector tabs on both ends. When installing SIMMs and DIMMs, take care not to force the module into the socket. If the module does not slip easily into the slot and then snap into place, there is a good chance the module is not oriented or aligned correctly. Forcing the module could break the module or the socket. If the retaining clips on the socket break, the memory isn't held firmly in place, and there is a good chance you will get random memory errors because the module can't make consistent electrical contact if it is loose.

Figure 6.12 This close-up shows the backside of a SIMM inserted in the SIMM socket with the notch aligned, the locking clip locked, and the hole in the SIMM aligned with the tab that sticks out from the socket.

As explained earlier in this chapter, DIMMs can come in several different varieties, including unbuffered or buffered and 3.3v or 5v. Buffered DIMMs have additional buffer chips on them to interface to the motherboard. Unfortunately, these buffer chips slow the DIMM down and are not effective at higher speeds. For this reason, all PC systems use unbuffered DIMMs. The voltage is simple—DIMM designs for PCs are almost universally 3.3v. If you install a 5v DIMM in a 3.3v socket, it would be damaged, but fortunately, keying in the socket and on the DIMM prevents that.

Figure 6.13 DIMM keys match the protrusions in the DIMM sockets.

Modern PC systems use only unbuffered 3.3v DIMMs. Apple and other non-PC systems may use the buffered 5v versions. Fortunately, the key notches along the connector edge of a DIMM are spaced differently for RFU and buffered DIMMs and 5.0v DIMMs, as shown in Figure 6.14. This prevents inserting a DIMM of the wrong type into a socket.

Figure 6.14 168-pin DRAM DIMM notch key definitions.

Before installing memory, make sure the system power is off. Then remove the PC cover and any installed cards. SIMMs and DIMMs snap easily into place, but chips can be more difficult to install. A chip-installation tool is not required, but it can make inserting the chips into sockets much easier. To remove chips, use a chip extractor or small screwdriver. Never try removing a RAM chip with your fingers because you can bend the chip's pins or poke a hole in your finger with one of the pins. You remove SIMMs and DIMMs by releasing the locking tabs and either pulling or rolling them out of their sockets.

After adding the memory and putting the system back together, you might have to run the CMOS Setup and resave with the new amount of memory. Most newer systems automatically detect the new amount of memory and reconfigure it for you. Most newer systems also don't require setting any jumpers or switches on the motherboard to configure them for your new memory. Older motherboards that use individual RAM chips rather than SIMMs or DIMMs for memory are more likely to need changes to jumper and switch settings. If you install individual RAM chips on a motherboard and the CMOS does not recognize the new RAM, check the system documentation to see if changes to motherboard jumpers or switches are required.

Note

Information on installing memory on older memory-expansion cards can be found in Chapter 7 of the Sixth Edition of *Upgrading and Repairing PCs* on the CD-ROM accompanying this book.

After configuring your system to work properly with the additional memory, you should run a memory-diagnostics program to make sure the new memory works properly. At least two and sometimes three memory-diagnostic programs are available for all systems. In order of accuracy, these programs are as follows:

- POST (power on self test)
- Disk-based advanced diagnostics software

The POST is used every time you power up the system.

Many additional diagnostics programs are available from aftermarket utility software companies. More information on aftermarket testing facilities can be found in Chapter 25, "PC Diagnostics, Testing, and Maintenance."

Troubleshooting Memory

Memory problems can be difficult to troubleshoot. For one thing, computer memory is still mysterious to people, as it is a kind of "virtual" thing that can be hard to grasp. The other difficulty is that memory problems can be intermittent and often look like problems with other areas of the system, even software. This section will show simple troubleshooting steps you can perform if you suspect you are having a memory problem.

To troubleshoot memory, you first need some memory diagnostics testing programs. You already have several, and might not know it! Every motherboard BIOS has a memory diagnostic in the POST that runs when you first turn on the system. In most cases, you also received a memory diagnostic on a utility disk that came with your system.

When the POST runs, it not only tests memory, but also counts it. The count is compared to the amount counted the last time BIOS SETUP was run; if it is different, an error message is issued. As the POST runs, it writes a pattern of data to all the memory locations in the system and reads that pattern back to verify that the memory works. If any failure is detected, you see or hear a

message. Audio messages (beeping) are used for critical or “fatal” errors that occur in areas important for the system’s operation. If the system can access enough memory to at least allow video to function, then you see error messages instead of hearing beep codes.

See Chapter 5 for detailed listings of the BIOS beep and other error codes, which are specific to the type of BIOS you have. For example, most Intel motherboards use the Phoenix BIOS. Several different beep codes are used in that BIOS to indicate fatal memory errors.

If your system makes it through the POST with no memory error indications, then there might not be a hardware memory problem, or the POST might not be able to detect the problem. Intermittent memory errors are often not detected during the POST, and other subtle hardware defects can be hard for the POST to catch. The POST is designed to run quickly, so the testing is not nearly as thorough as it could be. That is why you often have to boot from a DOS or diagnostic disk and run a true hardware diagnostic to do more extensive memory testing. These types of tests can be run continuously, and left running for days if necessary to hunt down an elusive intermittent defect.

Still, even these programs do only pass/fail type testing; that is, all they can do is write patterns to memory and read them back. They cannot determine how close the memory is to failing—only that it worked or not. For the highest level of testing, the best thing to have is a dedicated memory test machine, normally called a *SIMM/DIMM tester*. These devices allow you to insert a module and test it thoroughly at a variety of speeds, voltages, and timings to let you know for certain whether the memory is good or bad. I have defective SIMMs, for example, that work in some systems (slower ones) but not others. What I mean is that the *same* memory test program fails the SIMM in one machine but passes it in another. In the SIMM tester, it is always identified as bad right down to the individual bit, and it even tells me the actual speed of the device, not just its rating. Several companies that offer SIMM/DIMM testers are included in the vendor list, including Darkhorse Systems and Aristo. They can be expensive, but for a professional in the PC repair business, using one of these SIMM/DIMM testers is the only way to go.

After your operating system is running, memory errors can still occur, normally identified by error messages you might receive. These are the most common:

- *Parity errors.* Indicates that the parity checking circuitry on the motherboard has detected a change in memory since the data was originally stored. (See the “Parity Checking” section earlier in this chapter.)
- *General or global protection faults.* A general-purpose error indicating that a program has been corrupted in memory, usually resulting in immediate termination of the application. This can also be caused by buggy or faulty programs.
- *Fatal exception errors.* Error codes returned by a program when an illegal instruction has been encountered, invalid data or code has been accessed, or the privilege level of an operation is invalid.
- *Divide error.* A general-purpose error indicating that a division by zero was attempted or the result of an operation does not fit in the destination register.

If you are encountering these errors, they could be caused by defective or improperly configured memory, but they can also be caused by software bugs (especially drivers), bad power supplies, static discharges, close proximity radio transmitters, timing problems, and more.

If you suspect the problems are caused by memory, there are ways to test the memory to determine whether that is the problem. Most of this testing involves running one or more memory test programs.

I am amazed that most people make a critical mistake when they run memory test software. The biggest problem I see is that people run memory tests with the system caches enabled. This effectively invalidates memory testing because most systems have what is called a *write-back cache*. This means that data written to main memory is first written to the cache. Because a memory test program first writes data and then immediately reads it back, the data is read back from the cache, not the main memory. It makes the memory test program run very quickly, but all you tested was the cache. The bottom line is that if you test memory with the cache enabled, then you aren't really writing to the SIMM/DIMMs, but only to the cache. Before you run any memory test programs, be sure your cache is disabled. The system will run very slowly when you do this, and the memory test will take much longer to complete, but you will be testing your actual RAM, not the cache.

The following steps will allow you to effectively test and troubleshoot your system RAM. Figure 6.15 provides a boiled-down procedure to help you step through the process quickly.

First, let's cover the memory testing and troubleshooting procedures.

1. Power up the system and observe the POST. If the POST completes with no errors, then basic memory functionality has been tested. If errors are encountered, go to the defect isolation procedures.
2. Restart the system, and enter your BIOS (or CMOS) Setup. In most systems, this is done by pressing the F2 key during the POST but before the boot process begins. Once in BIOS setup, verify that the memory count is equal to the amount that has been installed. If the count does not match what has been installed, go to the defect isolation procedures.
3. Find the BIOS setup options for cache, and set all cache options to disabled. Save the settings and reboot to a DOS formatted system disk (floppy) containing the diagnostics program of your choice. If your system came with a diagnostics disk, you can use that, or you can use one of the many commercial PC diagnostics programs on the market, such as PC-Technician by Windsor Technologies (which comes in self-booting form), the Norton Utilities by Symantec, or others.
4. Follow the instructions that came with your diagnostic program to have it test the system base and extended memory. Most programs have a mode that allows them to loop the test—that is, to run it continuously, which is great for finding intermittent problems. If the program encounters a memory error, proceed to the defect isolation procedures.
5. If no errors are encountered in the POST or in the more comprehensive memory diagnostic, then your memory has tested okay in hardware. Be sure at this point to reboot the system, enter the BIOS setup, and re-enable the cache. The system will be running very slowly until the cache is turned back on.

Figure 6.15 Testing and troubleshooting memory.

6. If you are having memory problems yet the memory still tests okay, then you might have a problem undetectable by simple pass/fail testing, or your problems are caused by software or one of many other defects or problems in your system. You might want to bring the memory to a SIMM/DIMM tester for a more accurate analysis. Most PC repair shops have such a tester. I would also check the software (especially drivers, which might need updating), power supply, and system environment for problems such as static, radio transmitters, and so forth.

Memory Defect Isolation Procedures

To use these steps, I am assuming you have identified an actual memory problem that is being reported by the POST or disk-based memory diagnostics. If this is the case, see the following steps and Figure 6.16 to see the steps to identify or isolate which SIMM or DIMM in the system is causing the problem.

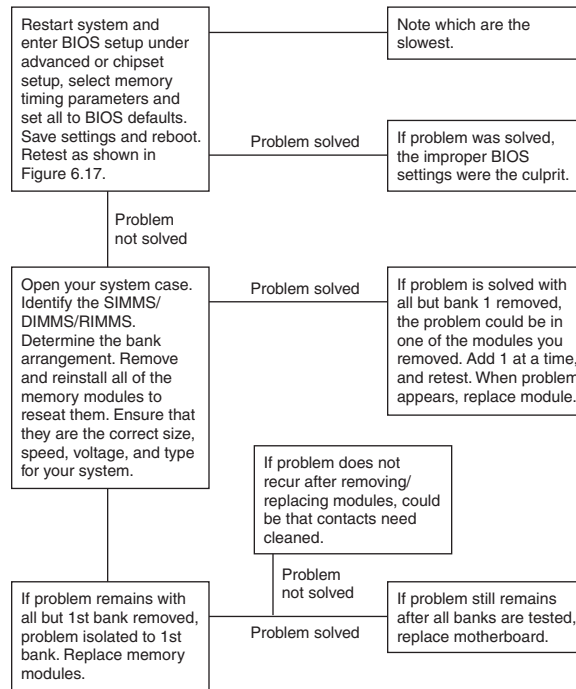

Figure 6.16 Follow these steps if you are still encountering memory errors after completing the steps in Figure 6.15.

1. Restart the system and enter the BIOS setup. Under a menu usually called Advanced or Chipset Setup, there may be memory timing parameters. Select BIOS or Setup defaults, which are usually the slowest settings. Save the settings, reboot, and retest using the testing and troubleshooting procedures listed earlier. If the problem has been solved, improper BIOS settings were the problem. If the problem remains, you likely do have defective memory, so continue to the next step.
2. Open the system up for physical access to the SIMM/DIMMs on the motherboard. Identify the bank arrangement in the system. For example, Pentium systems use 64-bit banks, which means two 72-pin SIMMs or one 168-pin DIMM per bank. Using the manual or the legend silk-screened on the motherboard, identify which SIMMs or DIMM correspond to which bank. Most Pentium boards that use SIMMs have four, six, or eight total SIMMs installed in two, three, or four banks. Most boards using DIMMs have two, three, or four total DIMMs, each of which represents a single bank.
3. Remove all the memory except the first bank, and retest using the troubleshooting and testing procedures listed earlier. If the problem remains with all but the first bank removed, then the problem has been isolated to the first bank, which must be replaced.
4. Replace the memory in the first bank, preferably with known good spare modules, but you can also swap in others that you have removed and retest. If the problem *still* remains after testing all the memory banks (and finding them all to be working properly), it is likely the

- motherboard itself is bad (probably one of the memory sockets). Replace the motherboard and retest.
5. At this point, the first (or previous) bank has tested good, so the problem must be in the remaining modules that have been temporarily removed. Install the next bank of memory and retest. If the problem resurfaces now, then the memory in that bank is defective. Continue testing each bank until you find the defective module.
 6. Repeat the preceding step until all remaining banks of memory are installed and have been tested. If the problem has not resurfaced after removing and reinstalling all the memory, then the problem was likely intermittent or caused by poor conduction on the memory contacts. Often simply removing and replacing memory can resolve problems because of the self-cleaning action between the SIMM/DIMM and the socket during removal and reinstallation.

The System Logical Memory Layout

The original PC had a total of 1MB of addressable memory, and the top 384KB of that was reserved for use by the system. Placing this reserved space at the top (between 640KB and 1024KB instead of at the bottom, between 0KB and 640KB) led to what is often called the *conventional memory barrier*. The constant pressures on system and peripheral manufacturers to maintain compatibility by never breaking from the original memory scheme of the first PC has resulted in a system memory structure that is (to put it kindly) a mess. Almost two decades after the first PC was introduced, even the newest Pentium II-based systems are limited in many important ways by the memory map of the first PCs.

What we end up with is a PC with a split personality. There are two primary modes of operation that are very different from each other. The original PC used an Intel 8088 processor that could run only 16-bit instructions or code, which ran in what was called the *real mode* of the processor. These early processors had only enough address lines to access up to 1MB of memory, and the last 384KB of that was reserved for use by the video card as video RAM, other adapters (for on-card ROM BIOS), and finally the motherboard ROM BIOS.

The 286 processor brought more address lines, enough to allow up to 16MB of RAM to be used, and a new mode called *protected mode* that you had to be in to use it. Unfortunately, all the operating systems software at the time was designed to run only within the first 1MB, so extender programs were added and other tricks performed to eventually allow DOS and Windows 3.x access up to the first 16MB. One area of confusion was that RAM was now noncontiguous; that is, the operating system could use the first 640KB and the last 15MB, but not the 384KB of system reserved area that sat in between.

When the first 32-bit processor was released by Intel in 1985 (the 386DX), the memory architecture of the system changed dramatically. There were now enough address lines for the processor to use 4GB of memory, but this was accessible only in a new 32-bit *protected mode* in which only 32-bit instructions or code could run. This mode was designed for newer, more advanced operating systems, such as Windows 9x, NT, OS/2, Linux, UNIX, and so forth. With the 386 came a whole new memory architecture in which this new 32-bit software could run. Unfortunately, it

took 10 years for the mainstream user to upgrade to 32-bit operating systems and applications, which shows how stubborn we are! From a software instruction perspective, all of the processors since the 386 are really just faster versions of the same. Other than the recent addition of MMX and MMX2 (Katmai) instructions to the processor, for all intents and purposes, a Pentium II is just a turbo-386.

The real problem now is that from that point on, the machine has two distinctly different modes, with different memory architectures in each. For backward compatibility, you could still run the 386 and higher processors in real mode, but only 16-bit software could run in that mode, and such software could access only the first 1MB or 16MB, depending on how it was written. For example, 16-bit drivers could load into and access only the first 1MB. Also, it is worth noting that the system ROM BIOS, including the POST, BIOS configuration, boot code, and all the internal drivers, is virtually all 16-bit software. This is because all Intel processors, even including the latest Pentium IIs, all begin operation in 16-bit real mode when they are powered on. When a 32-bit operating system loads, it is that operating system code that instructs the processor to switch into 32-bit protected mode.

When an operating system like Windows 9x is loaded, the processor is switched into 32-bit protected mode early in the loading sequence. Then 32-bit drivers for all the hardware can be loaded, and then the rest of the operating system can load. In 32-bit protected mode, the operating systems and applications can access all the memory in the system, up to the maximum limit of the processor (64TB for a Pentium II).

Unfortunately, one problem with protected mode is just that: It is protected. The name comes from the fact that only driver programs are allowed to talk directly to the hardware in this mode; programs loaded by the operating system, such as by clicking on an icon in Windows, are not allowed to access memory or other hardware directly. This protection is provided so that a single program cannot crash the machine by doing something illegal. You may have seen the error message in Windows 9x indicating this, and that the program will be shut down.

Diagnostics software by nature must talk to the hardware directly. This means that little intensive diagnostics testing can be done while a protected mode operating system like Windows 9x, NT, Linux, and so forth is running. For system testing, you normally have to boot from a DOS floppy or interrupt the loading of Windows (press the F8 key when “Starting Windows” appears during the boot process) and select Command Prompt Only, which boots you into DOS, or by executing a shutdown and select “Restart the computer in MS-DOS mode.” Many of the higher end hardware diagnostics programs include their own special limited 16-bit operating system so they can more easily access memory areas even DOS would use.

When you boot from a Windows 9x startup disk you are running 16-bit DOS, for example, and if you want to access your CD-ROM drive to install Windows, for example, you need to load a 16-bit CD-ROM driver program from that disk as well. In this mode, you can do things like partition and format your hard disk, install Windows, or test the system completely.

The point of all this is that although you might not be running DOS or Windows 3.x very much these days, at least for system configuration and installation, as well as for high-level hardware

diagnostics testing, data recovery, and so forth, you will still need to boot a 16-bit OS occasionally. When you are in that mode, the systems architecture changes, there is less memory accessible, and some of the software you are running (16-bit drivers and most application code) will have to fight over the first 1MB or even 640KB for space.

The system memory areas discussed in this chapter, including the 384KB at the top of the first megabyte, which is used for video, adapter BIOS, and motherboard BIOS, as well as the remaining extended memory, are all part of the PC hardware design. They exist whether you are running 16-bit or 32-bit software; however, the limitations on their use in 16-bit (real) mode are much more severe. Because most people run 32-bit operating systems like Windows 9x, NT, Linux, and so on, these operating systems automatically manage the use of RAM, meaning you don't have to interact with and manage this memory yourself as you often did with the 16-bit operating systems.

The following sections are intended to give you an understanding of the PC hardware memory layout, which is consistent no matter which operating system you use. The only thing that changes is how your operating system uses these areas and how they are managed by the OS.

Someone who wants to become knowledgeable about personal computers must at one time or another come to terms with the types of memory installed on his system—the small and large pieces of different kinds of memory, some accessible by software application programs and some not. The following sections detail the different kinds of memory installed on a modern PC. The kinds of memory covered in the following sections include the following:

- Conventional (base) memory
- Upper memory area (UMA)
- High memory area (HMA)
- Extended memory (XMS)
- Expanded memory (obsolete)
- Video RAM memory (part of UMA)
- Adapter ROM and special purpose RAM (part of UMA)
- Motherboard ROM BIOS (part of UMA)

Subsequent sections also cover preventing memory conflicts and overlap, using memory managers to optimize your system's memory, and making better use of memory. In a 16-bit or higher system, the memory map extends beyond the 1MB boundary and can continue to 16MB on a system based on the 286 or higher processor, 4GB (4,096MB) on a 386DX or higher, or as much as 64GB (65,536MB) on a Pentium II. Any memory past 1MB is called extended memory.

Figure 6.17 shows the logical address locations for a 16-bit or higher system. If the processor is running in real mode, only the first megabyte is accessible. If the processor is in protected mode, the full 16MB, 4,096MB, or 65,536MB are accessible. Each symbol is equal to 1KB of memory, and each line or segment is 64KB. This map shows the first two megabytes of system memory.

◀◀ See "Processor Modes," p. 58.

Note

To save space, this map stops after the end of the second megabyte. In reality, this map continues to the maximum of addressable memory.

Conventional (Base) Memory

The original PC/XT-type system was designed to use 1MB of RAM. This 1MB of RAM is divided into several sections, some of which have special uses. DOS can read and write to the entire megabyte, but can manage the loading of programs only in the portion of RAM space called conventional memory, which was 512KB at the time the first PC was introduced. The other 512KB was reserved for use by the system, including the motherboard and adapter boards plugged into the system slots.

After introducing the system, IBM decided that only 384KB was needed for these reserved uses, and the company began marketing PCs with 640KB of user memory. Therefore, 640KB became the standard for memory that can be used by DOS for running programs, and is often termed the 640KB memory barrier. The remaining memory after 640KB was reserved for use by the graphics boards, other adapters, and the motherboard ROM BIOS.

This barrier largely affects 16-bit software, such as DOS and Windows 3.1, and is much less of a factor with 32-bit software and operating systems, such as Windows 9x, NT/2000, and so on.

Upper Memory Area (UMA)

The term *Upper Memory Area (UMA)* describes the reserved 384KB at the top of the first megabyte of system memory on a PC/XT and the first megabyte on an AT-type system. This memory has the addresses from A0000 through FFFFF. The way the 384KB of upper memory is used breaks down as follows:

- The first 128KB after conventional memory is called video RAM. It is reserved for use by video adapters. When text and graphics are displayed onscreen, the data bits that make up those images reside in this space. Video RAM is allotted the address range from A0000–BFFFF.
- The next 128KB is reserved for the adapter BIOS that resides in read-only memory chips on some adapter boards plugged into the bus slots. Most VGA-compatible video adapters use the first 32KB of this area for their onboard BIOS. Any other adapters installed can use the rest. Many network adapters also use this area for special-purpose RAM called *Shared Memory*. Adapter ROM and special-purpose RAM is allotted the address range from C0000–DFFFF.
- The last 128KB of memory is reserved for motherboard BIOS (the basic input/output system, which is stored in read-only RAM chips or ROM). The POST (power on self test) and bootstrap loader, which handles your system at boot-up until the operating system takes over, also reside in this space. Most systems use only the last 64KB (or less) of this space, leaving the first 64KB or more free for remapping with memory managers. Some systems also include the CMOS Setup program in this area. The motherboard BIOS is allotted the address range from E0000–FFFFF.

Not all the 384KB of reserved memory is fully used on most 16-bit and higher systems. For example, according to the PC standard, reserved video RAM begins at address A0000, which is right at the 640KB boundary. Normally, it is used for VGA graphics modes, while the monochrome and color text modes use B0000–B7FFF and B8000–BFFFF, respectively. Older non-VGA adapters used memory only in the B0000 segment. Different video adapters use varying amounts of RAM for their operations, depending mainly on the mode they are in. To the processor, however, it always appears as the same 128KB area, no matter how much RAM is really on the video card. This is managed by bank switching areas of memory on the card in and out of the A0000–BFFFF segments.

Although the top 384KB of the first megabyte was originally termed *reserved memory*, it is possible to use previously unused regions of this memory to load 16-bit device drivers (such as the ANSI.SYS screen driver that comes with DOS) and memory-resident programs (such as MOUSE.COM, the DOS mouse driver), which frees up the conventional memory they would otherwise require. Note that this does not affect 32-bit device drivers such as those used with Windows 9x, NT/2000, and so forth because they load into extended memory with no restrictions. The amount of free UMA space varies from system to system, depending mostly on the adapter cards installed on the system. For example, most video adapters, SCSI adapters, and some network adapters require some of this area for built-in ROMs or special-purpose RAM use.

Segment Addresses and Linear Addresses

One thing that can be confusing is the difference between a segment address and a full linear address. The use of segmented address numbers comes from the internal structure of the Intel processors and is used primarily by older, 16-bit operating systems. They use a separate register for the segment information and another for the offset. The concept is very simple. For example, assume that I am staying in a hotel room, and somebody asks for my room number. The hotel has 10 floors, numbered from zero through nine; each floor has 100 rooms, numbered from 00 to 99. A segment is defined as any group of 100 rooms starting at a multiple of 10, and indicated by a two-digit number. So a segment address of 54 would indicate the actual room 540, and you could have an offset of 00 to 99 rooms from there.

In this hotel example, then, each segment is specified as a two-digit number from 00–99, and an offset can be specified from any segment starting with a number from 00–99.

Say that I'm staying in room 541. If the person needs this information in segment:offset form, and each number is two digits, I could say that I am staying at a room segment starting address of 54 (room 540), and an offset of 01 from the start of that segment. I could also say that I am in room segment 50 (room 500), and an offset of 41. You could even come up with other answers, such as I am at segment 45 (room 450) offset 91 (450+91=541). Here is an example of how this adds up:

Segment	Offset	Total
54	01	541
50	41	541
45	91	541

As you can see, although the particular segment and offset are different, they all add up to the same room address. In the Intel x86 processors, a similar scheme is used when a segment and offset are added internally to produce the actual address. It can be somewhat confusing, especially if you are writing assembly language or machine language software!

This is exactly how segmented memory in an Intel processor works. Notice that the segment and offset numbers essentially overlap on all digits except the first and last. By adding them together with the proper alignment, you can see the linear address total.

With 32-bit operating systems, segment addresses are not an issue. A linear address is one without segment:offset boundaries, such as saying room 541. It is a single number, not two numbers added together. For example, a SCSI host adapter might have 16KB ROM on the card addressed from D4000 to D7FFF. These numbers expressed in segment:offset form are D400:0000 to D700:0FFF. The segment portion is composed of the most significant four digits, and the offset portion is composed of the least significant four digits. Because each portion overlaps by one digit, the ending address of its ROM can be expressed in four different ways, as follows:

```

D000:7FFF =  D000  segment
+ 7FFF  offset
----
= D7FFF  total
D700:0FFF =  D700  segment
+ 0FFF  offset
----
= D7FFF  total
D7F0:00FF =  D7F0  segment
+ 00FF  offset
----
= D7FFF  total
D7FF:000F =  D7FF  segment
+ 000F  offset
----
= D7FFF  total

```

As you can see, although the segment and offset differ slightly in each case, the total ends up being the same. Adding the segment and offset numbers makes even more combinations possible, as in the following examples:

```

D500:2FFF =  D500  segment
+ 2FFF  offset
----
= D7FFF  total
D6EE:111F =  D6EE  segment
+ 111F  offset
----
= D7FFF  total

```

As you can see, several combinations are possible. The correct and generally accepted way to write this address as a linear address is D7FFF, although most would write the segment:offset address as D000:7FFF. Keeping the segment mostly zeros makes the segment:offset relationship easier to understand and the number easier to comprehend. If you understand the segment:offset relationship to the linear address, you now know why when a linear address number is discussed it is five digits, but a segment number is only four.

Video RAM Memory

A video adapter installed in your system uses a portion of your system's first megabyte of memory to hold graphics or character information for display, but this is normally used or active only when in basic VGA mode. A video card can have 4MB, 8MB, or more on board, but most of that is used by the video chipset on the card, not directly accessed by your system processor. When in basic VGA mode, such as when at a DOS prompt or when running in Windows safe mode, your processor can directly access up to 128KB of the video RAM from address A0000–BFFFFh. All modern video cards also have onboard BIOS normally addressed at C0000–C7FFFh, which is part of the memory space reserved for adapter card BIOS. Generally, the higher the resolution and color capabilities of the video adapter, the more system memory the video adapter uses, but again, that additional memory (past 128KB) is not normally accessible by the processor. Instead, the system tells the video chip what should be displayed, and the video chip generates the picture by putting data directly into the video RAM on the card.

In the standard system-memory map, a total of 128KB is reserved for use by the video card to store currently displayed information when in basic VGA mode. The reserved video memory is located in segments A000 and B000. The video adapter ROM uses additional upper memory space in segment C000. Even with the new multiple monitor feature in Windows 98, only one video card (the primary video card) is in the memory map; all others use no low system memory.

Note

The location of video adapter RAM is responsible for the 640KB DOS conventional memory barrier. DOS can use all available contiguous memory in the first megabyte of memory up to the point where the video adapter RAM is encountered. The use of ancient video adapters, such as the MDA and CGA, can allow DOS access to more than 640KB of system memory. For more information, see Chapter 5 of *Upgrading and Repairing PCs, Tenth Anniversary Edition*, included on the CD.

To learn how standard video adapters use the system's memory, see "Obsolete Video Adapter Types," also in Chapter 5 of the *Tenth Edition*.

Video Graphics Array (VGA) Memory

All VGA-compatible cards, including Super VGA cards, are almost identical to the EGA in terms of memory use. Just as with the EGA, they use all 128KB of the video RAM from A0000–BFFFF, but not all at once. Again, the video RAM area is split into three distinct regions, and each of these regions is used only when the adapter is in the corresponding mode. One minor difference with the EGA cards is that virtually all VGA cards use the full 32KB allotted to them for onboard ROM (C0000 to C7FFF). Figure 6.18 shows the VGA adapter memory map.

You can see that the typical VGA card uses a full 32KB of space for the onboard ROM containing driver code. Some VGA cards might use slightly less, but this is rare. Just as with the EGA card, the video RAM areas are active only when the adapter is in the particular mode designated. In other words, when a VGA adapter is in graphics mode, only segment A000 is used; when it is in color text mode, only the last half of segment B000 is used. Because the VGA adapter is almost

Needless to say, nothing could be done about this 2KB of scratch pad memory hanging out there, and I had to work around it as long as I had this card in the system. I solved my SCSI adapter problem by merely moving the SCSI adapter BIOS to a different address.

Note

I have seen other VGA-type video adapters use scratch pad memory, but they have all kept it within the C0000–C7FFF 32KB region allotted normally for the video ROM BIOS. By using a 24KB BIOS, I have seen other cards with up to 8KB of scratch pad area, but none—except for IBM’s—in which the scratch pad memory goes beyond C8000.

Adapter ROM and Special Purpose RAM Memory

The second 128KB of upper memory beginning at segment C000 is reserved for the software programs, or BIOS (basic input/output system), on the adapter boards plugged into the system slots. These BIOS programs are stored on special chips known as read-only memory (ROM). Most adapters today use EEPROM (Electrically Erasable Programmable ROM) or flash ROM, which can be erased and reprogrammed right in the system without removing the chip or card. Updating the flash ROM is as simple as running the update program you get from the manufacturer and following the directions onscreen. It pays to check periodically with your card manufacturers to see if they have flash ROM updates for their cards.

ROM is useful for semipermanent programs that must always be present while the system is running, and especially for booting. Graphics boards, hard disk controllers, communications boards, and expanded memory boards, for example, are adapter boards that might have adapter ROM. These adapter ROMs are in an area of memory separate from the VGA video RAM and motherboard ROM areas.

On systems based on the 386 CPU chip or higher, memory managers that are included with DOS 6 or third-party programs can load device drivers and memory-resident programs into unused regions in the UMA.

To actually move the RAM usage on any given adapter requires that you consult the documentation for the card. Most older cards require that specific switches or jumpers be changed, and the settings will probably not be obvious without the manual. Most newer cards, especially those that are Plug and Play, allow these settings to be changed by software that comes with the card or the Device Manager program that goes with some of the newer operating systems, such as Windows 9x or Windows 2000 and newer.

Video Adapter BIOS

The video adapter BIOS handles the translation between the video card and basic VGA mode graphics instructions. Remember that your system is in a basic VGA mode during boot and whenever you are running Windows in safe mode. Although 128KB of upper memory beginning at segment C000 is reserved for use by adapter BIOSes, not all this space is used by video adapters commonly found on PCs. Table 6.13 details the amount of space used by the BIOS on each type of common video adapter card.

Table 6.13 Memory Used by Different Video Cards

Type of Adapter	Adapter BIOS Memory Used
Monochrome display adapter (MDA)	None; drivers in motherboard BIOS
Color graphics adapter (CGA)	None; drivers in motherboard BIOS
Enhanced graphics adapter (EGA)	16KB onboard (C0000–C3FFF)
Video graphics array (VGA)	32KB onboard (C0000–C7FFF)
Super VGA (SVGA)	32KB onboard (C0000–C7FFF)

Depending on the basic VGA mode selected (color text, monochrome text, or VGA graphics), the video card uses all the 128KB of upper memory beginning at segment C000. In addition, these graphics cards can contain up to 8MB or more of onboard memory for use in their native high-resolution modes in which to store currently displayed data and more quickly fetch new screen data for display.

Hard Disk Controller and SCSI Host Adapter BIOS

The upper memory addresses C0000 to DFFFF are also used for the built-in BIOS contained on many hard drive and SCSI controllers. Table 6.14 lists the amount of memory and the addresses commonly used by the BIOS contained on hard drive adapter cards.

Table 6.14 Memory Addresses Used by Different Hard Drive Adapter Cards

Disk Adapter Type	Onboard BIOS Size	BIOS Address Range
Most XT compatible controllers	8KB	C8000–C9FFF
Most AT controllers	None	Drivers in motherboard BIOS
Most standard IDE adapters	None	Drivers in motherboard BIOS
Most enhanced IDE adapters	16KB	C8000–CBFFF
Some SCSI host adapters	16KB	C8000–CBFFF
Some SCSI host adapters	16KB	DC000–DFFFF

The hard drive or SCSI adapter card used on a particular system might use a different amount of memory, but it is most likely to use the memory segment beginning at C800 because this address is considered part of the IBM standard for personal computers. Virtually all the disk controller or SCSI adapters today that have an onboard BIOS allow the BIOS starting address to be easily moved in the C000 and D000 segments. The locations listed in Table 6.14 are only the default addresses that most of these cards use. If the default address is already in use by another card, you have to consult the documentation for the new card to see how to change the BIOS starting address to avoid any conflicts.

Figure 6.20 shows a sample memory map for an Adaptec AHA-2940 SCSI adapter.

optimal and causes fragmentation of the UMB space. By adjusting the location of the shared memory, this setup can be greatly improved. Figure 6.23 shows an optimal setup with the Token-Ring adapter and the SCSI adapter in the same machine.

```

Figure 6.23 Adaptec AHA-2940U SCSI adapter and network adapter with optimized memory use.

This configuration allows a single 120KB UMB that can be efficiently used to load software drivers. Notice that the IPL ROM was moved to D0000, which places it as the last item installed before the free memory space. This is done because if the IPL function is not needed, it can be disabled and the UMB space would increase to 128KB and still be contiguous. If the default settings are used for both the SCSI and network adapters, the UMB memory is fragmented into three regions of 16KB, 40KB, and 64KB. The memory still functions, but it is hardly an optimal situation.

Note that the Plug-and-Play feature in Win9x, Windows NT, and Windows 2000 does not attempt to optimize memory use, only to resolve conflicts. Of course, with 32-bit drivers, the location and size of free Upper Memory Blocks don't really matter because 32-bit drivers will be loaded into extended memory. If you are still occasionally running DOS-based programs, such as games, you should manually optimize the upper memory area configuration for maximum memory and performance.

Other ROMs in the Upper Memory Area

In addition to the BIOS for hard drive controllers, SCSI adapters, and network cards, upper memory segments C000 and D000 are used by some terminal emulators, security adapters, memory boards, and other devices and adapter boards. Some adapters might require memory only for BIOS information, and others could require RAM in these upper memory segments. For information on a specific adapter, consult the manufacturer's documentation.

Motherboard BIOS Memory

The last 128KB of reserved memory is used by the motherboard BIOS. The BIOS programs in ROM control the system during the boot-up procedure and remain as drivers for various hardware in the system during normal operation. Because these programs must be available immediately, they cannot be loaded from a device such as a disk drive. Four main programs stored in most motherboard ROMs are as follows:

- The POST is a set of routines that test the motherboard, memory, disk controllers, video adapters, keyboard, and other primary system components. This routine is useful when you troubleshoot system failures or problems.
- ▶▶ See "The Power On Self Test (POST)," p. 1289.
- The bootstrap loader routine initiates a search for an operating system on a floppy disk or hard disk. If an operating system is found, it is loaded into memory and given control of the system.
- ▶▶ See "The Boot Process," p. 1351.
- The BIOS is the software interface to all the hardware in the system. The BIOS is a collection of individual drivers for the hardware in the system. With the BIOS, a program can easily access features in the system by calling on a standard BIOS driver function instead of talking directly to the device.
- ◀◀ See "BIOS," p. 345.
- The CMOS Setup program is a menu-driven application used for system configuration and setup. It is normally activated at boot time by pressing the proper key. This program is used to set basic system configuration parameters and BIOS features, motherboard and chipset features, user preferences, and security features (passwords), and in some cases to run limited diagnostics. Not all systems have the CMOS Setup program in ROM; some must load it from a floppy disk or hard disk.

Both segments E000 and F000 in the memory map are considered reserved for the motherboard BIOS, but only some systems actually use this entire area. Older 8-bit systems require only segment F000 and enable adapter card ROM or RAM to use segment E000. Most 16-bit or greater systems use all F000 for the BIOS and may decode but not use any of segment E000. By decoding an area, the motherboard essentially grabs control of the addresses, which precludes installing any other hardware in this region. In other words, it is not possible to configure adapter cards to use this area. That is why you will find that most adapters that use memory simply do not allow any choices for memory use in segment E000. Although this might seem like a waste of 64KB of memory space, any 386 or higher system can use the powerful MMU in the processor to map RAM from extended memory into segment E000 as an Upper Memory Block. The system can subsequently load 16-bit driver software in this UMB if necessary. This is a nice solution to what otherwise would be wasted memory, although it is not important if you use 32-bit drivers.

Many different ROM-interface programs are in the IBM motherboards, but the location of these programs is mostly consistent.

Figure 6.24 shows the motherboard ROM BIOS memory use of most 16-bit or greater systems.

Figure 6.24 Motherboard ROM BIOS memory use of most systems.

Note that the standard system BIOS uses only segment F000 (64KB). In almost every case, the remainder of the BIOS area (segment E000) is completely free and can be used as UMA block space.

Extended Memory

As mentioned previously in this chapter, the memory map on a system based on the 286 or higher processor can extend beyond the 1MB boundary that exists when the processor is in real mode. On a 286 or 386SX system, the extended memory limit is 16MB; on a 386DX, 486, Pentium, Pentium MMX, or Pentium Pro system, the extended memory limit is 4GB (4,096MB). Systems based on the Pentium II processor have a limit of 64GB (65,536MB).

For a system to address memory beyond the first megabyte, the processor must be in protected mode—the native mode of 286 and higher processors. On a 286, only programs designed to run in protected mode can take advantage of extended memory; 386 and higher processors offer another mode, called virtual real mode, which enables extended memory to be, in effect, chopped into 1MB pieces (each its own real-mode session). Virtual real mode also allows for several of these sessions to be running simultaneously in protected areas of memory. They can be seen as DOS prompt sessions or windows within Windows 9x, NT, or OS/2. Although several DOS programs can be running at once, each is still limited to a maximum of 640KB of memory because each session simulates a real-mode environment, right down to the BIOS and Upper Memory Area. Running several programs at once in virtual real mode, called *multitasking*, requires software that can manage each program and keep them from crashing into one another. OS/2, Windows 9x, and Windows NT all do this.

The 286 and higher CPU chips also run in what is termed *real mode*, which enables full compatibility with the 8088 CPU chip installed on the PC/XT-type computer. Real mode enables you to run DOS programs one at a time on an AT-type system just as you would on a PC/XT. However, an AT-type system running in real mode, particularly a 386-, 486-, Pentium-, Pentium Pro-, or Pentium II-based system, is really functioning as little more than a turbo PC. In real mode, these processors can emulate the 8086 or 8088, but they cannot operate in protected mode at the same time. For that reason, the 386 and above also provide a virtual real mode that operates under protected mode. This allows real-mode programs to execute under the control of a protected-mode operating system, such as Win9x, NT/2000, or OS/2.

Note

Extended memory is basically all memory past the first megabyte, which can be accessed only while the processor is in protected mode.

XMS Memory

Microsoft, Intel, AST Corp., and Lotus Development developed the extended memory specification (XMS) in 1987 to specify how programs would use extended memory. The XMS specification functions on systems based on the 286 or higher and allows real-mode programs (those designed to run in DOS) to use extended memory and another block of memory usually out of the reach of DOS.

Before XMS, there was no way to ensure cooperation between programs that switched the processor into protected mode and used extended memory. There was also no way for one program to know what another had been doing with the extended memory because none of them could see that memory while in real mode. HIMEM.SYS becomes an arbitrator of sorts that first grabs all the extended memory for itself and then doles it out to programs that know the XMS protocols. In this manner, several programs that use XMS memory can operate together under DOS on the same system, switching the processor into and out of protected mode to access the memory. XMS rules prevent one program from accessing memory that another has in use. Because Windows 3.x is a program manager that switches the system to and from protected mode in running several programs at once, it has been set up to require XMS memory to function. Windows 95 operates mostly in protected mode, but still calls on real mode for access to many system components. Windows NT and Windows 2000 are true protected-mode operating systems, as is OS/2.

Extended memory can be made to conform to the XMS specification by installing a device driver in the CONFIG.SYS file. The most common XMS driver is HIMEM.SYS, which is included with Windows 3.x and later versions of DOS, starting with 4.0 and up. Windows 9x and NT automatically allow XMS functions in DOS prompt sessions, and you can configure full-blown DOS-mode sessions to allow XMS functions as well.

Note

To learn more about the High Memory Area (HMA) and Expanded Memory, see Chapter 5 of *Upgrading and Repairing PCs, Tenth Anniversary Edition*, on the CD.

Preventing ROM BIOS Memory Conflicts and Overlap

As explained previously, C000 and D000 are reserved for use by adapter-board ROM and RAM. If two adapters have overlapping ROM or RAM addresses, usually neither board operates properly. Each board functions if you remove or disable the other one, but they do not work together.

With many adapter boards, you can change the actual memory locations to be used with jumpers, switches, or driver software, which might be necessary to allow two boards to coexist in one system. This type of conflict can cause problems for troubleshooters. You must read the documentation for each adapter to find out what memory addresses the adapter uses and how to

change the addresses to allow coexistence with another adapter. Most of the time, you can work around these problems by reconfiguring the board or changing jumpers, switch settings, or software-driver parameters. This change enables the two boards to coexist and stay out of each other's way.

Additionally, you must ensure that adapter boards do not use the same IRQ (Interrupt Request Line), DMA (direct memory access) channel, or I/O port address. You can easily avoid adapter board memory, IRQ, DMA channel, and I/O port conflicts by creating a chart or template to mock up the system configuration by penciling on the template the resources already used by each installed adapter. You end up with a picture of the system resources and the relationship of each adapter to the others. This procedure helps you anticipate conflicts and ensures that you configure each adapter board correctly the first time. The template also becomes important documentation when you consider new adapter purchases. New adapters must be configurable to use the available resources in your system.

◀◀ See "System Resources," p. 311.

If your system has Plug-and-Play capabilities, and you use PnP adapters, it can resolve conflicts between the adapters by moving the memory usage on any conflict. Unfortunately, this routine is not intelligent and still requires human intervention—that is, manual specification of addresses to achieve the most optimum location for the adapter memory.

ROM Shadowing

Virtually all 386 and higher systems enable you to use what is termed *shadow memory* for the motherboard and possibly some adapter ROMs as well. Shadowing essentially moves the programming code from slow ROM chips into fast 32-bit system memory. Shadowing slower ROMs by copying their contents into RAM can greatly speed up these BIOS routines—sometimes making them four to five times faster.

Note that shadowing ROMs is not very important when running a 32-bit operating system, such as Win9x or NT. This is because those operating systems use only the 16-bit BIOS driver code during booting; then they load 32-bit replacement drivers into faster extended memory and use them. Therefore, shadowing normally affects only DOS or other 16-bit software and operating systems. Because of this, some people are tempted to turn off the Video BIOS shadowing feature in the BIOS setup. Unfortunately, it won't gain you any memory back (you've lost it anyway) and will make the system slightly slower to boot up and somewhat slower when in Windows safe mode. The 16-bit BIOS video driver code is used at those times.

Note

To learn more about ROM shadowing, see Chapter 5 of *Upgrading and Repairing PCs, Tenth Anniversary Edition*, on the CD accompanying this book.

Total Installed Memory Versus Total Usable Memory

Most people don't realize that not all the SIMM or other RAM memory you purchase and install in a system is available. Because of some quirks in system design, the system usually has to "throw away" up to 384KB of RAM to make way for the Upper Memory Area.

For example, most systems with 16MB of RAM (which is 16,384KB) installed show a total of only 16,000KB installed during the POST or when running Setup. This indicates that $16,384\text{KB} - 16,000\text{KB} = 384\text{KB}$ of missing memory! Some systems might show 16,256KB with the same 16MB installed, which works out to $16,384\text{KB} - 16,256\text{KB} = 128\text{KB}$ missing.

If you run your Setup program and check out your base and extended memory values, you will find more information than just the single figure for the total shown during the POST. In most systems with 4,096KB (4MB), you have 640KB base and 3,072KB extended. In some systems, Setup reports 640KB base and 3,328KB extended memory, which is a bonus. In other words, most systems come up 384KB short, but some come up only 128KB short.

This shortfall is not easy to explain, but it is consistent from system to system. Say that you have a 486 system with two installed 72-pin (32-bit) 16MB SIMMs. This results in a total installed memory of 32MB in two separate banks because the processor has a 32-bit data bus. Each SIMM is a single bank in this system. Most cheaper 486 systems use the 30-pin (8-bit) SIMMs; four are required to make a single bank. The first bank (or SIMM, in this case) starts at address 0000000h (the start of the first megabyte), and the second starts at 1000000 (the start of the seventeenth megabyte).

One of the cardinal rules of memory is that you absolutely cannot have two hardware devices wired to the same address. This means that 384KB of the first memory bank in this system would be in direct conflict with the video RAM (segments A000 and B000), any adapter card ROMs (segments C000 and D000), and of course the motherboard ROM (segments E000 and F000). That means all SIMM RAM that occupies these addresses must be shut off or the system will not function! Actually, a motherboard designer can do three things with the SIMM memory that would overlap from A0000–FFFFFF:

- Use the faster RAM to hold a copy of any slow ROMs (shadowing), disabling the ROM in the process.
- Turn off any RAM not used for shadowing, eliminating any UMA conflicts.
- Remap any RAM not used for shadowing, adding to the stack of currently installed extended memory.

Most systems shadow the motherboard ROM (usually 64KB) and the video ROM (32KB), and simply turn off the rest. Some motherboard ROMs allow additional shadowing to be selected between C8000–DFFFF, usually in 16KB increments.

Note

You can shadow only ROM, never RAM, so if any card (such as a network card) has a RAM buffer in the C8000–DFFFF area, you must not shadow the RAM buffer addresses or the card will not function. For the same reason, you cannot shadow the A0000–BFFFF area because it is the video adapter RAM buffer.

Most motherboards do not do any remapping, which means that any of the 384KB not shadowed is simply turned off. That is why enabling shadowing does not seem to use any memory. The memory used for shadowing would otherwise be discarded in most systems. These systems would appear to be short by 384KB compared to what is physically installed in the system. For example, in a system with 32MB, no remapping would result in 640KB of base memory and 31,744KB of extended memory, for a total of 32,384KB of usable RAM—384KB short of the total (32,768KB–384KB).

Some systems shadow what they can and then remap any segments that do not have shadowing into extended memory so as not to waste the nonshadowed RAM. PS/2 systems, for example, shadow the motherboard BIOS area (E0000–FFFFF or 128KB in these systems) and remap the rest of the first bank of SIMM memory (256KB from A0000–DFFFF) to whatever address follows the last installed bank.

Note

Many newer systems don't allow selecting ROM shadowing functions, nor do they do any remapping. These days, the small amount of memory or performance gain just isn't worth the trouble in system engineering and design to accomplish it.

In my sample system with two 16MB (32-bit) SIMMs, the 256KB not used for shadowing would be remapped to 2000000–203FFFF, which is the start of the 33rd megabyte. This affects diagnostics because if you had any memory error reported in those addresses (2000000–203FFFF), it would indicate a failure in the first SIMM, even though the addresses point to the end of installed extended memory. The addresses from 1000000–1FFFFFF would be in the second SIMM, and the 640KB base memory 0000000–009FFFF would be back in the first SIMM. As you can see, figuring out how the SIMMs are mapped into the system is not easy!

Most systems that do remapping can remap an entire segment only if no shadowing is going on within it. The video RAM area in segments A000 and B000 can never contain shadowing, so at least 128KB can be remapped to the top of installed extended memory in any system that supports remapping. Because most systems shadow in segments F000 (motherboard ROM) and C000 (video ROM), these two segments cannot be remapped. This leaves 256KB maximum for remapping. Any system remapping the full 384KB must not be shadowing at all, which would slow down the system and is not recommended. Shadowing is always preferred over remapping, and remapping what is not shadowed is definitely preferred over simply turning off the RAM.

Systems that have 384KB of “missing” memory do not do remapping. If you want to determine whether your system has any missing memory, all you need to know are three things. One is the total physical memory actually installed. Running your Setup program can discover the other two items. You want to know the total base and extended memory numbers recognized by the system. Then simply subtract the base and extended memory from the total installed to determine the missing memory. You will usually find that your system is “missing” 384KB, but you could be lucky and have a system that remaps 256KB of what is missing and thus shows only 128KB of memory missing.

Virtually all systems use some of the missing memory for shadowing ROMs, especially the motherboard and video BIOS, so what is missing is not completely wasted. Systems “missing” 128KB will find that it is being used to shadow your motherboard BIOS (64KB from F0000–FFFFF) and video BIOS (32KB from C0000–C8000). The remainder of segment C0000 (32KB from C8000–CFFFF) is simply being turned off. All other segments (128KB from A0000–BFFFF and 128KB from D0000–EFFFF) are being remapped to the start of the fifth megabyte (400000–43FFFF). Most systems simply disable these remaining segments rather than take the trouble to remap them.

Note

If your system is doing remapping, any errors reported near the end of installed extended memory are likely in the first bank of memory because that is where they are remapped from. The first bank in a 32-bit system would be constructed of either four 30-pin (8-bit) SIMMs or one 72-pin (32-bit) SIMM. The first bank in a 64-bit system would be constructed of either two 72-pin (32-bit) SIMMs or one 168-pin (64-bit) DIMM.

Adapter Memory Configuration and Optimization

Ideally, all adapter boards would be Plug-and-Play devices that require you to merely plug the adapter into a motherboard slot and then use it. With the Plug-and-Play specification, we are moving toward that goal. However, sometimes it almost seems that adapter boards are designed as though they were the only adapter likely to be on a system. They usually require you to know the upper memory addresses and IRQ and DMA channels already on your system and how to configure the new adapter so that it does not conflict with your already installed adapters.

Adapter boards use upper memory for their BIOS and as working RAM. If two boards attempt to use the same BIOS area or RAM area of upper memory, a conflict occurs that can keep your system from booting. The following sections cover ways to avoid these potential conflicts and how to troubleshoot if they do occur. In addition, these sections discuss moving adapter memory to resolve conflicts and provide some ideas on optimizing adapter memory use.

How to Determine What Adapters Occupy the UMA

You can determine what adapters are using space in upper memory in the following two ways:

- Study the documentation for each adapter on your system to determine the memory addresses they use.
- Use a software utility that can quickly determine for you what upper memory areas your adapters are using.

The simplest way (although by no means always the most foolproof) is to use a software utility to determine the upper memory areas used by the adapters installed on your system. One such utility, Microsoft Diagnostics (MSD), comes with Windows 3.x and DOS 6 or higher versions. The Device Manager under System in the Windows 95 Control Panel also supplies this information, as does the new System Information utility that comes with Windows 98. These utilities examine your system configuration and determine not only the upper memory used by your adapters, but also the IRQs used by each of these adapters.

True Plug-and-Play systems also shut down one of the cards involved in a conflict to prevent a total system lockup. This could cause Windows to boot in safe mode.

After you run MSD, Device Manager, or another utility to determine your system's upper memory configuration, make a printout of the memory addresses used. Thereafter, you can quickly refer to the printout when you are adding a new adapter to ensure that the new board does not conflict with any devices already installed on your system.

Moving Adapter Memory to Resolve Conflicts

After you identify a conflict or potential conflict using one of the two methods discussed in the previous section, you might have to reconfigure one or more of your adapters to move the upper memory space used by a problem adapter.

Most adapter boards make moving adapter memory a somewhat simple process, enabling you to change a few jumpers or switches to reconfigure the board. With Plug-and-Play cards, use the configuration program that comes with the board or the Windows Device Manager to make the changes. The following steps help you resolve most problems that arise because adapter boards conflict with one another:

1. Determine the upper memory addresses currently used by your adapter boards and write them down.
2. Determine if any of these addresses are overlapping, which results in a conflict.
3. Consult the documentation for your adapter boards to determine which boards can be reconfigured so that all adapters have access to unique memory addresses.
4. Configure the affected adapter boards so that no conflict in memory addresses occurs.

For example, if one adapter uses the upper memory range C8000–CBFFF and another adapter uses the range CA000–CCFFF, you have a potential address conflict. One of them must be changed. Note that Plug-and-Play cards allow these changes to be made directly from the Windows Device Manager.

Optimizing Adapter Memory Use

On an ideal PC, adapter boards would always come configured so that the upper memory addresses they use immediately follow the upper memory addresses used by the previous adapter, with no overlap that could cause conflicts. Such an upper memory arrangement would not only be “clean,” but would make it much easier to use available upper memory for loading device drivers and memory-resident programs. However, this is not the case. Adapter boards often leave gaps of unused memory between one another—this is, of course, preferable to an overlap, but still is not the best use of upper memory.

Those who wanted to make the most of their upper memory might consider studying the documentation for each adapter board installed on their systems to determine a way to compact the upper memory used by each of these devices. For example, the use of upper memory could be simpler if you configured your adapter boards so that the blocks of memory they use fit together

like bricks in a wall, rather than like a slice of Swiss cheese, as is the case on most systems. The more you can reduce your free upper memory to as few contiguous chunks as possible, the more completely and efficiently you can take advantage of the UMA.

Memory optimization in this manner is not really necessary if you are running 32-bit drivers as you would in a normal Win9x or NT system. This is mostly useful for running older DOS applications, games, and so on.

Note

On systems using an older 16-bit operating system, such as Windows 3.1 or DOS, memory-resident programs and device drivers can be moved into the UMA by using a memory manager such as the MEMMAKER utility or some other aftermarket utility. See Chapter 5 of *Upgrading and Repairing PCs, Tenth Anniversary Edition*, on the CD.

The IDE Interface

Obsolete IDE Versions

An Overview of the IDE Interface

The primary interface used to connect a hard disk drive to a modern PC is called IDE. This stands for Integrated Drive Electronics and refers to the fact that the interface electronics or controller is built into the drives themselves. IDE did not spring up overnight; it is actually an evolutionary version of earlier interfaces that used separate drives and controllers.

Today IDE is used to connect not only hard disks, but also CD-ROM drives, DVD drives, high-capacity floppy drives, and tape drives. Even so, IDE is still thought of primarily as a hard disk interface, and it evolved directly from the separate controller and hard drive interfaces that were used prior to IDE. This chapter covers the IDE interface in detail, as well as the original interfaces from which IDE evolved.

Precursors to IDE

This section covers the different hard disk drive interfaces used prior to IDE, giving you all the technical information you need to deal with them in any way—troubleshooting, servicing, upgrading, and even mixing the different types.

A variety of hard disk interfaces have been available for PC hard disks over the years. As time has passed, the number of choices has increased, and many of the older designs are no longer viable in newer systems. You need to know about all these interfaces, from the oldest to the newest designs, because you will encounter all of them whenever upgrading or repairing systems is necessary.

These interfaces have different cabling and configuration options, and the setup and format of drives will vary as well. Special problems might arise when you are trying to install more than one drive of a particular interface type or (especially) when you are mixing drives of different interface types in one system.

The primary job of the hard disk controller or interface is to transmit and receive data to and from the drive. The different interface types limit how fast data can be moved from the drive to the system and offer different levels of performance. If you are putting together a system in which performance is a primary concern, you need to know how these different interfaces affect performance and what you can expect from them. Many of the statistics that appear in technical literature are not indicative of the real performance figures you will see in practice. I will separate the myths presented by some of these overly optimistic figures from the reality of what you will actually see.

With regard to disk drives, and especially hard disk drives, the specification on which people seem to focus the most is the drive's reported average *seek time*—the (average) time it takes for the heads to be positioned from one track to another. Unfortunately, the importance of this specification often is overstated, especially in relation to other specifications, such as the data transfer rate.

The transfer rate of data between the drive and the system is more important than access time, because most drives spend more time reading and writing information than they do moving the heads around. The speed at which a program or data file is loaded or read is affected most by the

data transfer rate. Specialized operations such as sorting large files, which involves a lot of random access to individual records of the file (and, therefore, many seek operations), are helped greatly by a faster-seeking disk drive. Seeking performance is important in these cases. Most normal file load and save operations, however, are affected mainly by the rate at which data can be read and written to and from the drive. The data transfer rate depends on both the drive and the interface.

Several types of hard disk interfaces have been used in PC systems over the years, as shown in the following table.

Interface	When Used
ST-506/412	1978–1989
ESDI	1986–1991
SCSI	1986–Present
IDE	1988–Present

As you can see, only IDE and SCSI remain popular today. Of these interfaces, only ST-506/412 and ESDI are what you could call true disk-controller-to-drive interfaces. SCSI and IDE are system-level interfaces that usually incorporate a chipset-based variation of one of the other two types of disk controller interfaces internally. For example, most SCSI and IDE drives incorporate the same basic controller circuitry used in separate ESDI controllers. The SCSI interface adds another layer of interface that attaches the controller to the system bus, whereas IDE is a direct bus-attachment interface. Even so, virtually all modern disk drives use either IDE or SCSI interfaces to connect to a system.

In data recovery, it helps to know the disk interface you are working with, because many data-recovery problems involve drive setup and installation problems. Each interface requires a slightly different method of installation and drive configuration. If the installation or configuration is incorrect or accidentally altered by the system user, it may prevent access to data on a drive. Accordingly, anyone who wants to become proficient in data recovery must be an expert on installing and configuring various types of hard disks and controllers.

The PC's reliance on industry-standard interfaces such as IDE allows a great deal of cross-system and cross-manufacturer compatibility. The use of industry-standard interfaces such as IDE allows you to pick up a mail-order catalog, purchase a hard disk, CD-ROM drive, high-capacity floppy, etc. for the lowest possible price, and be assured that it will work with your system. This Plug-and-Play capability results in affordable hard disk storage and a variety of options in capacities and speed.

The ST-506/412 Interface

The ST-506/412 interface was developed by Seagate Technologies around 1980. The interface originally appeared in the Seagate ST-506 drive, which was a 5MB formatted (or 6MB unformatted) drive in a full-height, 5 1/4-inch form factor. By today's standards, this drive is a tank! In 1981, Seagate introduced the ST-412 drive, which added a feature called buffered seek to the interface. This drive was a 10MB formatted (12MB unformatted) drive that also qualifies as a tank by

today's standards. Besides the Seagate ST-412, IBM also used the Miniscribe 1012 as well as the International Memories, Inc. (IMI) model 5012 drive in the XT. IMI and Miniscribe are long gone, but Seagate remains as one of the largest drive manufacturers. Since the original XT, Seagate has supplied drives for numerous systems made by many different manufacturers.

Most drive manufacturers that made hard disks for PC systems adopted the Seagate ST-506/412 standard, a situation that helped make this interface popular. One important feature is the interface's Plug-and-Play design. No custom cables or special modifications are needed for the drives, which means that virtually any ST-506/412 drive will work with any ST-506/412 controller. The only real compatibility issue with this interface is the level of BIOS support provided by the system.

When introduced to the PC industry by IBM in 1983, ROM BIOS support for this hard disk interface was provided by a BIOS chip on the controller. Contrary to what most believed, the PC and XT motherboard BIOS had no inherent hard disk support. When the AT system was introduced, IBM placed the ST-506/412 interface support in the motherboard BIOS and eliminated it from the controller. All 16-bit and higher systems since then have an enhanced version of the same support in the motherboard BIOS as well. Because this support has been limited, especially in the older BIOS versions, many disk controller manufacturers also placed BIOS support for their controllers directly on the controllers themselves. In some cases, you would use the controller BIOS and motherboard BIOS together; in other cases, you would disable the controller or motherboard BIOS and then use one or the other. These issues will be discussed more completely in Chapter 14, "Physical Drive Installation and Configuration."

◀◀ See "Motherboard BIOS," p. 349.

The ST-506/412 interface does not quite make the grade in today's high-performance PC systems. This interface was designed for a 5MB drive, and I have not seen any drives larger than 152MB (Modified Frequency Modulation encoding) or 233MB (Run-Length Limited encoding) available for this type of interface. Because the capacity, performance, and expandability of ST-506/412s are so limited, this interface is obsolete and generally unavailable in new systems. However, many older systems still use drives that have this interface.

Disk Drive Encoding Schemes and Problems

As indicated in Chapter 9, "Magnetic Storage Principles," in the section "Data Encoding Schemes," encoding schemes are used in communications for converting digital data bits to various tones for transmission over a telephone line. For disk drives, the digital bits are converted, or encoded, in a pattern of magnetic impulses, or flux transitions (also called flux reversals), which are written on the disk. These flux transitions are decoded later, when the data is read from the disk.

A device called an *endec* accomplishes the conversion to flux transitions for writing on the media and the subsequent reconversion back to digital data during read operations. The function of the endec is very similar to that of a modem (modulator/demodulator) in that digital data is converted to an analog waveform, which then is converted back to digital data. Sometimes, the

endec is called a data separator, because it is designed to separate data and clocking information from the flux-transition pulse stream read from the disk.

One of the biggest problems with the original ST-506/412 interface used in the first PC hard disks was the fact that this endec resided on the disk controller (rather than the drive), which resulted in the possibility of corruption of the analog data signal before it reached the media. This problem became especially pronounced when the ST-506/412 controllers later switched to using RLL endecs to store 50 percent more data on the drive. With the RLL encoding scheme, the actual density of magnetic flux transitions on the disk media remains the same as with MFM encoding, but the timing between the transitions must be measured much more precisely.

In RLL encoding, the intervals between flux changes are approximately the same as with MFM, but the actual timing between them is much more critical. As a result, the transition cells in which signals must be recognized are much smaller and more precisely placed than with MFM. RLL encoding places more stringent demands on the timing of the controller and drive electronics. With RLL encoding, accurately reading the timing of the flux changes is paramount. Additionally, because RLL encodes variable-length groups of bits rather than single bits, a single error in one flux transition can corrupt two to four bits of data. For these reasons, an RLL controller usually has a more sophisticated error-detection and error-correction routine than an MFM controller.

The bottom line is that other than improved precision, there is no real difference between an ST-506/412 drive that is sold as an MFM model and one that is sold as an RLL model.

One method for avoiding reliability problems in the conversion process is to place an endec directly on the drive rather than on the controller. This method reduces the susceptibility to noise and interference that can plague some drive systems running RLL encoding. IDE and SCSI drives both have the endec (and often the entire controller) built into the drive by default. Because the endec is attached to the drive without cables and with an extremely short electrical distance, the propensity for timing- and noise-induced errors is greatly reduced or eliminated. This situation is analogous to a local telephone call between the endec and the disk platters. This local communication makes the ESDI, IDE, and SCSI interfaces much more reliable than the older ST-506/412 interface; they share none of the reliability problems that were once associated with RLL encoding over the ST-506/412 interface. Virtually all ESDI, IDE, and SCSI drives use RLL encoding today with tremendously increased reliability over even MFM ST-506/412 drives.

Note

For a complete historical reference covering the original ST-506/412 controllers used in the PC environment, see *Upgrading and Repairing PCs, Sixth Edition*, found in its entirety on the CD included with this book.

The ESDI Interface

ESDI, or Enhanced Small Device Interface, is a specialized hard disk interface established as a standard in 1983, primarily by Maxtor Corporation. Maxtor led a consortium of drive manufacturers to adopt its proposed interface as a high-performance standard to succeed ST-506/412. ESDI

later was adopted by the ANSI (American National Standards Institute) organization and published under the ANSI X3T9.2 Committee. The latest version of the ANSI ESDI document is known as X3.170a-1991. You can obtain this document, and other ANSI-standard documents, from ANSI or from Global Engineering Documents. These companies are listed in the Vendor List database on the CD included with this book.

Compared with ST-506/412, ESDI has provisions for increased reliability, such as building the endec into the drive. ESDI was much faster than the older ST-506/412 that preceded it, and was capable of a maximum 24Mbit/sec transfer rate. Most drives running ESDI, however, are limited to a maximum 10- or 15Mbit/sec. Unfortunately, compatibility problems between different ESDI implementations, combined with pressure from low-cost, high-performance IDE interface drives, served to make the ESDI interface obsolete by the early '90s. ESDI became somewhat popular in high-end (especially file server) systems during the late '80s.

Enhanced commands enabled some ESDI controllers to read a drive's capacity parameters directly from the drive and control defect mapping, but several manufacturers had different methods for writing this information on the drive. When you install an ESDI drive, in some cases the controller automatically reads the parameter and defect information directly from the drive. In other cases, however, you still have to enter this information manually, as with ST-506/412.

The ESDI's enhanced defect-mapping commands provide a standard way for the PC system to read a defect map from a drive, which means that the manufacturer's defect list can be written to the drive as a file. The defect list file then can be read by the controller and low-level format software, eliminating the need for the installer to type these entries from the keyboard. This also enables the format program to update the defect list with new entries if it finds new defects during the low-level format or the surface analysis.

Most ESDI implementations have drives formatted to 32 sectors or more per track (80 or more sectors per track are possible)—many more sectors per track than the standard ST-506/412 implementation of 17 to 26. The greater density results in two or more times the data-transfer rate, with a 1:1 interleave. Almost without exception, ESDI controllers support a 1:1 interleave, which allows for a transfer rate of 1MB/sec or greater.

Because ESDI is much like the ST-506/412 interface, it can replace that interface without affecting software in the system. Most ESDI controllers are register-compatible with the older ST-506/412 controllers, which enables OS/2 and other non-DOS operating systems to run with few or no problems. The ROM BIOS interface to ESDI is similar to the ST-506/412 standard; many low-level disk utilities that run on one interface will run on the other. To take advantage of ESDI defect mapping and other special features, however, use a low-level format and surface-analysis utility designed for ESDI (such as the ones usually built into the controller ROM BIOS and called by DEBUG).

During the late 1980s, most high-end systems from major manufacturers were equipped with ESDI controllers and drives. Starting with the early 1990s, manufacturers began equipping high-end systems such as network file servers and workstations with SCSI. The SCSI interface allows for much greater expandability, supports more types of devices than ESDI does, and offers equal or greater performance.

Note

For a complete historical reference covering the ESDI controllers used in the PC environment, see *Upgrading and Repairing PCs, Sixth Edition*, found in its entirety on the CD included with this book.

The IDE Interface

Integrated Drive Electronics (IDE) is a generic term applied to any drive with an integrated (built-in) disk controller. The IDE interface, as we know it, is officially called *ATA (AT Attachment)* and is an ANSI standard. However, IDE can roughly apply to any disk drive with a built-in controller. Note that the “AT” in the name AT Attachment comes from the original IBM AT that debuted the 16-bit ISA (Industry Standard Architecture) bus. ATA therefore refers basically to a hard disk drive that plugs directly into a version of the AT-bus, otherwise known as the ISA bus.

The first drives with integrated ISA (AT-bus) controllers were called hardcards; they consisted of a hard disk bolted directly to an ISA bus controller card and plugged into a slot as a single unit. Today, a variety of drives with integrated controllers are available. In a drive with IDE, the disk controller is integrated into the drive, and this combination drive/controller assembly usually plugs into a bus connector on the motherboard or bus adapter card. Combining the drive and controller greatly simplifies installation, because there are no separate power or signal cables from the controller to the drive. Also, when the controller and drive are assembled as a unit, the number of total components is reduced, signal paths are shorter, and the electrical connections are more noise-resistant. This results in a more reliable design than is possible when a separate controller, connected to the drive by cables, is used.

Placing the controller, including the digital to analog encoder/decoder (endec) on the drive gives IDE drives an inherent reliability advantage over interfaces with separate controllers. Reliability is increased because the data encoding, from digital to analog, is performed directly on the drive in a tight noise-free environment. The timing-sensitive analog information does not have to travel along crude ribbon cables that are likely to pick up noise and insert propagation delays into the signals. The integrated configuration allows for increases in the clock rate of the encoder and the storage density of the drive.

Integrating the controller and drive also freed the controller and drive engineers from having to adhere to the strict standards imposed by the earlier interface standards. Engineers can design what essentially are custom drive and controller implementations because no other controller would ever have to be connected to the drive. The resulting drive and controller combinations can offer higher performance than earlier standalone controller and drive setups. IDE drives sometimes are called drives with embedded controllers.

The IDE connector on motherboards in many systems is nothing more than a stripped-down bus slot. In ATA IDE installations, these connectors normally contain a 40-pin subset of the 98 pins that would be available in a standard 16-bit ISA bus slot. Note that smaller 2 1/2-inch ATA drives use a superset 44-pin connection, which includes pins for power and configuration. The pins used are only the signal pins required by a standard-type XT or AT hard disk controller. For example, because an AT-style disk controller uses only interrupt line 14, the motherboard ATA IDE

connector supplies only that interrupt line; no other interrupt lines are needed. The XT IDE motherboard connector supplies interrupt line 5 because that is what an XT controller would use. Note that even if your ATA interface is connected to the South Bridge chip and runs at PCI bus speeds, the pinout and functions of the pins are still the same.

◀◀ See “Motherboard Interface Connectors,” p. 272.

◀◀ See “The ISA Bus,” p. 283.

Note

Many people who use systems with IDE connectors on the motherboard believe that a hard disk controller is built into their motherboard, but the controller really is in the drive. I do not know of any PC systems that have hard disk controllers built into the motherboard.

When IDE drives are discussed, the ATA IDE variety usually is the only kind mentioned because it is so popular. But other forms of IDE drives exist, based on other buses. For example, several PS/2 systems came with Micro-Channel (MCA) IDE drives that plug directly into a Micro-Channel Bus slot (through an angle adapter or interposer card). An 8-bit ISA form of IDE also existed >but was never very popular. Most IBM-compatible systems with the ISA or EISA bus use AT-Bus (16-bit) IDE drives. The ATA IDE interface is by far the most popular type of drive interface available.

Note

IDE is a generic name that could be given to any interface where the controller portion of the circuit is on the drive; ATA refers to a specific type of IDE interface. Because the only popular form of IDE interface is ATA, the terms are often used interchangeably, even though on a technical level that is not correct.

The primary advantage of IDE drives over the older separate controller based interfaces and newer host bus interface alternatives such as SCSI or IEEE-1394 (iLink or FireWire) is cost. Because the separate controller or host adapter is eliminated and the cable connections are simplified, IDE drives cost much less than a standard controller and drive combination. These drives also are more reliable because the controller is built into the drive. Therefore, the endec or data separator (the converter between the digital and analog signals on the drive) stays close to the media. Because the drive has a short analog signal path, it is less susceptible to external noise and interference.

Another advantage is performance. IDE drives are some of the highest performance drives available—but they also are among the lowest performance drives. This apparent contradiction is a result of the fact that all IDE drives are different. You cannot make a blanket statement about the performance of IDE drives because each drive is unique. The high-end models, however, offer performance that is equal or superior to that of any other type of drive on the market for a single-user, single-tasking operating system.

IDE Origins

The earliest IDE drives were called hardcards—nothing more than hard disks and controllers bolted directly together and plugged into a slot as a single unit. Companies such as the

Plus Development Division of Quantum took small 3 1/2-inch drives (either ST-506/412 or ESDI) and attached them directly to a standard controller. The assembly then was plugged into an ISA bus slot as though it were a normal disk controller. Unfortunately, the mounting of a heavy, vibrating hard disk in an expansion slot with nothing but a single screw to hold it in place left a lot to be desired. Not to mention the possible interference with adjacent cards due to the fact that many of these units were much thicker than a controller card alone.

Several companies got the idea that you could redesign the controller to replace the logic-board assembly on a standard hard disk, and then mount it in a standard drive bay just like any other drive. Because the built-in controller in these drives still needed to plug directly into the expansion bus just like any other controller, a cable was run between the drive and one of the slots.

These connection problems were solved in different ways. Compaq was the first to incorporate a special bus adapter in its system to adapt the 98-pin AT (ISA) bus edge connector on the motherboard to a smaller 40-pin header style connector that the drive would plug into. The 40-pin connectors were all that was needed, because it was known that a disk controller never would need more than 40 of the ISA-bus lines.

In 1987, IBM developed its own MCA IDE drives and connected them to the bus through a bus adapter device called an interposer card. These bus adapters (sometimes called paddle boards or angle boards) needed only a few buffer chips and did not require any real circuitry because the drive-based controller was designed to plug directly into the bus. The paddle board nickname came from the fact that they resembled game paddle or joystick adapters, which do not have much circuitry on them. Another 8-bit variation of IDE appeared in 8-bit ISA systems such as the PS/2 Model 30. The XT IDE interface uses a 40-pin connector and cable that is similar to, but not compatible with, the 16-bit version.

IDE Bus Versions

Three main types of IDE interfaces were available at one time, with the differences based on three different bus standards:

- AT Attachment (ATA) IDE (16-bit ISA)
- XT IDE (8-bit ISA)
- MCA IDE (16-bit Micro Channel)

Of these, only the ATA version is used today, and it has evolved with newer, faster, and more powerful versions becoming available. These improved versions of ATA are referred to as ATA-2 and higher. They are also called EIDE, which stands for Enhanced IDE, Fast-ATA, or ultra-ATA.

Note

Many people are confused about 16- versus 32-bit bus connections and 16- versus 32-bit hard drive connections. A PCI connection allows for a 32-bit (and possibly 64-bit in the future) bandwidth from the bus to the IDE host interface, which is normally in the motherboard chipset South Bridge. However, the actual ATA-IDE interface between the host connector on the motherboard and the drive (or drives) themselves is only a 16-bit interface. Thus, in an IDE (or EIDE) drive configuration, you are still getting only 16-bit bandwidth between the drive and the motherboard-based host interface. This usually does not create a bottleneck, because one or two hard drives cannot supply the controller enough data to saturate even a 16-bit channel.

The XT and ATA versions have standardized on 40-pin connectors and cables, but the connectors have slightly different pinouts, rendering them incompatible with one another. MCA IDE uses a completely different 72-pin connector and is designed for MCA bus systems only.

In most cases, you must use the type of IDE drive that matches your system bus. This situation means that XT IDE drives work only in XT-class, 8-bit ISA slot systems (obsolete today). AT IDE (ATA) drives work only in AT-class, 16-bit or greater ISA/PCI slot systems. MCA IDE drives work only in obsolete Micro-Channel systems (such as the IBM PS/2 Model 50 or higher). A company called Silicon Valley offers adapter cards for XT systems that will run ATA IDE drives. Other companies, such as Arco Electronics and Sigma Data, have IDE adapters for Micro-Channel systems that allow ATA IDE drives to be used on MCA systems. (You can find these vendors in Appendix A.) These adapters are useful for older XT or PS/2 systems, because there is a very limited selection of XT or MCA IDE drives, whereas the selection of ATA IDE drives is virtually unlimited.

In most modern ISA/PCI systems, you will find an ATA connector on the motherboard. If your motherboard does not have one of these connectors and you want to attach an AT IDE drive to your system, you can purchase an adapter card that adds an ATA interface (or two) to a system via the ISA or PCI bus slots. Some of the cards offer additional features, such as an on-board ROM BIOS or cache memory.

Because the ATA variety of IDE is the primary one in use today, that is what most of this chapter discusses.

ATA IDE

CDC, Western Digital, and Compaq actually created what could be called the first ATA-type IDE interface drive and were the first to establish the 40-pin IDE connector pinout. The first ATA IDE drives were 5 1/4-inch half-height CDC 40MB units with integrated WD controllers sold in the first Compaq 386 systems in 1986.

Eventually, the 40-pin IDE connector and drive interface method was placed before one of the ANSI standards committees which, in conjunction with drive manufacturers, ironed out some deficiencies, tied up some loose ends, and published what is known as the CAM ATA (Common Access Method AT Attachment) interface. The CAM Committee was formed in October 1988, and the first working document of the AT Attachment interface was introduced in March 1989. Before the CAM ATA standard, many companies that followed CDC, such as Conner Peripherals, made proprietary changes to what had been done by CDC. As a result, many older ATA drives from the late '80s are very difficult to integrate into a dual-drive setup that has newer drives. By the early '90s, most drive manufacturers brought their drives into full compliance with the official standard, which eliminated many of these compatibility problems.

Some areas of the ATA standard have been left open for vendor-specific commands and functions. These vendor-specific commands and functions are the main reason why it is so difficult to low-level format IDE drives. To work to full capability, the formatter you are using usually must know the specific vendor-unique commands for rewriting sector headers and remapping defects. Unfortunately, these and other specific drive commands differ from OEM to OEM, clouding the

“standard” somewhat. Most ATA drive manufacturers have formatting software available on their Web sites.

Note

It is important to note that only the ATA IDE interface has been standardized by the industry. The XT IDE and MCA IDE never were adopted as industry-wide standards and never became very popular. These interfaces no longer are in production, and no new systems of which I am aware come with these non-standard IDE interfaces.

ATA Standards

Today what we call the ATA interface is controlled by an independent group of representatives from major PC, drive, and component manufacturers. This group is called Technical Committee T13, and is responsible for all interface standards relating to the AT Attachment (ATA) storage interface. T13 is a part of the National Committee on Information Technology Standards (NCITS), which operates under rules approved by the American National Standards Institute (ANSI), a governing body that sets rules which control non-proprietary standards in the computer industry as well as many other industries.

The rules are designed to ensure that voluntary industry standards are developed by the consensus of people and organizations in the affected industry. NCITS specifically develops Information Processing System standards, whereas ANSI approves the process under which they are developed and publishes them. Since T13 is essentially a public organization, all the working drafts, discussions, and meetings of T13 are open for all to see.

The ATA interface has evolved into several successive standard versions introduced as follows:

- ATA-1 (1988–1994)
- ATA-2 (1996, also called Fast-ATA, Fast-ATA-2, or EIDE)
- ATA-3 (1997)
- ATA-4 (1998, also called ultra-ATA/33)
- ATA-5 (1999–present, also called ultra-ATA/66)

Each version of ATA is backward compatible with the previous versions. In other words older ATA-1 or ATA-2 devices will work fine on ATA-4 or ATA-5 interfaces. In cases where the device version and interface version don't match, they will work together at the capabilities of the lesser of the two. Newer versions of ATA are built on older versions, and with few exceptions can be thought of as extensions of the previous versions. This means that ATA-5, for example, is equal to ATA-4 with the addition of additional features. The following sections describe all the ATA versions in more detail.

ATA-1 (AT Attachment Interface for Disk Drives)

Although first published and used since 1988 in various draft forms, ATA-1 wasn't officially approved until 1994 (committees often work slowly). ATA-1 defined the original AT Attachment

interface, which was an integrated bus interface between disk drives and host systems based on the ISA (AT) bus. The major features that were introduced and documented in the ATA-1 specification are

- 40/44-pin connectors and cabling
- Master/slave/cable Select drive configuration options
- Signal timing for basic PIO (Programmed I/O) and DMA (Direct Memory Access) modes
- CHS (Cylinder Head Sector) and LBA (Logical Block Address) drive parameter translations

ATA-1 has been officially published as ANSI X3.221-1994, AT Attachment Interface for Disk Drives.

You can obtain the current version of these or virtually any other computer standards from Global Engineering Documents, which is listed in the Vendor's List on the CD-ROM accompanying this book. The ATA standards have gone a long way toward eliminating incompatibilities and problems with interfacing IDE drives to ISA/PCI bus systems. The ATA specifications define the signals on the 40-pin connector, the functions and timings of these signals, cable specifications, and so on. The following section lists some of the elements and functions defined by the ATA specification.

ATA I/O Connector

The ATA interface connector is a 40- or 44-pin header-type connector that generally is keyed to prevent the possibility of installing it upside down (see Figures 7.1 and 7.2). To create a keyed connector, the manufacturer removes pin 20 to prevent the user from installing the cable backward. The use of keyed connectors and cables is highly recommended; plugging an IDE cable in backward can damage both the drive and the bus adapter circuits (although I have done it myself many times with no smoked parts yet!).

Figure 7.1 Typical ATA (IDE) hard drive connectors.

Figure 7.2 ATA (IDE) 40-pin interface connector detail.

Table 7.1 shows the ATA-IDE interface connector pinout.

Table 7.1 ATA Connector

Signal Name	Pin	Pin	Signal Name
-RESET	1	2	GROUND
Data Bit 7	3	4	Data Bit 8
Data Bit 6	5	6	Data Bit 9
Data Bit 5	7	8	Data Bit 10
Data Bit 4	9	10	Data Bit 11
Data Bit 3	11	12	Data Bit 12
Data Bit 2	13	14	Data Bit 13
Data Bit 1	15	16	Data Bit 14
Data Bit 0	17	18	Data Bit 15
GROUND	19	20	KEY (pin missing)
DRQ 3	21	22	GROUND
-IOW	23	24	GROUND
-IOR	25	26	GROUND
I/O CH RDY	27	28	SPSYNC:CSEL
-DACK 3	29	30	GROUND
IRQ 14	31	32	-IOCS16
Address Bit 1	33	34	-PDIAG
Address Bit 0	35	36	Address Bit 2
-CS1FX	37	38	-CS3FX
-DA/SP	39	40	GROUND
+5 Vdc (Logic)	41	42	+5 Vdc (Motor)
GROUND	43	44	-TYPE (0=ATA)

Note that the connector pinout shows 44 total pins, although only the first 40 are used on most 3 1/2-inch or larger ATA drives. The additional four pins shown (pins 41–44) are a superset found primarily on the smaller 2 1/2-inch drives used in notebook and laptop systems. Those drives don't have room for a separate power connector, so the additional pins are primarily designed to supply power to the drive.

ATA I/O Cable

A 40-conductor ribbon cable is specified to carry signals between the bus adapter circuits and the drive (controller). To maximize signal integrity and eliminate potential timing and noise problems, the cable should not be longer than 0.46 meters (18 inches).

Note that the newer high-speed IDE interfaces are especially susceptible to cable problems and cables that are too long. If the cable is too long, you will experience data corruption and other errors that can be maddening. This will be manifested in any type of problems reading from or writing to the drive. I always keep a special high-quality short IDE cable in my toolbox for testing drives where I suspect this problem. Figure 7.3 shows the typical ATA cable layout and dimensions.

Figure 7.3 ATA (IDE) cable.

ATA Signals

This section describes some of the most important signals in more detail.

Pin 20 is used as a key pin for cable orientation and is not connected through in the interface. This pin should be missing from any ATA connectors, and the cable should have the pin-20 hole in the connector plugged off to prevent the cable from being plugged in backward.

Pin 39 carries the Drive Active/Slave Present (DASP) signal, which is a dual-purpose, time-multiplexed signal. During power-on initialization, this signal indicates whether a slave drive is present on the interface. After that, each drive asserts the signal to indicate that it is active. Early drives could not multiplex these functions and required special jumper settings to work with other drives. Standardizing this function to allow for compatible dual-drive installations is one of the features of the ATA standard. This is why some drives require a slave present (SP) jumper, while others do not.

Pin 28 carries the Cable Select or Spindle Synchronization signal (CSEL or SPSYNC), which is a dual-purpose conductor; a given installation, however, may use only one of the two functions. The CSEL function is the most widely used and is designed to control the designation of a drive

as master (drive 0) or slave (drive 1) without requiring jumper settings on the drives. If a drive sees the CSEL as being grounded, the drive is a master; if CSEL is open, the drive is a slave.

You can install special cabling to ground CSEL selectively. This installation normally is accomplished through a Y-cable arrangement, with the IDE bus connector in the middle and each drive at opposite ends of the cable. One leg of the Y has the CSEL line connected through, indicating a master drive; the other leg has the CSEL line open (conductor interrupted or removed), making the drive at that end the slave.

Dual-Drive Configurations

Dual-drive ATA installations can be problematic because each drive has its own controller, and both controllers must function while being connected to the same bus. There has to be a way to ensure that only one of the two controllers will respond to a command at a time.

The ATA standard provides the option of operating on the AT bus with two drives in a daisy-chained configuration. The primary drive (drive 0) is called the master, and the secondary drive (drive 1) is the slave. You designate a drive as being master or slave by setting a jumper or switch on the drive or by using a special line in the interface called the Cable Select (CSEL) pin, and by setting the CS jumper on the drive.

When only one drive is installed, the controller responds to all commands from the system. When two drives (and, therefore, two controllers) are installed, all commands from the system are received by both controllers. Each controller then must be set up to respond only to commands for itself. In this situation, one controller then must be designated as the master and the other as the slave. When the system sends a command for a specific drive, the controller on the other drive must remain silent while the selected controller and drive are functioning. Setting the jumper to master or slave allows discrimination between the two controllers by setting a special bit (the DRV bit) in the Drive/Head Register of a command block.

Configuring IDE drives can be simple, as is the case with most single-drive installations, or troublesome, especially when it comes to mixing two drives from different manufacturers on a single cable.

Most IDE drives can be configured with four possible settings:

- Master (single-drive)
- Master (dual-drive)
- Slave (dual-drive)
- Cable Select

Because each IDE drive has its own controller, you must specifically tell one drive to be the master and the other to be the slave. There is no functional difference between the two, except that the drive that's specified as the slave will assert a signal called DASP (Drive Active/Slave Present) after a system reset informs the master that a slave drive is present in the system. The master drive then pays attention to the Drive Select line, which it otherwise ignores. Telling a drive that it's the slave also usually causes it to delay its spinup for several seconds to allow the master to get going, and thus to lessen the load on the system's power supply.

Until the ATA IDE specification, no common implementation for drive configuration was in use. Some drive companies even used different master/slave methods for different models of drives. Because of these incompatibilities, some drives work together only in a specific master/slave or slave/master order. This situation affects mostly older IDE drives that were introduced before the ATA specification.

Most drives that fully follow the ATA specification now need only one jumper (master/slave) for configuration. A few also need a slave present jumper as well. Table 7.2 shows the jumper settings required by most ATA IDE drives.

Table 7.2 Jumper Settings for Most ATA IDE-Compatible Drives

Jumper Name	Single-Drive	Dual-Drive Master	Dual-Drive Slave
Master (M/S)	On	On	Off
Slave Present (SP)	Off	On	Off

Figure 7.4 shows the jumpers on a typical ATA drive.

Figure 7.4 ATA (IDE) drive jumpers.

The Master jumper indicates that the drive is a master or a slave. Some drives also require a Slave Present jumper, which is used only in a dual-drive setup and then installed only on the master drive, which is somewhat confusing. This jumper tells the master that a slave drive is attached.

With many ATA IDE drives, the Master jumper is optional and may be left off. Installing this jumper doesn't hurt in these cases and may eliminate confusion; I recommend that you install the jumpers listed here.

ATA Commands

One of the best features of the ATA IDE interface is the enhanced command set. The ATA IDE interface was modeled after the WD1003 controller that IBM used in the original AT system. All ATA IDE drives must support the original WD command set (eight commands) with no exceptions, which is why IDE drives are so easy to install in systems today. All IBM-compatible systems have built-in ROM BIOS support for the WD1003, which means that essentially they support ATA IDE as well.

In addition to supporting all the WD1003 commands, the ATA specification added numerous other commands to enhance performance and capabilities. These commands are an optional part of the ATA interface, but several of them are used in most drives available today and are very important to the performance and use of ATA drives in general.

Perhaps the most important is the Identify Drive command. This command causes the drive to transmit a 512-byte block of data that provides all details about the drive. Through this command, any program (including the system BIOS) can find out exactly what type of drive is connected, including the drive manufacturer, model number, operating parameters, and even the serial number of the drive. Many modern BIOSes use this information to automatically receive and enter the drive's parameters into CMOS memory, eliminating the need for the user to enter these parameters manually during system configuration. This arrangement helps prevent mistakes that can later lead to data loss when the user no longer remembers what parameters he or she used during setup.

The Identify Drive data can tell you many things about your drive, including the following:

- Number of cylinders in the recommended (default) translation mode
- Number of heads in the recommended (default) translation mode
- Number of sectors per track in the recommended (default) translation mode
- Number of cylinders in the current translation mode
- Number of heads in the current translation mode
- Number of sectors per track in the current translation mode
- Manufacturer and model number
- Firmware revision
- Serial number
- Buffer type, indicating sector buffering or caching capabilities

Several public-domain programs can execute this command to the drive and report the information onscreen. I use the IDEINFO (available at <http://www.dc.ee/Files/Utils/IDEINFO.ARJ>) or IDEDIAG (available from many of the popular shareware sites) program. I find these programs especially useful when I am trying to install IDE drives and need to know the correct parameters for a user-definable BIOS type. These programs get the information directly from the drive.

Two other very important commands are the Read Multiple and Write Multiple commands. These commands permit multiple-sector data transfers and, when combined with block-mode Programmed I/O (PIO) capabilities in the system, can result in incredible data-transfer rates many times faster than single-sector PIO transfers.

There are many other enhanced commands, including room for a given drive manufacturer to implement what are called vendor-unique commands. These commands often are used by a particular vendor for features unique to that vendor. Often, features such as low-level formatting and defect management are controlled by vendor-unique commands. This is why low-level format programs can be so specific to a particular manufacturer's IDE drives and why many manufacturers make their own LLF programs available.

ATA-2 (AT Attachment Interface with Extensions)

Approved in 1996, ATA-2 was a major upgrade to the original ATA standard. Perhaps the biggest change was almost a philosophical one. ATA-2 was updated to define an interface between host systems and storage devices in general and not only disk drives. The major features added to ATA-2 as compared to the original ATA standard include

- Faster PIO and DMA transfer modes
- Support for power management
- Support for removable devices
- PCMCIA (PC card) device support
- Defined drive support for up to 137.4GB
- Defined standard CHS/LBA (Cylinder Head Sector/Logical Block Address) translation methods for drives up to 8.4GB in capacity

ATA-2 is also known by unofficial marketing terms such as fast-ATA or fast-ATA-2 (Seagate/Quantum) and EIDE (Enhanced IDE, Western Digital). ATA-2 was officially published as ANSI X3.279-1996 AT Attachment Interface with Extensions.

ATA-3 (AT Attachment 3 Interface)

First published in 1997, ATA-3 was a comparatively minor revision to the ATA-2 standard that preceded. It consisted of a general cleanup of the specification and had mostly minor clarifications and revisions. The most major changes included the following:

- Eliminated single word (8-bit) DMA transfer protocols
- Added S.M.A.R.T. (Self-Monitoring, Analysis, and Reporting Technology) support for prediction of device performance degradation
- Added security mode, allowing password protection for device access
- Recommendations for source and receiver bus termination to solve noise issues at higher transfer speeds

ATA-3 has been officially published as ANSI X3.298-1997, AT Attachment 3 Interface.

ATA-2 and ATA-3 are extensions of the original ATA (IDE) specification. The most important additions are performance-enhancing features such as fast PIO and DMA modes. ATA-2 also features improvements in the Identify Drive command allowing a drive to tell the software exactly what its characteristics are; this is essential for both Plug and Play (PnP) and compatibility with future revisions of the standard. ATA-3 adds improved reliability, especially of the faster mode 4 transfers; note that ATA-3 does not define any faster modes. ATA-3 also adds a simple password-based security scheme, more sophisticated power management, and Self Monitoring Analysis and Report Technology (S.M.A.R.T.). This allows a drive to keep track of problems that might result in a failure.

ATA-2 and 3 are often called Enhanced IDE (or EIDE). EIDE is technically a marketing program from Western Digital. Fast-ATA and Fast-ATA-2 are similar Seagate-inspired marketing programs, which are also endorsed by Quantum. As far as the hard disk and BIOS are concerned, these are all different terms for basically the same thing.

There are four main areas where ATA-2 (EIDE), ATA-3, and ATA-4 have improved the original ATA/IDE interface in several ways:

- Increased maximum drive capacity
- Faster data transfer
- Secondary two-device channel
- ATAPI (ATA Program Interface)

The following sections describe these improvements.

Increased Drive Capacity

ATA-2/EIDE allows for increased drive capacity over the original ATA/IDE specification. This is done through an Enhanced BIOS, which makes it possible to use hard disks exceeding the 504MB barrier. The origin of this limit is the disk geometry (cylinders, heads, sectors) supported by the combination of an IDE drive and the BIOS' software interface. Both IDE and the BIOS are capable of supporting huge disks, but their combined limitations conspire to restrict the useful capacity to 504MB.

An Enhanced BIOS circumvents this by using a different geometry when talking to the drive than when talking to the software. What happens in between is called *translation*. For example, if your drive has 2,000 cylinders and 16 heads, a translating BIOS will make programs think that the drive has 1,000 cylinders and 32 heads.

You can usually tell if your BIOS is enhanced by the capability to specify more than 1,024 cylinders in the BIOS setup, although this is inconclusive. If you see drive-related settings such as LBA, ECHS, or even Large, these are telltale signs of a BIOS with translation support. Most BIOSes with a date of 1994 or later are enhanced. If your system currently does not have an Enhanced BIOS, you may be able to get an upgrade.

Table 7.3 shows the three ways today's BIOSes can handle translation: Standard CHS addressing, Extended CHS addressing, and LBA addressing. They are summarized in the following table.

Table 7.3 ATA-2 Translation Methods

BIOS Mode	Operating System to BIOS	BIOS to Drive Ports
Standard CHS	Logical CHS Parameters	Logical CHS Parameters
Extended CHS	Translated CHS Parameters	Logical CHS Parameters
LBA	Translated CHS Parameters	LBA Parameters

In Standard CHS, there is only one possible translation step internal to the drive. The drive's actual physical geometry is completely invisible from the outside with all zoned recorded ATA drives today. The Cylinders, Heads, and Sectors printed on the label for use in the BIOS setup are purely logical geometry, and do not represent the actual physical parameters. Standard CHS addressing is limited to 16 heads and 1,024 cylinders, which gives us a limit of 504MB.

This is often called "Normal" in the BIOS setup, and causes the BIOS to behave like an old-fashioned one without translation. Use this setting if your drive has fewer than 1,024 cylinders or if you want to use the drive with a non-DOS operating system that doesn't understand translation.

In Extended CHS, a translated logical geometry is used to communicate between the drive and the BIOS, while a different translated geometry is used to communicate between the BIOS and everything else. In other words, there are normally two translation steps. The drive still translates internally, but has logical parameters that exceed the 1,024 cylinder limitation of the standard BIOS. In this case, the drive's cylinder count is usually divided by 2, and the head count is multiplied by 2 to get the translated values from those actually stored in the CMOS Setup. This type of setting breaks the 504/528MB barrier.

This is often called "Large" or "ECHS" in the BIOS setup, and tells the BIOS to use Extended CHS translation. It uses a different geometry (cylinders/heads/sectors) when talking to the drive than when talking to the BIOS. This type of translation should be used with drives that have more than 1,024 cylinders but that do not support LBA (Logical Block Addressing). Note that the geometry entered in your BIOS setup is the logical geometry, not the translated one.

LBA is a means of linearly addressing sector addresses, beginning at Cylinder 0, Head 0, Sector 1 as LBA 0, and proceeding on to the last physical sector on the drive. This is new in ATA-2, but has always been the one and only addressing mode in SCSI.

With LBA, each sector on the drive is numbered starting from 0. The number is a 28-bit binary number internally, which translates to a sector number from 0 to 268,435,456. Because each sector represents 512 bytes, this results in a maximum drive capacity of exactly 128GB, or 137 billion bytes. Unfortunately, the operating system still needs to see a translated CHS, so the BIOS determines how many sectors there are and comes up with Translated CHS to match. The BIOS CHS limits are 1,024 cylinders, 256 heads, and 63 sectors per track, which limits total drive capacity to just under 8GB.

In other words, this breaks the 528MB barrier in essentially the same way as Extended CHS does. Because it is somewhat simpler to use a single linear number to address a sector on the hard disk compared to a CHS type address, this is the preferred method if the drive supports LBA.

Caution

A word of warning with these BIOS translation settings: If you switch between Standard CHS, Extended CHS, or LBA, the BIOS may change the (translated) geometry. The same thing can happen if you transfer a disk that has been formatted on an old, non-LBA computer to a new one that uses LBA. This causes the logical CHS geometry seen by the operating system to change and the data to appear in the wrong locations from where it actually is! This can cause you to lose access to your data if you are not careful. I always recommend recording the CMOS Setup screens associated with the hard disk configuration so that you can properly match the setup of a drive to the settings to which it was originally set.

Systems using ATA drives have been plagued by size limitations because of ATA interface and BIOS issues. The first two limits were mostly BIOS related, the first was at 528MB, and the second at 8.4GB. Along with ATA-4 and ATA-5, the T13 committee has also defined an extension or enhancement to the BIOS originally designed by Phoenix called Enhanced BIOS Services for Disk Drives. This document describes new services provided by the BIOS to support storage devices of over 9.4 trillion GB (9.4×10 to the 21st power, or to be more precise 9,444,732,965,739,292,000,000 bytes!) Older BIOS services have a compatibility limit of 528MB and a theoretical limit of 8.4GB. Starting in mid-1998, most systems incorporated the enhanced BIOS services. Note that even though the BIOS can handle drives with up to 2^{64} th sectors, an ATA drive is still currently limited in size to 2^{28} th sectors, or 137.4GB maximum.

Faster Data Transfer

ATA-2/EIDE and ATA-3 define several high-performance modes for transferring data to and from the drive. These faster modes are the main part of the new specifications and were the main reason they were initially developed. The following section discusses these modes.

The PIO mode determines how fast data is transferred to and from the drive. In the slowest possible mode, PIO mode 0, the data cycle time cannot exceed 600 nanoseconds (ns). In a single cycle, 16 bits are transferred in to or out of the drive making the theoretical transfer rate of PIO Mode 0 (600ns cycle time) 3.3MB/sec. Most of the high-performance ATA-2 (EIDE) drives today support PIO Mode 4, which offers a 16.6MB/sec transfer rate.

Table 7.4 shows the PIO modes, with their respective transfer rates.

Table 7.4—PIO Modes and Transfer Rates

PIO Mode	Cycle Time (ns)	Transfer Rate (MB/sec)	Specification
0	600	3.33	ATA
1	383	5.22	ATA
2	240	8.33	ATA
3	180	11.11	ATA-2, EIDE, fast-ATA
4	120	16.67	ATA-2, EIDE, fast-ATA

To run in Mode 3 or 4 requires that the IDE port on the system be a local bus port. This means that it must operate through either a VL-Bus or PCI bus connection. Most motherboards with

ATA-2/EIDE support have dual IDE connectors on the motherboard, and most of them now allow full throughput. Most of the motherboard chipsets include the ATA interface in their South Bridge component, which in modern systems is tied into the PCI bus.

Older 486 and some early Pentium boards have only the primary connector running through the system's PCI local bus. The secondary connector on those boards usually runs through the ISA bus, and therefore supports up to Mode 2 operation only.

When interrogated with an Identify Drive command, a hard disk returns, among other things, information about the PIO and DMA modes it is capable of using. Most enhanced BIOSes will automatically set the correct mode to match the capabilities of the drive. If you set a mode faster than the drive can handle, data corruption will result.

ATA-2 and newer drives also perform Block Mode PIO, which means that they use the Read/Write Multiple commands that greatly reduce the number of interrupts sent to the host processor. This lowers the overhead, and the resulting transfers are even faster.

DMA Transfer Modes

ATA-2 and newer drives also support *Direct Memory Access* (DMA) transfers. DMA means that the data is transferred directly between drive and memory without using the CPU as an intermediary, as opposed to PIO. This has the effect of offloading much of the work of transferring data from the processor, in effect allowing the processor to do other things while the transfer is taking place.

There are two distinct types of direct memory access: DMA and busmastering DMA. Ordinary DMA relies on the legacy DMA controller on the system's mainboard to perform the complex task of arbitration, grabbing the system bus and transferring the data. In the case of busmastering DMA, all this is done by logic in the interface.

Systems using the Intel PIIX (PCI IDE ISA eXcelerator) and later South Bridge chips have the capability of supporting busmaster IDE. This uses the busmaster mode on the PCI bus to execute data transfers. The busmaster IDE modes and transfer rates are shown in Table 7.5.

Table 7.5 Busmaster IDE Modes and Transfer Rates

BMIDE Mode	Cycle Time (ns)	Transfer Rate (MB/sec)	Specifications
0	480	4.16	ATA-1
1	150	3.33	ATA-2, EIDE, fast-ATA
2	120	16.67	ATA-2, EIDE, fast-ATA

Note that busmaster DMA modes are also called multiword DMA modes because they do 16-bit transfers. Unfortunately, even the fastest multiword DMA mode 2 results in the same 16.67MB/sec transfer speed as PIO Mode 4, so DMA never really caught on as being desirable. However, even though the transfer speed is the same as PIO, since DMA offloads much of the work from the processor, overall system performance would be higher. Even so, multiword DMA modes were never very popular and have now been superseded by the newer ultra-DMA modes supported in ATA-4 compatible devices.

The following table shows the ultra-DMA modes now supported in the ATA-4 and ATA-5 specifications.

UDMA Mode	Cycle Time (ns)	Transfer Rate (MB/sec)	Specification
0	240	16.67	ATA-4, ultra-ATA/33
1	160	25.00	ATA-4, ultra-ATA/33
2	120	33.33	ATA-4, ultra-ATA/33
3	90	44.44	ATA-5, ultra-ATA/66
4	60	66.67	ATA-5, ultra-ATA/66

ATAPI (ATA Packet Interface)

ATAPI is a standard designed for devices such as CD-ROMs and tape drives that plug into an ordinary ATA (IDE) connector. The principal advantage of ATAPI hardware is that it's cheap and works on your current adapter. For CD-ROMs, it has a somewhat lower CPU usage compared to proprietary adapters, but there's no performance gain otherwise. For tape drives, ATAPI has potential for superior performance and reliability compared to the popular floppy controller attached tape devices. ATAPI is also used to run other removable storage devices such as the LS-120 superdisk drives and internal Iomega Zip and Jaz drives.

Although ATAPI CD-ROMs use the hard disk interface, this does not mean they look like ordinary hard disks; to the contrary, from a software point of view, they are a completely different kind of animal. They actually most closely resemble a SCSI device. All modern IDE CD-ROMs support the ATAPI protocols and generally the terms are synonymous. In other words, an ATAPI CD-ROM is an IDE CD-ROM and vice versa.

Caution

ATAPI support is not found directly in the BIOS of many systems. Systems without ATAPI support in the BIOS cannot boot from an ATAPI CD-ROM and you still must load a driver to use ATAPI under DOS or Windows. Windows 95 and Windows NT have native ATAPI support, and newer systems with ATAPI-aware BIOS are now available, which will allow booting from an ATAPI CD-ROM. Some versions of the Windows 98 and Windows 2000 CD-ROMs are directly bootable on those systems, greatly easing installation.

I normally recommend keeping different types of IDE devices on separate channels. Some older chipsets cannot support setting different transfer rates for different devices, which means the channel must be set to the speed of the slowest device. Because most CD-ROM and tape drives run at lower IDE mode speeds, this would force your hard disk to run slower if they shared a single cable. Even if the chipset you have supports separate speed settings for devices on the same channel (cable), I still recommend keeping them separate because IDE does not normally support overlapping access such as SCSI. In other words, when one drive is running, the other cannot be accessed. By keeping the CD-ROM and hard disk on separate channels, you can more effectively overlap accessing between them.

ATA/ATAPI-4 (AT Attachment 4 with Packet Interface Extension)

First published in 1998, ATA-4 includes several important additions to the standard. It includes the Packet Command feature known as the AT Attachment Packet Interface (ATAPI), which allows devices such as CD-ROM drives, LS-120 SuperDisk floppy drives, tape drives, and other types of storage devices to be attached through a common interface. Until ATA-4 came out, ATAPI was a separately published standard. ATA-4 also adds the 33MB/sec transfer mode known as ultra-DMA or ultra-ATA. ATA-4 is backward compatible with ATA-3 and earlier definitions of the ATAPI. The major revisions added in ATA-4 are as follows:

- Ultra-DMA (UDMA) transfer modes up to 33MB/sec (called UDMA/33 or ultra-ATA/33)
- Integral ATAPI support
- Advanced power management support
- Defined an optional 80-conductor, 40-pin cable for improved noise resistance
- Compact Flash Adapter (CFA) support
- Introduced enhanced BIOS support for drives over 9.4 trillion GB in size (even though ATA is still limited to 137.4GB)

ATA-4 has been published as ANSI NCITS 317-1998, ATA-4 with Packet Interface Extension.

The newer PIIX4 and later South Bridge chips from the Intel motherboard chipsets support ATA-4, and many of the new drives support the high-speed UDMA (ultra-DMA) transfer mode.

◀◀ See "Chipsets," p. 235.

ATA-4 makes ATAPI support a full part of the ATA standard, and thus ATAPI is no longer an auxiliary interface to ATA but is merged completely within. This should promote ATA for use as an interface for many other types of devices. ATA-4 also adds support for new ultra-DMA modes (also called ultra-ATA) for even faster data transfer. The highest-performance mode, called UDMA/33, has 33MB/second bandwidth, twice that of the fastest programmed I/O mode or DMA mode previously supported. In addition to the higher transfer rate, because UDMA modes relieve the load on the processor, further performance gains are realized.

Also included is support for queuing commands, which is similar to that provided in SCSI-2. This allows for better multitasking as multiple programs make requests for IDE transfers.

▶▶ See "SCSI Versus IDE," p. 557.

ATA/ATAPI-5 (AT Attachment 5 with Packet Interface)

This version of the ATA standard is still in the draft stages, and builds on ATA-4. The major additions in the draft standard so far include the following:

- Ultra-DMA (UDMA) transfer modes up to 66MB/sec (called UDMA/66 or ultra-ATA/66)
- 80-conductor cable required for UDMA/66 operation

- Added automatic detection of 40 or 80-conductor cables
- UDMA modes faster than UDMA/33 are enabled only if an 80-conductor cable is detected

Each of the standards from the original ATA to ATA-5 are compatible; in other words, you can plug a so-called ATA-5 drive into an ATA-1 system or an ATA-1 drive into an ATA-5 system. In such cases, the drive or system will operate at the lowest common denominator with regard to performance and features.

Another standard recently approved by the T13 committee is an IEEE-1394 (iLink or FireWire) extension to the ATA interface protocol. This specifies a bridge protocol between the iLink/FireWire bus and ATA, allowing ATA drives to be adapted to this newer interface.

▶▶ See "IEEE-1394 (Also called i.Link or FireWire)," p. 896.

Copies of any of the published standards can be purchased from ANSI or Global Engineering Documents (see the Vendor's List on the CD).

ATA-5 includes ultra-ATA/66, which doubles the ultra-ATA burst transfer rate by reducing setup times and increasing the clock rate. The faster clock rate increases interference, which causes problems with the standard 40-pin cable used by ATA and ultra-ATA. To eliminate noise and interference, a new 40-pin, 80-conductor cable was developed. This cable was first announced in ATA-4, but is now mandatory in ATA-5 to support the ultra-ATA/66 mode. This cable adds 40 additional ground lines between each of the original 40 ground and signal lines, which help shield the signals from interference. Note that this cable works with older non-ultra-ATA devices as well, because it still has the same 40-pin connectors.

The 40-pin, 80-conductor cables will support the Cable Select feature and have color coded connectors. The blue (end) connector should be connected to the ATA host interface (usually the motherboard). The black (opposite end) connector is known as the master position, which is where the primary drive will plug in. The gray (middle) connector is for slave devices.

To use any of the ultra-DMA modes, both your ATA interface and drive must support the mode you want to use. The operating system must also be capable of handling Direct Memory Access (DMA); Windows 95 OSR2 or later, Windows 98, and Windows 2000 are ready out of the box, but older versions of Windows 95 and NT will require additional or updated drivers. To use the fastest ultra-ATA/66 mode, you will also need an ultra-ATA/66-capable, 80-conductor cable.

For reliability, ultra-DMA modes incorporate an error-detection mechanism known as cyclical redundancy checking (CRC). CRC is an algorithm that calculates a checksum used to detect errors in a stream of data. Both the host (controller) and the drive calculate a CRC value for each ultra-DMA transfer. After the data is sent, the drive calculates a CRC value and this is compared to the original host CRC value. If a difference is reported, the host might be required to select a slower transfer mode and retry the original request for data.

Obsolete IDE Versions

As mentioned earlier, other versions of the IDE interface were used in some early systems. While you may find some systems based on these interfaces if you are supporting legacy hardware, none of these has been used in any new system since the approval of the ATA-1 standard in 1994.

XT-Bus (8-bit) IDE

Many systems with XT ISA bus architecture used XT IDE hard drives. The IDE interface in these systems usually is built into the motherboard. The IBM PS/2 Models 25, 25-286, 30, and 30-286 systems used an 8-bit XT IDE interface. These 8-bit XT IDE drives are difficult to find. Few manufacturers other than IBM, Western Digital, and Seagate made them; none of these drives were available in capacities beyond 40MB.

Because the ATA IDE interface is a 16-bit design, it could not be used in 8-bit (XT type) systems, so some of the drive manufacturers standardized an XT-Bus (8-bit) IDE interface for XT class systems. These drives were never very popular, and were usually only available in capacities from 20MB–40MB.

MCA IDE

The IBM PS/2 Models 50 and higher come with Micro-Channel Architecture (MCA) bus slots. IBM used a type of MCA IDE drive in many of these systems. MCA IDE is a form of IDE interface, but it is designed for the MCA bus and is not compatible with the more industry-standard ATA IDE interface. Few companies other than IBM and Western Digital make replacement MCA IDE drives for these systems. I recommend replacing these drives with ATA IDE drives, using adapters from Arco Electronics or Sigma Data or switching to SCSI drives instead. The IBM MCA IDE drives are expensive for the limited capacity they offer.

SCSI Versus IDE

Small Computer System Interface (SCSI)

SCSI (pronounced “scuzzy”) stands for Small Computer System Interface, and is a general-purpose interface used for connecting many types of devices to a PC. This interface has its roots in SASI, the Shugart Associates System Interface. SCSI is the most popular interface for attaching high-speed disk drives to higher performance PCs such as workstations or network servers. SCSI is also very flexible; it is not only a disk interface, but also a systems-level interface allowing many different types of devices to be connected. SCSI is a bus that supports as many as 7 or 15 total devices. Multichannel adapters exist that can support up to 7 or 15 devices per channel.

The SCSI controller, called the *host adapter*, functions as the gateway between the SCSI bus and the PC system bus. Each device on the bus has a controller built in. The SCSI bus does not talk directly with devices such as hard disks; instead, it talks to the controller that is built into the drive.

A single SCSI bus can support as many as 8 or 16 physical units, usually called SCSI IDs. One of these units is the SCSI host adapter card in your PC; the other 7 or 15 can be other peripherals. You could have hard disks, tape drives, CD-ROM drives, a graphics scanner, or other devices (up to 7 or 15 additional devices) attached to a single SCSI host adapter. Most systems can support up to four host adapters, each with up to 15 devices, for a total of 60 devices! There are even dual channel adapters which could double that figure.

When you purchase an SCSI device such as an SCSI hard disk, you usually are purchasing the device, controller, and SCSI adapter in one circuit; as such the device is ready to connect directly to the SCSI bus. This type of drive usually is called an embedded SCSI device—the SCSI interface is built in. For example, most SCSI hard drives are technically the same as their IDE counterparts except for the addition of the SCSI bus adapter circuits (normally a single chip) added to the controller board. You do not need to know what type of controller is inside the SCSI drive, because your system cannot talk directly to the controller as though it were plugged into the system bus, like on a standard IDE drive. Instead, communications go through the SCSI host adapter installed in the system bus. You can access the drive only with the SCSI protocols.

Apple originally rallied around SCSI as being an inexpensive way out of the bind in which it put itself with the Macintosh. When the engineers at Apple realized the problem in making the Macintosh a closed system (with no expansion slots), they decided that the easiest way to gain expandability was to build an SCSI port into the system, which is how external peripherals can be added to the slotless Macs. Now that they are designing their newest systems with slots, SCSI has dropped from most of them as a built-in option. Because PC systems always have been expandable, the push toward SCSI has not been as urgent. With up to eight or more bus slots supporting different devices and controllers in PC compatible systems, it seemed as though SCSI was not needed as much.

SCSI has since become popular in the PC-based workstation market because of the performance and expandability that it offers. One block that stalled acceptance of SCSI in the PC marketplace was the lack of a real standard; the SCSI standard was originally designed by one company, and then taken over by a committee. Since then no single manufacturer has controlled it. Originally,

companies had their own interpretation of how SCSI should be implemented, particularly at the host-adapter level.

SCSI today is a standard, in much the same way that RS-232 (the serial communications port for modems, and so on) is a standard. The SCSI standard (like the RS-232 standard), however, defines only the hardware connections, not the driver specifications required to communicate with the devices. Software ties the SCSI subsystem into your PC, but unfortunately, most of the driver programs work only for a specific device and host adapter. With an SCSI driver for most common adapters and devices built into Windows 95 and 98, it is now much easier to get multiple SCSI devices to work using a single adapter.

Note

Some SCSI host adapters bundled with hardware, such as graphics scanners or a “bargain” SCSI CD-ROM drive, will not include all the features needed to support multiple SCSI devices or bootable SCSI hard drives. This has nothing to do with any limitations in the SCSI specification. The situation is simply that the manufacturer has included the most stripped-down version of an SCSI adapter available to save money. It has all the functionality needed to support the device it came with, but nothing else. Fortunately, with the right adapter and drivers, one card could do it all, most likely the one used for the hard disk, as it would be the most full-featured of the bunch.

SCSI can be troublesome at times because of the lack of a single host-adapter standard, a software interface standard, and standard ROM BIOS support for hard disk drives attached to the SCSI bus. Fortunately, some simple recommendations can keep you from living this compatibility nightmare!

In the beginning, SCSI lacked the capability to run hard disks off the SCSI bus. To boot from these drives and use a variety of operating systems was a problem that resulted from the lack of an interface standard. The standard BIOS software is designed to talk to ST-506/412, ESDI, or ATA (IDE) hard disks and devices. SCSI is so different from IDE that a new set of ROM BIOS routines are necessary to support the system so it can self-boot. Also, this BIOS support is unique to the SCSI host adapter you are using; so, unless the host adapter is built into your motherboard, this support won't be in your motherboard BIOS. Instead, SCSI host adapters are available with BIOS support right on the SCSI host adapter itself.

▶▶ See “The ST-506/412 Interface,” p. 505.

▶▶ See “The ESDI Interface,” p. 507.

Because of the lead taken by Apple in developing systems software (operating systems and ROM) support for SCSI, peripherals connect to Apple systems in fairly standard ways. Until recently, this kind of standard-setting leadership was lacking for SCSI in the PC world. This situation changed dramatically with Windows 95 and later versions, which include drivers for most standard SCSI adapters and peripherals on the market. These days Windows 98 and Windows 2000 include drivers and support for most SCSI adapters and devices built in.

Many PC manufacturers have standardized SCSI for high-end systems. In these systems, an SCSI host adapter card is placed in one of the slots, or the system has an SCSI host adapter built into

the motherboard. This arrangement is similar in appearance to the IDE interface, because a single cable runs from the motherboard to the SCSI drive. SCSI supports as many as 7 or 15 additional devices (some of which may not be hard disks), whereas IDE supports only four devices (two per controller). Additionally, SCSI supports more types of devices other than hard disks than IDE supports. IDE devices must be either a hard disk, IDE-type CD-ROM drive, or a tape drive, LS-120 SuperDisk drive, Zip drive, and so on. Systems with SCSI drives are easy to upgrade, because virtually any third-party SCSI drive will plug in and function.

ANSI SCSI Standards

The SCSI standard defines the physical and electrical parameters of a parallel I/O bus used to connect computers and peripheral devices in daisy-chain fashion. The standard supports devices such as disk drives, tape drives, and CD-ROM drives. The original SCSI standard (ANSI X3.131-1986) was approved in 1986, SCSI-2 was approved in January 1994, and the first portions of SCSI-3 were approved in 1995. Note that SCSI-3 has evolved into an enormous standard with numerous different sections, and is an evolving, growing standard still very much under development. Since it has been broken down into multiple standards, there really is no single SCSI-3 standard.

The SCSI interface is defined as a standard by ANSI (American National Standards Institute), specifically a committee currently known as T10. T10 is a technical committee of the National Committee on Information Technology Standards (NCITS, pronounced “insights”). NCITS is accredited by, and operates under rules that are approved by ANSI. These rules are designed to ensure that voluntary standards are developed by the consensus of industry groups. NCITS develops information processing system standards, while ANSI approves the process under which they are developed and publishes them.

NCITS was formerly known as the X3 Committee, and SCSI was originally published under the T9 Committee. NCITS was formerly known as the X3 Task Group. The original SCSI-1 standard was published by the X3T9 ANSI group in 1986, and is officially published by ANSI as X3.131-1986.

One problem with the original SCSI-1 document was that many of the commands and features were optional, and there was little or no guarantee that a particular peripheral would support the expected commands. This problem caused the industry as a whole to define a set of 18 basic SCSI commands called the Common Command Set (CCS) to become the minimum set of commands supported by all peripherals. CCS became the basis for what is now the SCSI-2 specification.

Along with formal support for CCS, SCSI-2 provided additional definitions for commands to access CD-ROM drives (and their sound capabilities), tape drives, removable drives, optical drives, and several other peripherals. In addition, an optional higher speed called Fast SCSI-2 and a 16-bit version called Wide SCSI-2 were defined. Another feature of SCSI-2 is *command queuing*, which enables a device to accept multiple commands and execute them in the order that the device deems to be most efficient. This feature is most beneficial when you are using a multitasking operating system that could be sending several requests on the SCSI bus at the same time.

The X3T9 group approved the SCSI-2 standard as X3.131-1990 in August 1990, but the document was recalled in December 1990 for changes before final ANSI publication. Final approval for the SCSI-2 document was finally made in January 1994, although it has changed little from the original 1990 release. The SCSI-2 document is now called ANSI X3.131-1994. The official document is available from Global Engineering Documents or the ANSI committee—both are listed in the Vendor List on the CD. You can also download working drafts of these documents from the NCR SCSI BBS, listed in the Vendor List on the CD under “NCR Microelectronics.”

Most companies indicate that their host adapters follow both the ANSI X3.131-1986 (SCSI-1) as well as the x3.131-1994 (SCSI-2) standards. Note that because virtually all parts of SCSI-1 are supported in SCSI-2, virtually any SCSI-1 device is also considered SCSI-2 by default. Many manufacturers advertise that their devices are SCSI-2, but this does not mean that they support any of the additional optional features that were incorporated in the SCSI-2 revision.

For example, an optional part of the SCSI-2 specification includes a fast synchronous mode that doubles the standard synchronous transfer rate from 5MB/sec to 10MB/sec. This Fast SCSI transfer mode can be combined with 16-bit Wide SCSI for transfer rates of up to 20MB/sec. There was an optional 32-bit version defined in SCSI-2, but component manufacturers have shunned this as too expensive. In essence, 32-bit SCSI was a stillborn specification, as it has been withdrawn from the SCSI-3 standards. Most SCSI implementations are 8-bit standard SCSI or 16-bit Fast/Wide SCSI. Even devices which support none of the Fast or Wide modes can still be considered SCSI-2.

The first SCSI-3 standards were approved in 1998. Even before it was fully completed, portions of this specification, although not final, have been sold in products. These include the Fast-20 and Fast-40 modes, which are also called Ultra-SCSI and Ultra2-SCSI respectively.

Table 8.1 shows the maximum transfer rates for the SCSI bus at various speeds and widths, and the cable type required for the specific transfer widths.

Note

The A cable is the standard 50-pin SCSI cable, whereas the P cable is a 68-pin cable designed for 16-bit transfers. High Voltage Differential (HVD) signaling was never popular and is now considered obsolete. LVD (Low Voltage Differential) signaling is used in the Ultra2 and Ultra3 modes to increase performance and cabling lengths. Pinouts for the cable connections are listed in this chapter in Tables 8.2 through 8.5.

SCSI is both forward and backward compatible, meaning one can run faster devices on buses with slower host adapters or vice versa. In each case, the entire bus will run at the lowest common denominator speed. In fact, as was stated earlier, virtually any SCSI-1 device can also legitimately be called SCSI-2 (or even SCSI-3). Of course you can't take advantage of the faster modes on an older, slower host adapter. By the same token, you can purchase an Ultra3 capable SCSI host adapter and still run older standard SCSI devices. You can even mix standard 8-bit and wide 16-bit devices on the same bus using cable adapters.

Table 8.1 SCSI Types, Data-Transfer Rates, and Cables

SCSI Technology	Marketing Term	Clock Speed	Transfer Width	Transfer Speed (MHz)
Fast-5	Standard	5	8-bit	5
Fast-5/Wide	Wide	5	16-bit	10
Fast-10	Fast	10	8-bit	10
Fast-10/Wide	Fast/Wide	10	16-bit	20
Fast-20	Ultra	20	8-bit	20
Fast-20/Wide	Ultra/Wide	20	16-bit	40
Fast-40	Ultra2	40	8-bit	40
Fast-40/Wide	Ultra2/Wide	40	16-bit	80
Fast-80	Ultra3	40 ³	8-bit	80
Fast-80/Wide	Ultra3/Wide	40 ³	16-bit	160

Cable Lengths are in meters, 25M = 80ft., 12M = 40ft., 6M = 20ft., 3M = 10ft., 1.5M = 5ft.

SE = Single-ended signaling

HVD = High Voltage Differential signaling, obsolete

LVD = Low Voltage Differential signaling

SCSI Signaling

"Normal" or standard SCSI uses a signaling technique called Single-ended (SE) signaling. SE signaling is a low cost technique, but it also has performance and noise problems.

Single-ended signaling is also called unbalanced signaling. Each signal is carried on a pair of wires, normally twisted to help reduce noise. With SE one of the pair is grounded, often to a common ground for all signals, and the other carries the actual voltage transitions. It is up to a receiver at the other end of the cable to detect the voltage transitions, which are really just changes in voltage.

Unfortunately, this type of unbalanced signaling is very prone to problems with noise, electromagnetic interference, and ground leakage; these problems get worse the longer the cable. This is the reason that Ultra SCSI was limited to such short maximum bus lengths, as little as 1 1/2 meters or 5 feet.

When SCSI was first developed, a signaling technique called High Voltage Differential (HVD) signaling was also introduced into the standard. Differential signaling, also known as balanced signaling, is still done with a pair of wires. In fact, the first in the pair carries the same type of signal that single-ended SCSI carries. The second in the pair, however, carries the logical inversion of that signal. The receiving device detects the difference between the pair (hence the name differential). By using the wires in a balanced pair, it no longer becomes necessary for the receiver to detect voltage magnitude, only the differential between voltage in two wires. This is

Max. No. of Devices	Cable Type	Max. Length (SE)	Max. Length (HVD)	Max. Length (LVD)
7	A (50-pin)	6MB	25M	-
15	P (68-pin)	6MB	25M	-
7	A (50-pin)	3MB	25M	-
15	P (68-pin)	3MB	25M	-
7	A (50-pin)	3/1.5M ¹	25M	-
7 ¹	P (68-pin)	3/1.5M ¹	25M	-
7	A (50-pin)	-	-	12M ²
15	P (68-pin)	-	-	12M ²
7	A (50-pin)	-	-	12M ²
15	P (68-pin)	-	-	12M ²

1 = Ultra SCSI cable total length is restricted to 1.5M if there are more than three devices on the bus (not including the host adapter). A maximum of seven devices are allowed.

2 = A 25MB cable may be used with Ultra2 and Ultra3 SCSI if there is only one device.

3 = Ultra3 SCSI transfers twice per clock cycle.

much easier for circuits to do reliably, which makes them less susceptible to noise and allows for greater cable length. Because of this, differential SCSI can be used with cable lengths of up to 25 meters, whereas single-ended SCSI is good only for 6 meters maximum, or as little as 1 1/2 meters in the faster modes.

Figure 8.1 shows the circuit differences between balanced (differential) and unbalanced (single-ended) transmission lines.

Figure 8.1 Balanced (differential) versus unbalanced (single-ended) signaling.

Unfortunately the original standard for HVD signaling called for high voltage differentials between the two wires. This means that small, low-power, single chip interfaces using HVD signaling could not be developed. Instead circuits using several chips were required. This works at both ends, meaning both the host adapter and device circuitry had to be larger and more expensive.

Another problem with HVD SCSI is that although the cables and connectors look (and are) exactly the same as for SE SCSI, both types of devices cannot be mixed on the same bus. If they are, the high voltage from the HVD device will burn out the receiver circuits on all SE devices attached to the bus. In other words, the result will be smoked hardware— not a pretty sight.

Because SE SCSI worked well enough for the speeds that were needed up until recently, HVD SCSI signaling never really caught on. It was only used in minicomputers and very rarely, if at all, in PCs. Because of this, the extra cost of this interface, and the fact that it is electrically incompatible with standard SE SCSI devices, HVD signaling was removed from the SCSI specification in the latest SCSI-3 documents. In other words, as far as you are concerned, it is obsolete.

Still, there was a need for a more reliable signaling technique that would allow for longer cable lengths. The answer came in the form of LVD, or Low Voltage Differential signaling. By designing a new version of the differential interface, it can be made to work with inexpensive and low power SCSI chips. Another advantage of LVD is that because it uses low-voltage, if you plug an LVD device into an SE SCSI bus, nothing will be damaged. In fact, as an optional part of the LVD standard, the LVD device can be designed as a multimode device, which means it will work on both SE or LVD buses. In the case of installing a multimode LVD device into an SE bus, the device will detect that it is installed in an SE bus and will default to SE mode.

This means that all multimode LVD/SE SCSI devices can be used on either LVD or SE SCSI buses. However, when on a bus with even one other SE device, all the LVD devices on the bus will run only in SE mode. Because SE mode only supports SCSI speeds of up to 20MHz (Fast-20 or UltraSCSI), and cable lengths of up to 1 1/2 or 3 meters, the devices will also work only at that speed or lower; you might also have problems with longer cables. Although you can purchase an Ultra3 SCSI multimode LVD/SE drive and install it on an SCSI bus along with single-ended devices, you will certainly be wasting the capabilities of the faster device.

Note that all Ultra2 and Ultra3 devices support LVD signaling, as that is the only way they can be run at the Ultra2 (40MHz) or Ultra3 (80MHz) speeds. It is possible for Ultra SCSI (20MHz) or slower devices to support LVD signaling, but in most cases LVD is synonymous with Ultra2 or Ultra3 only.

Table 8.1, shown earlier, lists all the SCSI speeds and maximum lengths for each speed using the supported signaling techniques for that speed.

Because the connectors are the same for SE, HVD, LVD, or multimode SE/LVD devices, and because putting an HVD device on any bus with SE or LVD devices will cause damage, it would be nice to be able to tell them apart. One way is to look for a special symbol on the unit; the industry has adopted different universal symbols for single-ended and differential SCSI. Figure 8.2 shows these symbols.

If you do not see such symbols, you can tell whether you have a high voltage differential device by using an ohmmeter to check the resistance between pins 21 and 22 on the device connector.

- On a single-ended or low voltage differential device, the pins should be tied together and also tied to the ground.

- On a high voltage differential device, the pins should be open or have significant resistance between them.

Figure 8.2 Universal symbol icons identifying SE, LVD, multimode LVD/SE, and HVD devices.

Although you will blow stuff up if you plug HVD devices into LVD or SE buses, this generally should not be a problem, because virtually all devices used in the PC environment are SE, LVD, or LVD/SE.

SCSI-1 and SCSI-2

The SCSI-2 specification essentially is an improved version of SCSI-1 with some parts of the specification tightened and several new features and options added. Normally, SCSI-1 and SCSI-2 devices are compatible, but SCSI-1 devices ignore the additional features in SCSI-2.

Some of the changes in SCSI-2 are very minor. For example, SCSI-1 allowed SCSI Bus parity to be optional, whereas parity must be implemented in SCSI-2. Parity is an extra bit that is sent as a verification bit to ensure that the data is not corrupted. Another requirement is that initiator devices, such as host adapters, provide terminator power to the interface; most devices already did so.

SCSI-2 also added several optional features:

- Fast SCSI (10MHz)
- Wide SCSI (16-bit transfers)
- Command queuing
- High-density cable connectors
- Improved Active (Alternative 2) termination

Command queuing is where commands can stack up at a device, which can then decide on the quickest way to execute them. This allows the initiator to disconnect and move on to something else while the device accomplishes the task(s). The high-density connectors allow for smaller more efficient connector and cable designs, and active termination uses a powered terminator that is much better at controlling noise than passive designs. These features are not required; they are optional under the SCSI-2 specification. If you connect a standard SCSI host adapter to a Fast SCSI drive, for example, the interface will work, but only at standard SCSI speeds.

SCSI-3

SCSI-3 is a term used to describe a set of standards currently being developed. Simply put, it is the next generation of documents a product conforms to. See the section “New Commands” later in this chapter. Unlike SCSI-1 and SCSI-2, SCSI-3 is not one document that covers everything in SCSI, but is instead a collection of documents that covers the physical connections, electrical interface, primary command set, and specific protocols. The specific protocols include hard disk interface commands, commands for tape drives, controller commands for RAID (Redundant Arrays of Inexpensive Drives), and other commands as well. There is also an overall SCSI Architectural Model (SAM). Each document within the standard is now a separate publication with its own revision level. Normally we don’t refer to SCSI-3 anymore as a specific interface, and instead refer to the specific variations in SCSI-3 such as Ultra-2 SCSI.

The main additions to SCSI-3 include

- Ultra2 (Fast-40) SCSI
- Ultra3 (Fast-80) SCSI
- Low Voltage Differential (LVD) signaling

By breaking up SCSI-3 into many smaller individual standards, it has allowed the standard as a whole to develop more quickly. The individual sub-standards can now be published rather than waiting for the entire standard to be approved.

Figure 8.3 shows the main parts of SCSI-3.

The primary changes being seen in the marketplace from SCSI-3 are the new Fast-40 (Ultra2) and Fast-80 (Ultra3) high-speed drives and adapters. These have taken the performance of SCSI up to 160MB/sec. Also new is the Low Voltage Differential (LVD) electrical standard, which allows for greater cable lengths.

A number of people are confused over the speed variations in SCSI. Part of the problem is that speeds are quoted as either clock speeds (MHz) or transfer speeds. With 8-bit transfers you get one byte per transfer, so if the clock is 40MHz (Fast-40 or Ultra2 SCSI), the transfer speed is 40 megabytes per second (MB/sec). On the other hand, if you are using a Wide (16-bit) interface, the transfer speed doubles to 80MB/sec even though the clock speed remains at 40MHz. Finally, there is confusion because SCSI speeds or modes are often discussed using either the official terms such as Fast-10, Fast-20, Fast-40, Fast-80 or the equivalent marketing terms such as Fast, Ultra, Ultra2, and Ultra3. Refer to Table 8.1 for a complete breakdown of SCSI official terms, marketing terms, and speeds.

SCSI-3 Architecture Roadmap

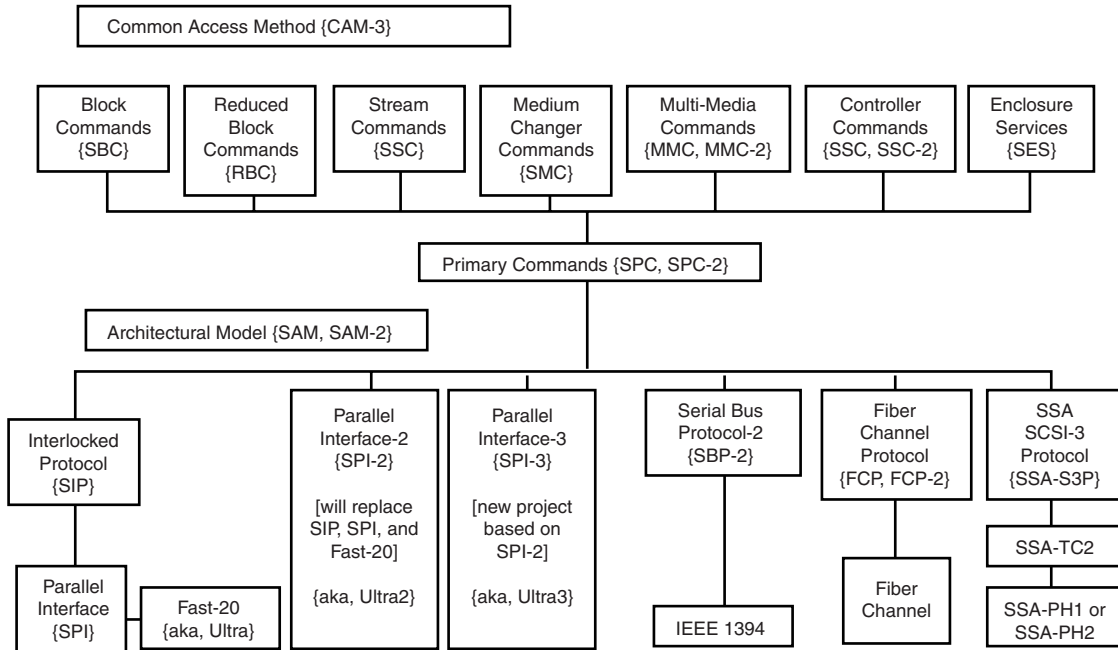

Figure 8.3 The SCSI-3 architecture.

Fast and Fast-Wide SCSI

Fast SCSI refers to high-speed synchronous transfer capability. Fast SCSI achieves a 10MB/sec transfer rate on the standard 8-bit SCSI cabling. When combined with a 16-bit Wide SCSI interface, this configuration results in data-transfer rates of 20MB/sec (called Fast/Wide).

Fast-20 (Ultra) SCSI

Fast-20 or Ultra SCSI refers to high-speed synchronous transfer capability that is twice as fast as Fast-SCSI. This has been introduced in the Draft (unfinished) SCSI-3 specification and has already been adopted by the marketplace, especially for high-speed hard disks. Ultra SCSI achieves a 20MB/sec transfer rate on the standard 8-bit SCSI cabling. When combined with a 16-bit Wide SCSI interface, this configuration results in data-transfer rates of 40MB/sec (called Ultra/Wide).

Fast-40 (Ultra2) SCSI

Fast-40 or Ultra2 SCSI is a part of SCSI-3 and is capable of achieving a 40MB/sec transfer rate over an 8-bit (narrow) SCSI bus, and 80MB/sec over a 16-bit (wide) SCSI bus.

Fast-80 SCSI

Fast-80 or Ultra3 SCSI is a part of SCSI-3 and is capable of achieving an 80MB/sec transfer rate over an 8-bit (narrow) SCSI bus, and 160MB/sec over a 16-bit (wide) SCSI bus.

Wide SCSI

Wide SCSI allows for parallel data transfer at a bus width of 16 bits. The wider connection requires a new cable design. The standard 50-conductor 8-bit cable is called the A cable. SCSI-2 originally defined a special 68-conductor B cable that was supposed to be used in conjunction with the A cable for 32-bit wide transfers. However, because of a lack of industry support and the added expenses involved, 32-bit SCSI was never actually implemented and was finally removed as a part of the SCSI-3 specifications. As such there are two different types of SCSI cables, called the A cable and the P cable. A cables are any SCSI cables with 50-pin connectors, whereas P cables are any SCSI cables with 68-pin connectors. You need a P cable if you are connecting a Wide SCSI device and want it to work in 16-bit mode.

Fiber Channel SCSI

Fiber Channel SCSI is a specification for a serial interface using a fiber channel physical and protocol characteristic, with SCSI command set. It can achieve 100MB/sec over either fiber or coaxial cable.

Termination

The single-ended SCSI bus depends on very tight termination tolerances to function reliably. Unfortunately, the original 132-ohm passive termination defined in the SCSI-1 document was not designed for use at the higher synchronous speeds now possible. These passive terminators can cause signal reflections to generate errors when transfer rates increase or when more devices are added to the bus. SCSI-2 defines an active (voltage-regulated) terminator that lowers termination impedance to 110 ohms and improves system integrity. Note that LVD SCSI requires special LVD terminators. If you use SE terminators on a bus with LVD devices, they either won't work or, if they are multimode devices, will default to SE operation.

Command Queuing

In SCSI-1, an initiator device, such as a host adapter, was limited to sending one command per device. In SCSI-2, the host adapter can send as many as 256 commands to a single device, which will store and process those commands internally before responding on the SCSI bus. The target device even can resequence the commands to allow for the most efficient execution or performance possible. This is especially useful in multitasking environments, such as OS/2 and Windows NT, which can take advantage of this feature.

New Commands

SCSI-2 took the Common Command Set that was being used throughout the industry and made it an official part of the standard. The CCS was designed mainly for disk drives and did not

include specific commands designed for other types of devices. In SCSI-2, many of the old commands are reworked, and several new commands have been added. New command sets have been added for CD-ROMs, optical drives, scanners, communications devices, and media changers (jukeboxes).

SCSI Cables and Connectors

The SCSI standards are very specific when it comes to cables and connectors. The most common connectors specified in this standard are the 50-position unshielded pin header connector for internal SCSI connections and the 50-position shielded Centronics latch-style connectors for external connections. The shielded Centronics style connector also is called Alternative 2 in the official specification. Passive or Active termination (Active is preferred) is specified for both single-ended and differential buses. The 50-conductor bus configuration is defined in the SCSI-2 standard as the A cable.

Older narrow (8-bit) SCSI adapters and external devices use a full size Centronics type connector that normally has wire latches on each side to secure the cable connector. Figure 8.4 shows what the low-density 50-pin SCSI connector looks like.

Figure 8.4 Low-density, 50-pin SCSI connector.

The SCSI-2 revision added a high-density, 50-position, D-shell connector option for the A-cable connectors. This connector now is called Alternative 1. Figure 8.5 shows the 50-pin high-density SCSI connector.

Figure 8.5 High-density, 50-pin SCSI connector.

The Alternative 2 Centronics latch-style connector remains unchanged from SCSI-1. A 68-conductor B cable specification was added to the SCSI-2 standard to provide for 16- and 32-bit data transfers; the connector, however, had to be used in parallel with an A cable. The industry did not widely accept the B-cable option, which has been dropped from the SCSI-3 standard.

To replace the ill-fated B cable, a new 68-conductor P cable was developed as part of the SCSI-3 specification. Shielded and unshielded high-density D-shell connectors are specified for both the A and P cable. The shielded high-density connectors use a squeeze-to-release latch rather than

the wire latch used on the Centronics-style connectors. Active termination for single-ended buses is specified, providing a high level of signal integrity. Figure 8.6 shows the 68-pin high-density SCSI connector.

Figure 8.6 High-density, 68-pin SCSI connector.

Drive arrays normally use special SCSI drives with what is called an 80-pin Alternative-4 connector, which is capable of Wide SCSI and also includes power signals. Drives with the 80-pin connector are normally *hot swappable*—they can be removed and installed with the power on—in drive arrays. The 80-pin Alt-4 connector is shown in Figure 8.7.

Figure 8.7 80-pin Alt-4 SCSI connector.

Apple and some other non-standard implementations from other vendors used a 25-pin cable and connector for SCSI devices.

They did this by eliminating most of the grounds from the cable, which unfortunately results in a noisy, error prone connection. I don't recommend using 25-pin cables and connectors; you should avoid them if possible. The connector used in these cases was a standard female DB-25 connector, which looks exactly like a PC parallel port (printer) connector. Unfortunately, it is possible to damage equipment by plugging printers into DB-25 SCSI connectors or by plugging SCSI devices into DB-25 printer connectors. So, if you use this type of SCSI connection, be sure it is marked well, as there is no way to tell DB-25 SCSI from DB-25 parallel printer connectors by looking at them. The DB-25 connector is shown Figure 8.8.

Figure 8.8 DB-25 SCSI connector.

Again I recommend you avoid making SCSI connections using this type of cable or connector.

SCSI Cable and Connector Pinouts

The following section details the pinouts of the various SCSI cables and connectors. There are two electrically different versions of SCSI: Single-ended and Differential. These two versions are electrically incompatible and must not be interconnected or damage will result. Fortunately, there are very few Differential SCSI applications available in the PC industry, so you will rarely (if ever) encounter one. Within each electrical type (Single-ended or Differential), there are basically two SCSI cable types:

- A Cable (Standard 8-bit SCSI)
- P Cable (16-bit Wide SCSI)

The 50-pin A-cable is used in most SCSI-1 and SCSI-2 installations, and is the most common cable you will encounter. SCSI-2 Wide (16-bit) applications use a P cable instead, which has 68-pins. You can intermix standard and Wide SCSI devices on a single SCSI bus by interconnecting A and P cables with special adapters. SCSI-3 applications that are 32-bit wide would have used an additional Q cable, but this was finally dropped from the SCSI-3 standard after it was never implemented in actual products.

SCSI cables are specially shielded with the most important high-speed signals carried in the center of the cable, and less important, slower ones in two additional layers around the perimeter. A typical SCSI cable is constructed as shown in Figure 8.9.

Figure 8.9 Cross section of a typical SCSI cable.

This specialized construction is what makes SCSI cables so expensive as well as thicker than other types of cables. Note this specialized construction is only necessary for external SCSI cables. Cables used to connect devices inside a shielded enclosure (such as inside a PC) can use much less expensive ribbon cables.

The A cables can have Pin Header (Internal) type connectors or External Shielded connectors, each with a different pinout. The P cables feature the same connector pinout on either Internal or External cable connections.

Single-Ended SCSI Cables and Connectors

The single-ended electrical interface is the most popular type for PC systems. Tables 8.2 and 8.3 show all the possible single-ended cable and connector pinouts. The A cable is available in both internal unshielded and external shielded configurations. A hyphen preceding a signal name indicates the signal is Active Low. The RESERVED lines have continuity from one end of the SCSI bus to the other. In an A cable bus, the RESERVED lines should be left open in SCSI devices (but may be connected to ground), and are connected to ground in the bus terminator assemblies. In the P and Q cables, the RESERVED lines are left open in SCSI devices and in the bus terminator assemblies.

IBM used the SCSI interface in virtually all PS/2 systems introduced after 1990. These systems use a Micro-Channel SCSI adapter or have the SCSI Host Adapter built into the motherboard. In either case, IBM's SCSI interface uses a special 60-pin mini-Centronics type external shielded connector that is unique in the industry. A special IBM cable is required to adapt this connector to the standard 50-pin Centronics style connector used on most external SCSI devices. The pinout of the IBM 60-pin mini-Centronics style External Shielded connector is shown in Table 8.4. Notice that although the pin arrangement is unique, the pin-number-to-signal designations correspond with the standard unshielded internal pin header type of SCSI connector. IBM has discontinued this design and all their systems because after the PS/2 series, all have used conventional SCSI connectors.

Differential SCSI Signals

High Voltage Differential (HVD) SCSI is not normally used in a PC environment, but is very popular with minicomputer installations due to the very long bus lengths that are allowed. Recently, this is changing with the introduction of Low Voltage Differential signaling for SCSI.

Differential signaling uses drivers on both the initiator and target ends of the bus and makes each signal work in a push/pull arrangement, rather than a signal/ground arrangement as with

standard single-ended SCSI. This allows for much greater cable lengths and eliminates some of the problems with termination.

Most all PC peripherals produced since the beginning of SCSI have been SE (single-ended) types. These are incompatible with HVD devices, although HVD devices can be used on a SE bus with appropriate (and expensive) adapters. The new LVD (Low-Voltage Differential) devices, on the other hand, can be used on a SE bus if they are multimode devices, in which case they will switch into SE mode. If all devices including the host adapter support LVD mode, all the devices will switch into that mode and much longer cable lengths and higher speeds can be used. The normal limit for an SE SCSI bus is 1.5 to 3 meters maximum (about 5–10 feet) and up to 20MHz. If run in LVD mode, the maximum bus length goes up to 12 meters (about 40 feet) and speeds can go up to 80MHz. HVD SCSI supports bus lengths of up to 25 meters (about 80 feet).

Note that almost all recently introduced SCSI hard disks are Ultra2 or Ultra3 devices, which means by default they are also LVD or multimode LVD/SE devices.

Expanders

SCSI expanders separate an SCSI bus into more than one physical segment, each of which can have the full SCSI cable length for that type of signaling. They provide a complete regeneration of the SCSI bus signals, allowing greater cable lengths and incompatible devices to essentially share the same bus. An expander can also be used to separate incompatible parts of an SCSI bus, for example to keep SE and HVD SCSI devices in separate domains.

Expanders are transparent to the software and firmware on the bus and they don't take up a device ID. They are normally capable of providing termination if located at the end of a bus segment, or they can have termination disabled if they are in the middle of a bus segment.

Due to their expense, expanders are not normally used except in extreme situations where no other alternative remains. In most cases it is better to stick within the recommended cable and bus length requirements, and keep incompatible devices such as High Voltage Differential (HVD) devices off of a standard SE (single-ended) or LVD (Low Voltage Differential) bus.

Termination

All buses need to be electrically terminated at each end; the SCSI bus is no exception. Improper termination still is one of the most common problems in SCSI installations. Three types of terminators typically are available for the SCSI bus:

- Passive
- Active (also called Alternative 2)
- Forced Perfect Termination (FPT): FPT-3, FPT-18, and FPT-27
- LVD (Low Voltage Differential) termination

Typical passive terminators (a network of resistors) allow signal fluctuations in relation to the terminator power signal on the bus. Usually, passive terminating resistors suffice over short

distances, such as two or three feet, but for longer distances, active termination is a real advantage. Active termination is required with Fast SCSI.

An active terminator actually has one or more voltage regulators to produce the termination voltage, rather than resistor voltage dividers. This arrangement helps ensure that the SCSI signals always are terminated to the correct voltage level. Active terminators will usually have some sort of LED indicating the termination activity. The SCSI-2 specification recommends active termination on both ends of the bus and requires active termination whenever Fast or Wide SCSI devices are used. Most high-performance host adapters have an “auto-termination” feature, so if it is the end of a chain, it will terminate itself.

A variation on active termination is available for single-ended buses: *Forced Perfect Termination*. Forced Perfect Termination is an even better form of active termination, in which diode clamps are added to eliminate signal overshoot and undershoot. The trick is that instead of clamping to +5 and Ground, these terminators clamp to the output of two regulated voltages. This arrangement enables the clamping diodes to eliminate signal overshoot and undershoot, especially at higher signaling speeds and over longer distances.

FPT terminators are available in several versions. FPT-3 and FPT-18 versions are available for 8-bit standard SCSI, while the FPT-27 is available for 16-bit (Wide) SCSI. The FPT-3 version forces perfect the three most highly active SCSI signals on the 8-bit SCSI bus, while the FPT-18 forces perfect all the SCSI signals on the 8-bit bus except grounds. FPT-27 also forces perfect all the 16-bit Wide SCSI signals except grounds.

Note that LVD buses that you want to run in LVD mode require LVD terminators. If you use SE terminators, the bus will default into SE mode.

►► See “SCSI Drive Configuration,” p. 549.

Note

Several companies make high-quality terminators for the SCSI bus, including Aeronics and the Data Mate division of Methode. Both of these companies make a variety of terminators. Aeronics is well-noted for some unique FPT versions that are especially suited to problem configurations that require longer cable runs or higher signal integrity. One of the best investments you can make in any SCSI installation is in high-quality cables and terminators. Contact information for both of these companies is listed in the Vendor List on the CD.

Special terminators are also required for LVD and HVD SCSI, so if you are using those interfaces, make sure your terminators are compatible.

SCSI Drive Configuration

SCSI drives are not too difficult to configure, but they are more complicated than IDE drives. The SCSI standard controls the way the drives must be set up. You need to set two or three items when you configure an SCSI drive:

- SCSI ID setting (0–7 or 0–15)
- Terminating resistors

The SCSI ID setting is very simple. Up to 7 SCSI devices can be used on a single narrow SCSI bus or up to 15 devices on a wide SCSI bus, and each device must have a unique SCSI ID address. There are 8 or 16 addresses respectively, and the host adapter takes one address, so the rest are free for up to 7 or 15 SCSI peripherals. Most SCSI host adapters are factory-set to ID 7 or 15, which is the highest priority ID. All other devices must have unique IDs that do not conflict with one another. Some host adapters boot only from a hard disk set to a specific ID. Older Adaptec host adapters required the boot hard disk to be ID 0; newer ones can boot from any ID.

Setting the ID usually involves changing jumpers on the drive. If the drive is installed in an external chassis, the chassis might have an ID selector switch that is accessible at the rear. This selector makes ID selection a simple matter of pressing a button or rotating a wheel until the desired ID number appears. If no external selector is present, you must open the external device chassis and set the ID via the jumpers on the drive.

Three jumpers are required to set the SCSI ID; the particular ID selected actually is derived from the binary representation of the jumpers themselves. For example, setting all three ID jumpers off results in a binary number of 000b, which translates to an ID of 0. A binary setting of 001b equals ID 1, 010b equals 2, 011b equals 3, and so on. (Notice that as I list these values, I append a lowercase b to indicate binary numbers.)

Unfortunately, the jumpers can appear either forward or backward on the drive, depending on how the manufacturer set them up. To keep things simple, I have recorded all the different ID jumper settings in the following tables. Table 8.6 shows the settings for drives that order the jumpers with the Most Significant Bit (MSB) to the left; Table 8.7 shows the settings for drives that have the jumpers ordered so that the MSB is to the right.

Table 8.6 SCSI ID Jumper Settings with the Most Significant Bit to the Left

SCSI	ID	Jumper	Settings
0	0	0	0
1	0	0	1
2	0	1	0
3	0	1	1
4	1	0	0
5	1	0	1
6	1	1	0
7	1	1	1

1 = Jumper On, 0 = Jumper Off

SCSI termination is very simple. Termination is required at both ends of the bus; there are no exceptions. If the host adapter is at one end of the bus, it must have termination enabled. If the host adapter is in the middle of the bus, and if both internal and external bus links are present, the host adapter must have its termination disabled, and the devices at each end of the bus must have terminators installed. Unfortunately, the majority of problems that I see with SCSI installations are the result of improper termination.

Figure 8.10 shows a representation of an SCSI bus with several devices attached. In this case the host adapter is at one end of the bus and a CD-ROM drive is at the other. For the bus to work properly, those devices must be terminated while the others do not.

When installing an external SCSI device, you will usually find the device in a storage enclosure with both input and output SCSI connectors, so that you can use the device in a daisy chain. If the enclosure is at the end of the SCSI bus, an external terminator module most likely will have to be plugged into the second (outgoing) SCSI port to provide proper termination at that end of the bus (see Figure 8.11).

External terminator modules are available in a variety of connector configurations, including pass-through designs, which are needed if only one port is available. Pass-through terminators also are commonly used in internal installations in which the device does not have built-in terminating resistors. Many hard drives use pass-through terminators for internal installations to save space on the logic-board assembly (see Figure 8.12).

The pass-through models are required when a device is at the end of the bus and only one SCSI connector is available.

Table 8.7 SCSI ID Jumper Settings with the Most Significant Bit to the Right

SCSI	ID	Jumper	Settings
0	0	0	0
1	1	0	0
2	0	1	0
3	1	1	0
4	0	0	1
5	1	0	1
6	0	1	1
7	1	1	1

1 = Jumper On, 0 = Jumper Off

Figure 8.10 SCSI bus daisy-chain connections; the first and last devices must be terminated.

Other configuration items on an SCSI drive can be set via jumpers. Following are several of the most common additional settings that you will find:

- Start on Command (delayed start)
- SCSI Parity
- Terminator Power
- Synchronous Negotiation

These configuration items are described in the following sections.

Figure 8.11 External SCSI device terminator.

Figure 8.12 Internal pin-header connector pass-through SCSI terminator.

Start On Command (Delayed Start)

If you have multiple drives installed in a system, it is wise to set them up so that all the drives do not start to spin immediately when the system is powered on. A hard disk drive can consume

three or four times more power during the first few seconds after power-on than during normal operation. The motor requires this additional power to get the platters spinning quickly. If several drives are drawing all this power at the same time, the power supply may be overloaded, which can cause the system to hang or have intermittent startup problems.

Nearly all SCSI drives provide a way to delay drive spinning so that this problem does not occur. When most SCSI host adapters initialize the SCSI bus, they send out a command called Start Unit to each of the ID addresses in succession. By setting a jumper on the hard disk, you can prevent the disk from spinning until it receives the Start Unit command from the host adapter. Because the host adapter sends this command to all the ID addresses in succession, from the highest priority address (ID 7) to the lowest (ID 0), the higher priority drives can be made to start first, with each lower priority drive spinning up sequentially. Because some host adapters do not send the Start Unit command, some drives might simply delay spinup for a fixed number of seconds rather than wait for a command that never will arrive.

If drives are installed in external chassis with separate power supplies, you need not implement the delayed-start function. This function is best applied to internal drives that must be run from the same power supply that runs the system. For internal installations, I recommend setting Start on Command (delayed start) even if you have only one SCSI drive; this setting will ease the load on the power supply by spinning the drive up after the rest of the system has full power. This method is especially good for portable systems and other systems in which the power supply is limited.

SCSI Parity

SCSI Parity is a limited form of error checking that helps ensure that all data transfers are reliable. Virtually all host adapters support SCSI parity checking, so this option should be enabled on every device. The only reason why it exists as an option is that some older host adapters do not work with SCSI parity, so the parity must be turned off.

Terminator Power

The terminators at each end of the SCSI bus require power from at least one device on the bus. In most cases, the host adapter supplies this terminator power; in some cases, however, it does not. For example, parallel port SCSI host adapters typically do not supply terminator power. It is not a problem if more than one device supplies terminator power because each source is diode-protected. For simplicity's sake, many will configure all devices to supply terminator power. If no device supplies terminator power, the bus will not be terminated correctly and will not function properly.

SCSI Synchronous Negotiation

The SCSI bus can run in two modes: asynchronous (the default) and synchronous. The bus actually switches modes during transfers through a protocol called *synchronous negotiation*. Before data is transferred across the SCSI bus, the sending device (called the *initiator*) and the receiving device (called the *target*) negotiate how the transfer will take place. If both devices support synchronous

transfers, they will discover this fact through the negotiation, and the transfer will take place at the faster synchronous rate.

Unfortunately, some older devices do not respond to a request for synchronous transfer and can actually be disabled when such a request is made. For this reason, both host adapters and devices that support synchronous negotiation often have a jumper that can be used to disable this negotiation so it can work with older devices. By default, all devices today should support synchronous negotiation, and this function should be enabled.

Plug-and-Play (PnP) SCSI

Plug-and-Play SCSI was originally released in April 1994. This specification allows SCSI device manufacturers to build PnP peripherals that will automatically configure when used with a PnP operating system. This will allow you to easily connect or reconfigure external peripherals, such as hard disk drives, backup tapes, and CD-ROMs.

To connect SCSI peripherals to the host PC, the specification requires a PnP SCSI host adapter such as PnP ISA or PCI. PnP add-in cards enable a PnP operating system to automatically configure software device drivers and system resources for the host bus interface.

The PnP SCSI specification version 1.0 includes these technical highlights:

- A single cable connector configuration
- Automatic termination of the SCSI bus
- SCAM (SCSI configured automatically) automatic ID assignment
- Full backward compatibility of PnP SCSI devices with the installed base of SCSI systems.

This should go a long way in making SCSI easier to use for the normal user.

Each SCSI peripheral that you add to your SCSI bus (other than hard disk drives) requires an external driver to make the device work. Hard disks are the exception; driver support for them normally is provided as part of the SCSI host adapter BIOS. These external drivers are specific not only to a particular device, but also to the host adapter.

Recently, two types of standard host adapter interface drivers have become popular, greatly reducing this problem. By having a standard host adapter driver to write to, peripheral makers can more quickly create new drivers that support their devices, and then talk to the universal host adapter driver. This arrangement eliminates dependence on one particular type of host adapter. These primary or universal drivers link the host adapter and the operating system.

The Advanced SCSI Programming Interface (ASPI) currently is the most popular universal driver, with most peripheral makers writing their drivers to talk to ASPI. The *A* in ASPI used to stand for Adaptec, the company that introduced it, but other SCSI device vendors have licensed the right to use ASPI with their products. DOS does not support ASPI directly, but it does when the ASPI driver is loaded. Windows 95, Windows 98, Windows NT, and OS/2 2.1 and later versions provide automatic ASPI support for several SCSI host adapters.

Future Domain and NCR have created another interface driver called the Common Access Method (CAM). CAM is an ANSI-approved protocol that enables a single driver to control several host adapters. In addition to ASPI, OS/2 2.1 and later versions currently offer support for CAM. Future Domain also provides a CAM-to-ASPI converter in the utilities that go with its host adapters.

SCSI Configuration Troubleshooting

When you are installing a chain of devices on a single SCSI bus, the installation can get complicated very quickly. If you have a problem during installation, check these items first:

- Make sure you are using the latest BIOS from your motherboard manufacturer. Some have had problems with their PCI bus slots not working properly.
- Check to be sure that all SCSI devices attached to the bus powered on.
- Make sure all SCSI cables and power cables properly connected. Try removing and reseating all the connectors to be sure.
- Check that the host adapter and each device on each SCSI bus channel have a unique SCSI ID setting.
- Make sure the SCSI bus is terminated properly. Remember there should only be two terminators on the bus, one at each end. All other termination should be removed or disabled.
- If your system BIOS setup has settings for controlling PCI bus configuration, make sure the PCI slot containing the SCSI adapter is configured for an available interrupt. If your system is Plug and Play, use the Windows Device Manager to check and possibly change the resource configuration.
- Make sure the host adapter installed in a PCI slot that supports bus mastering. Some older motherboards did not allow bus mastering to work in all PCI slots. Check your motherboard documentation and try moving the SCSI host adapter to a different PCI slot.
- If you have an SCSI hard disk installed and your system will not boot from the SCSI drive, there can be several causes for this problem. Note that if both SCSI and non-SCSI disk drives are installed in your computer; in almost all cases the non-SCSI drive will be the boot device. If you want to boot from an SCSI drive, check the boot sequence configuration in your BIOS. If your system allows, change the boot sequence to allow SCSI devices to boot first. If not, try removing the non-SCSI drives from your system.

If the system has only SCSI disk drives and it still won't boot, check the following items:

- Make sure your computer's BIOS Setup drive configuration is set to "No Drives Installed". The PC BIOS supports only ATA (IDE) drives; by setting this to no drives, the system will then try to boot from another device such as SCSI.
- Make sure the drive is partitioned and that a primary partition exists. Use FDISK from DOS or Windows to check.
- Make sure the boot partition of the boot hard disk is set to active. This can be checked or changed with the FDISK program.
- Finally as a last resort, you can try backing up all data on the SCSI hard disk, and then perform a low-level format with the Format utility built into or included with the host adapter.

Here are some tips for getting your setup to function quickly and efficiently:

- *Start by adding one device at a time.* Rather than plug numerous peripherals into a single SCSI card and then try to configure them at the same time, start by installing the host adapter and a single hard disk. Then you can continue installing devices one at a time, checking to make sure that everything works before moving on.
- *Keep good documentation.* When you add an SCSI peripheral, write down the SCSI ID address and any other switch and jumper settings, such as SCSI Parity, Terminator Power, and Delayed or Remote Start. For the host adapter, record the BIOS addresses, Interrupt, DMA channel, and I/O Port addresses used by the adapter, and any other jumper or configuration settings (such as termination) that might be important to know later.
- *Use proper termination.* Each end of the bus must be terminated, preferably with active or Forced Perfect (FPT) terminators. If you are using any Fast SCSI-2 device, you must use active terminators rather than the cheaper passive types. Even with standard (slow) SCSI devices, active termination is highly recommended. If you have only internal or external devices on the bus, the host adapter and last device on the chain should be terminated. If you have external and internal devices on the chain, you generally will terminate the first and last of these devices but not the SCSI host adapter (which is in the middle of the bus).
- *Use high-quality shielded SCSI cables.* Make sure that your cable connectors match your devices. Use high-quality shielded cables, and observe the SCSI bus-length limitations. Use cables designed for SCSI use, and if possible, stick to the same brand of cable throughout a single SCSI bus. Different brands of cables have different impedance values; this situation sometimes causes problems, especially in long or high-speed SCSI implementations.

Following these simple tips will help minimize problems and leave you with a trouble-free SCSI installation.

SCSI Versus IDE

When you compare the performance and capabilities of IDE and SCSI interfaced drives, you need to consider several factors. These two types of drives are the most popular drives used in PC systems today, and a single manufacturer may make identical drives in both interfaces. Deciding which drive type is best for your system is a difficult decision that depends on many factors.

In most cases, you will find that an IDE drive using the same head-disk assembly as an SCSI drive from the same manufacturer will perform about the same or outperform the equivalent SCSI drive at a given task or benchmark. This is mainly true when using a single drive with a single user operating system such as Windows 95/98. More powerful operating systems such as NT or Windows 2000 can more effectively use the command queuing and other features of SCSI, thus improving performance over IDE, especially when supporting multiple drives.

It is interesting to see that SCSI really evolved from IDE, or you could say that both evolved from the ST-506/412 and ESDI interfaces that were once used.

◀◀ See "The ESDI Interface," p. 507.

◀◀ See "The ST-506/412 Interface," p. 505.

SCSI Hard Disk Evolution and Construction

SCSI is not a disk interface, but a bus that supports SCSI bus interface adapters connected to disk and other device controllers. The first SCSI drives for PCs were standard ST-506/412 or ESDI drives with a separate SCSI bus interface adapter (sometimes called a bridge controller) that converted the ST-506/412 or ESDI interfaces to SCSI. This interface originally was in the form of a secondary logic board, and the entire assembly often was mounted in an external case.

The next step was to build the SCSI bus interface “converter” board directly into the drive’s own logic board. Today, we call these drives embedded SCSI drives, because the SCSI interface is built in.

At that point, there was no need to conform to the absolute specifications of ST-506/412 or ESDI on the internal disk interface, because the only other device that the interface ever would have to talk to was built in as well. Thus, the disk-interface and controller-chipset manufacturers began to develop more customized chipsets that were based on the ST-506/412 or ESDI chipsets already available, but offered more features and higher performance.

Today, if you look at a typical SCSI drive, you often can identify the chip or chipset that serves as the disk controller on the drive as being exactly the same kind that would be used on an ST-506/412 or ESDI controller, or as some evolutionary customized variation thereof.

Consider some examples. An ATA IDE drive must fully emulate the system-level disk-controller interface introduced with the Western Digital WD1003 controller series that IBM used in the AT. These drives must act as though they have a built-in ST-506/412 or ESDI controller; in fact, they actually do. Most of these built-in controllers have more capabilities than the original WD1003 series (usually in the form of additional commands), but they must at least respond to all the original commands that were used with the WD1003.

If you follow the hard drive market, you usually will see that drive manufacturers offer most of their newer drives in both ATA-IDE and SCSI versions. In other words, if a manufacturer makes a particular 20GB IDE drive, you invariably will see that the company also makes an SCSI model with the same capacity and specifications, which uses the same HDA (Head Disk Assembly) and even looks the same as the IDE version. If you study these virtually identical drives, the only major difference you will find is the additional chip on the logic board of the SCSI version, called an SCSI Bus Adapter Chip (SBIC).

Figures 8.13 and 8.14 show the logic-block diagrams of the WD-AP4200 (a 200MB ATA-IDE drive) and WD-SP4200 (a 200MB SCSI drive), respectively. These drives use the same HDA; they differ only in their logic boards, and even the logic boards are the same except for the addition of an SBIC on the SCSI drive’s logic board.

Notice that even the circuit designs of these two drives are almost identical. Both drives use an LSI (Large Scale Integrated circuit) chip called the WD42C22 Disk Controller and Buffer manager chip. In the ATA drive, this chip is connected through a DMA control chip directly to the AT bus. In the SCSI version, a WD33C93 SCSI bus interface controller chip is added to interface the disk-controller logic to the SCSI bus. In fact, the logic diagrams of these two drives differ only in the

fact that the SCSI version has a complete subset of the ATA drive, with the SCSI bus interface controller logic added. This essentially is a very condensed version of the separate drive and bridge controller setups that were used in the early days of PC SCSI.

◀◀ See "DMA Transfer Modes," p. 524.

Figure 8.13 Western Digital WD-AP4200 200MB ATA-IDE drive logic-board block diagram.

To top off this example, study the logic diagram in Figure 8.15 for the WD 1006V-MM1, which is an ST-506/412 controller.

You can clearly see that the main LSI chip onboard is the same WD42C22 disk controller chip used in the IDE and SCSI drives. Here is what the technical reference literature says about that chip:

The WD42C22 integrates a high performance, low cost Winchester controller's architecture. The WD42C22 integrates the central elements of a Winchester controller subsystem such as the host interface, buffer manager, disk formatter/controller, encoder/decoder, CRC/ECC (Cyclic Redundancy Check/Error Correction Code) generator/checker, and drive interface into a single 84-pin PQFP (Plastic Quad Flat Pack) device.

The virtually identical design of ATA-IDE and SCSI drives is not unique to Western Digital. Most drive manufacturers design their ATA-IDE and SCSI drives the same way, often using these very same WD chips, and disk controller and SCSI bus interface chips from other manufacturers. You now should be able to understand that most SCSI drives are “regular” ATA-IDE drives with SCSI bus logic added. This fact will come up again later in this chapter in the section “SCSI Versus IDE: Advantages and Limitations,” which discusses performance and other issues differentiating these interfaces.

For another example, I have several old IBM 320MB and 400MB embedded SCSI-2 hard disks; each of these drives has onboard a WD-10C00 Programmable Disk Controller in the form of a 68-pin PLCC (Plastic Leaded Chip Carrier) chip. The technical literature states:

This chip supports ST412, ESDI, SMD and Optical interfaces. It has 27Mbit/sec maximum transfer rate and an internal, fully programmable 48- or 32-bit ECC, 16-bit CRC-CCITT or external user defined ECC polynomial, fully programmable sector sizes, and 1.25 micron low power CMOS design.

In addition, these particular embedded SCSI drives include the 33C93 SCSI Bus Interface Controller chip, which also is used in the other SCSI drive that I mentioned. Again, there is a distinctly separate disk controller, and the SCSI interface is added on.

So again, most embedded SCSI drives have a built-in disk controller (usually based on previous ST-506/412 or ESDI designs) and additional logic to interface that controller to the SCSI bus (a built-in bridge controller, if you like). Now think about this from a performance standpoint. If virtually all SCSI drives really are ATA-IDE drives with an SCSI Bus Interface Controller chip added, what conclusions can you draw?

First, no drive can perform sustained data transfers faster than the data can actually be read from the disk platters. In other words, the HDA limits performance to whatever it is capable of achieving. Drives can transmit data in short bursts at very high speeds, because they often have built-in cache or read-ahead buffers that store data. Many of the newer high-performance SCSI and ATA-IDE drives have 1M or more of cache memory onboard. No matter how big or intelligent the cache is, however, sustained data transfer still will be limited by the HDA.

►► See “ATA IDE,” p. 512.

Figure 8.14 Western Digital WD-SP4200 200MB SCSI drive logic-board block diagram.

Data from the HDA must pass through the disk controller circuits, which, as you have seen, are virtually identical between similar SCSI and ATA-IDE drives. In the ATA-IDE drive, this data then is presented directly to the system bus. In the SCSI drive, however, the data must pass through an

SCSI bus interface adapter on the drive, travel through the SCSI bus, and then pass through another SCSI bus interface controller in the SCSI host adapter card in your system. The longer route that an SCSI transfer must take makes this type of transfer slower than the much more direct ATA-IDE transfer.

Figure 8.15 Western Digital WD1006V-MM1 ST-506/412 Disk Controller block diagram.

The conventional wisdom has been that SCSI always is much faster than IDE; unfortunately, this wisdom is usually wrong. This incorrect conclusion was derived by looking at the raw SCSI and ISA bus performance capabilities. A 16-bit Ultra3 SCSI drive can transfer data at claimed 160MB/sec, whereas an Ultra-ATA/66 IDE drive can transfer data at 66MB/sec. Based on these raw transfer rates, SCSI seems to be faster, but the raw transfer rate of the bus is not the limiting factor. Instead, the actual HDA (head disk assembly) and disk-controller circuitry place limits on performance. The key figure to check is what is reported as the internal transfer rate for the drive. For example, here are the specs on two similar drives (one IDE and one SCSI):

IDE Drive

Drive:	IBM Deskstar 18GXP ATA
Interface:	Ultra-ATA/66
Platters:	5
Data heads:	10
Capacity:	18.0GB
Recording density:	218.6KB/inch
Rotational speed:	7,200rpm
Internal cache buffer:	2MB
Interface transfer rate:	up to 66.7 MB/sec
Media transfer rate:	27.9MB/sec max.
Sustained data transfer rate:	10.7–17.9MB/sec max.
Average sustained transfer rate:	14.3MB/sec

SCSI Drive

Drive:	IBM Ultrastar 18ES SCSI
Interface:	Ultra2/Wide SCSI
Platters:	5
Data heads:	10
Capacity:	18.2GB
Recording density:	220KB/inch
Rotational speed:	7,200rpm
Internal cache buffer:	2MB
Interface transfer rate:	up to 80MB/sec
Media transfer rate:	30.5MB/sec maximum
Sustained data transfer rate:	12.7–20.2MB/sec
Average sustained transfer rate:	16.45MB/sec

Note that although the SCSI drive can claim a much higher external transfer rate of 80 MB/sec as compared to the ATA drive's 66.7 MB/sec, in actuality these drives are almost identical performers. The real specs to look at are in the last two lines of the tables, which detail how fast data can actually be read from the drive. In particular, the sustained transfer rates are the true transfer rates for reading data from these drives; as you can see they are very close indeed. The true transfer rate of a drive is mainly influenced by the rotational speed, track density, and things such as internal buffers or caches.

Then you have to factor in that the SCSI drive listed earlier would cost 50–100 percent more than the IDE counterpart. Not to mention the costs of springing for an Ultra2/Wide host adapter to plug the drive into. Decent SCSI adapters, especially Wide SCSI versions, can easily run \$300 or more. When you consider that the UltraATA interface is built into most modern motherboards for free, you can see that spending a ton of extra cash for SCSI can be foolish.

Now to present the counterpoint: Although these two drives are basically equivalent, the ATA version was one of the top ATA drives offered by IBM at the time, while the SCSI drive listed earlier was only a middle-of-the-pack performer. IBM and others make SCSI drives with rotational speeds of 10,000rpm, which have increased track density, and larger buffers. Of course, these drives cost even more. So the bottom line is that if you must have the absolute best performing drives, by all means get the top of the line SCSI drives and Ultra SCSI Wide adapters. However, if you want something that is literally 1/3 to 1/4 the cost and 3/4 or more the performance, stick with IDE.

Another point to remember is that unless you are using a PCI SCSI adapter, the SCSI data-transfer speeds will be limited by the host bus performance as well as the drive performance.

Modern operating systems are multitasking, and SCSI devices (with all their additional controller circuitry) function independently of one another, unlike IDE. Therefore, data can be read and written to any of the SCSI devices simultaneously. This allows for smoother multitasking and increased overall data throughput. The most advanced operating systems such as Windows NT even allow drive striping. A *striped drive set* is two or more drives that appear to the user as one drive. Data is split between the drives equally, again increasing overall throughput.

Performance

ATA IDE drives currently are used in most PC configurations on the market, because the cost of an IDE-drive implementation is low and the performance capabilities are high. In comparing any given IDE and SCSI drive for performance, you have to look at the capabilities of the HDAs that are involved.

To minimize the variables in this type of comparison, it is easiest to compare IDE and SCSI drives from the same manufacturer that also use the identical HDA. You will find that in most cases, a drive manufacturer makes a given drive available in both IDE and SCSI forms. For example, most hard drive companies make similar SCSI and IDE drives that use identical HDAs and that differ only in the logic board. The IDE version has a logic board with a built-in disk controller and a direct AT bus interface. The SCSI version has the same built-in disk controller and bus interface circuits, and also a SBIC chip. The SBIC chip is a SCSI adapter that places the drive on the SCSI bus. What you will find, in essence, is that virtually all SCSI drives actually are IDE drives with the SBIC chip added.

The HDAs in these sample drives are capable of transferring data at a sustained rate of up to 8MB/sec or more. Because the SCSI version always has the additional overhead of the SCSI bus to go through, in almost all cases the directly attached IDE version performs slightly faster.

SCSI Versus IDE: Advantages and Limitations

IDE drives have much less command overhead for a given sector transfer than do SCSI drives. In addition to the drive-to-controller command overhead that both IDE and SCSI must perform, an SCSI transfer involves negotiating for the SCSI bus; selecting the target drive; requesting data;

terminating the transfer over the bus; and finally converting the logical data addresses to the required cylinder, head, and sector addresses. This arrangement gives IDE an advantage in sequential transfers handled by a single-tasking operating system. In a multitasking system that can take advantage of the extra intelligence of the SCSI bus, SCSI can have the performance advantage.

SCSI drives offer significant architectural advantages over IDE and other drives. Because each SCSI drive has its own embedded disk controller that can function independently from the system CPU, the computer can issue simultaneous commands to every drive in the system. Each drive can store these commands in a queue and then perform the commands simultaneously with other drives in the system. The data could be fully buffered on the drive and transferred at high speed over the shared SCSI bus when a time slot was available.

Although IDE drives also have their own controllers, they do not operate simultaneously, and command queuing is not supported. In effect, the dual controllers in a dual-drive IDE installation work one at a time so as not to step on each other.

What are the limitations of IDE?

IDE does not support overlapped, multitasked I/O, which allows a device to take on multiple commands and work on them independently and in an order different from which they were received, releasing the bus for other devices to use. The ATA bus instead waits for each command to be completed before the next one can be sent.

As you can see, SCSI has some advantages over IDE, especially where expansion is concerned, and also with regard to support for multitasking operating systems. Unfortunately, it also costs more to implement.

One final advantage of SCSI is in the portability of external devices. It is easy to take an external SCSI CD-ROM, tape drive, scanner, or even a hard disk and quickly move it to another system. This allows moving peripherals more freely between systems and can be a bonus if you have several systems with which you might want to share a number of peripherals. It is easier to install a new external SCSI device on a system because you will not normally need to open it up.

Recommended SCSI Host Adapters

For SCSI host adapters, I normally recommend Adaptec. Their adapters work well and come with the necessary formatting and operating software. Windows 95, Windows 98, Windows NT, and OS/2 have built-in support for Adaptec SCSI adapters. This support is a consideration in many cases, because it frees you from having to deal with additional drivers.

Standard or Fast SCSI is adequately supported by the ISA bus, but if you are going to install a Fast-Wide SCSI bus, or especially an Ultra-Wide bus, you should consider some form of local bus SCSI adapter, normally PCI. This is because the ISA bus supports a maximum transfer speed of about 8MB/sec, while a Fast-Wide SCSI bus runs up to 20MB/sec, and an Ultra2-Wide SCSI bus

runs up to a blazing 80MB/sec! In most cases, a local bus SCSI adapter would be a PCI bus version, which is supported in most current PC systems.

◀◀ See "The ISA Bus," p. 283.

◀◀ See "The PCI Bus," p. 299.

One example of a popular SCSI adapter for the PCI bus is the Adaptec AHA-2940AU and 2940UW. The 2940AU is an Ultra-SCSI adapter and the 2940UW is Ultra-Wide. These adapters are most notable for their ease of installation and use. Virtually all functions on the card can be configured and set through software. No more digging through manuals or looking for interrupt, DMA, I/O port, and other jumper settings—everything is controlled by software and saved in a flash memory module on the card. Following are some of the features of this card:

- Complete configuration utility built into the adapter's ROM
- Software-configurable IRQ, ROM addresses, DMA, I/O port addresses, SCSI parity, SCSI ID, and other settings
- Software-selectable termination (no resistors to pull out!)
- Enhanced BIOS support for up to 15 drives
- No drivers required for more than two hard disks
- Drive spinup on a per-drive basis available
- Boots from any SCSI ID

Adaptec has full PnP support on all their SCSI adapters. These adapters will be automatically configured in any PC that supports the PnP specification, or they can be configured manually through supplied software in non-PnP systems. The PnP SCSI adapters are highly recommended because they can be configured without opening up the PC! All functions are set by software, and there are no jumpers or switches to attend to. Most peripheral manufacturers write drivers for Adaptec's cards first, so you will not have many compatibility or driver-support problems with any Adaptec card.

Magnetic Storage Principles

Data Encoding Schemes

Encoding Scheme Comparisons

PRML (Partial-Response, Maximum-Likelihood) Decoders

Capacity Measurements

Magnetic Storage

Permanent or semi-permanent computer data storage works by way of either optical or magnetic principles, or in some cases a combination of the two. In the case of magnetic storage, a stream of binary computer data bits (zeros and ones) are stored by magnetizing tiny pieces of metal embedded on the surface of a disk or tape in a pattern that represents the data. Later this magnetic pattern can be read and converted back into the exact same stream of bits you started with. This is the principle of magnetic storage, and the subject of this chapter.

Magnetic storage is often difficult for people to understand because magnetic fields cannot be seen by the human eye. This chapter explains the principles, concepts, and techniques behind modern computer magnetic storage, allowing you to understand what is happening behind the scenes. This information is designed for those who have an insatiable curiosity about how these things work; it is not absolutely necessary to use a PC or perform routine troubleshooting, maintenance, or upgrades. Since the data I store on my hard drives, tape drives, floppy drives, and other magnetic storage devices happens to be far more important to me than the devices themselves, knowing how my data is handled makes me feel much more comfortable with the system in general. Having an understanding of the underlying technology does help when it comes to dealing with problems that might arise.

This chapter covers magnetic storage principles and technology, and can be considered an introduction to several other chapters in the book, including the following:

- *Chapter 10. “Hard Disk Storage”*
- *Chapter 11. “Floppy Disk Storage”*
- *Chapter 12. “High-Capacity Removable Disk Storage”*
- *Chapter 14. “Physical Drive Installation and Configuration”*

Note

Optical Storage—CD-ROM technology—is covered in Chapter 14.

Consult these chapters for more specific information on different types of magnetic and optical storage, as well as drive installation and configuration.

History of Magnetic Storage

Before there was magnetic storage for computers, the primary storage medium was punched cards. What is amazing to me is that I missed contact with punched cards by about a year; the college I went to discontinued using them during my freshman year, before I was able to take any computer-related courses. I have to believe that this was more a reflection on their budget and lack of focus on current technology at the time (in 1979, there really weren't many punch-card readers being used in the field) than it is on my age!

The history of magnetic storage dates back to June 1949, when a group of IBM engineers and scientists began working on a new storage device. What they were working on was the first magnetic storage device for computers, and it revolutionized the industry. On May 21, 1952, IBM

announced the IBM 726 Tape Unit with the IBM 701 Defense Calculator, marking the transition from punched-card calculators to electronic computers.

Four years later, on September 13, 1956, a small team of IBM engineers in San Jose, California introduced the first computer disk storage system—the 305 RAMAC (Random Access Method of Accounting and Control).

The 305 RAMAC could store 5 million characters (that's right, only 5MB!) of data on 50 disks, each a whopping 24 inches in diameter. Unlike tape drives, RAMAC's recording heads could go directly to any location on a disk surface without reading all the information in between. This random accessibility had a profound effect on computer performance at the time, allowing data to be stored and retrieved significantly faster than if on tape.

From these beginnings, the magnetic storage industry has progressed such that today you can store 50GB or more on tiny 3.5-inch drives that fit into a single computer drive bay.

IBM's contributions to the history and development of magnetic storage are incredible; in fact, most have either come directly from IBM or as a result of IBM research. Not only did IBM invent computer magnetic tape storage as well as the hard disk drive, but they also invented the floppy drive. The same San Jose facility where the hard drive was created introduced the first floppy drive, then using 8-inch diameter floppy disks, in 1971. The team that developed the drive was led by Alan Shugart, a now legendary figure in computer storage.

Since then, IBM has pioneered advanced magnetic data encoding schemes such as MFM (Modified Frequency Modulation) and RLL (Run Length Limited); drive head designs such as Thin Film, Magneto-Resistive (MR), and Giant Magneto-Resistive (GMR) heads; and drive technologies such as PRML (Partial Response Maximum Likelihood), No-ID recording, and Self-Monitoring Analysis and Reporting Technology (S.M.A.R.T.). Today, IBM is arguably the leader in developing and implementing new drive technology, and is second in sales only to Seagate Technology in PC hard drives.

How Magnetic Fields Are Used to Store Data

All magnetic storage devices, such as floppy disk drives and hard disk drives, read and write data by using electromagnetism. This basic principle of physics states that as an electric current flows through a conductor (wire), a magnetic field is generated around the conductor (see Figure 9.1).

Figure 9.1 Current is induced in a wire when passed through a magnetic field.

Electromagnetism was discovered in 1819 by Hans Christian Oersted, a Danish physicist, when he found that a compass needle would deflect away from pointing north when brought near a wire conducting an electric current. When the current was shut off, the compass needle resumed its alignment with the Earth's magnetic field and again pointed north.

The magnetic field generated by a wire conductor can exert an influence on magnetic material in the field. When the direction of the flow of electric current or polarity is reversed, the magnetic field's polarity also is reversed. For example, an electric motor uses electromagnetism to exert pushing and pulling forces on magnets attached to a rotating shaft.

Another effect of electromagnetism is that if a conductor is passed through a moving magnetic field, an electrical current is generated. As the polarity of the magnetic field changes, so does the direction of the electric current's flow (see Figure 9.2).

Figure 9.2 Current is induced in a wire when passed through a magnetic field.

For example, a type of electrical generator used in automobiles, called an alternator, operates by rotating electromagnets on a shaft past coils of stationary wire conductors, which consequently generates large amounts of electrical current in those conductors. Since electromagnetism works two ways, a motor can become a generator and vice versa. When applied to magnetic storage devices, this two-way operation of electromagnetism makes it possible to record data on a disk and read that data back later. When recording, the head changes electrical impulses to magnetic fields, and when reading, the head changes magnetic fields back into electrical impulses.

The read/write heads in a magnetic storage device are U-shaped pieces of conductive material, with the ends of the U situated directly above (or next to) the surface of the actual data storage medium. The U-shaped head is wrapped with coils or windings of conductive wire, through which an electric current can flow (see Figure 9.3). When the drive logic passes a current through these coils, it generates a magnetic field in the drive head. Reversing the polarity of the electric

current causes the polarity of the generated field to change also. In essence, the heads are electromagnets whose voltage can be switched in polarity very quickly.

Figure 9.3 A magnetic read/write head.

The disk or tape that constitutes the actual storage medium consists of some form of substrate material (such as Mylar for floppy disks or aluminum or glass for hard disks) on which a layer of magnetizable material has been deposited. This material usually is a form of iron oxide with various other elements added. Each of the individual magnetic particles on the storage medium has its own magnetic field. When the medium is blank, the polarities of those magnetic fields are normally in a state of random disarray. Because the fields of the individual particles point in random directions, each tiny magnetic field is canceled out by one that points in the opposite direction; the cumulative effect of this is a surface with no observable field polarity. With many randomly oriented fields, the net effect is no observable unified field or polarity.

When a magnetic field is generated by the drive's read/write head, the field jumps the gap between the ends of the U-shape. Because a magnetic field passes through a conductor much more easily than through the air, the field bends outward from the gap in the head and actually uses the adjacent storage medium as the path of least resistance to the other side of the gap. As the field passes through the medium directly under the gap, it polarizes the magnetic particles that it passes through so they are aligned with the field. The field's polarity or direction—and, therefore, the polarity or direction of the field induced in the magnetic medium—are based on the direction of the flow of electric current through the coils. A change in the direction of the current flow produces a change in the direction of the magnetic field.

When the magnetic field passes through the medium, the particles in the area below the head gap are aligned in the same direction as the field emanating from the gap. When the individual magnetic domains of the particles are in alignment, they no longer cancel one another out, and an observable magnetic field exists in that region of the medium. This local field is generated by the many magnetic particles that now are operating as a team to produce a detectable cumulative field with a unified direction.

The term *flux* describes a magnetic field that has a specific direction or polarity. As the surface of the medium moves under the drive head, the head can generate what is called a magnetic flux of a given polarity over a specific region of the medium. When the flow of electric current through

the coils in the head is reversed, so is the magnetic field polarity or flux in the head gap. This flux reversal in the head causes the polarity of the magnetized particles on the disk medium to reverse.

The flux reversal or flux transition is a change in the polarity of the aligned magnetic particles on the surface of the storage medium. A drive head creates flux reversals on the medium to record data. For each data bit (or bits) that a drive writes, it creates a pattern of positive-to-negative and negative-to-positive flux reversals on the medium in specific areas known as bit or transition cells. A *bit cell* or *transition cell* is a specific area of the medium—controlled by the time and speed at which the medium travels—in which the drive head creates flux reversals. The particular pattern of flux reversals within the transition cells that are used to store a given data bit (or bits) is called the *encoding method*. The drive logic or controller takes the data to be stored and encodes it as a series of flux reversals over a period of time, according to the pattern dictated by the encoding method it uses.

Note

The two most popular encoding methods for magnetic media are Modified Frequency Modulation (MFM) and Run Length Limited (RLL). All floppy disk drives and some older hard disk drives use the MFM scheme. Today's hard disk drives use one of several variations on the RLL encoding method. These encoding methods are described in more detail later in this chapter in the section, "Data Encoding Schemes."

During the write process, voltage is applied to the head. As the polarity of this voltage changes, the polarity of the magnetic field being recorded also changes. The flux transitions are written precisely at the points where the recording polarity changes. Strange as it may seem, during the read process, a head does not generate exactly the same signal that was written. Instead, the head generates a voltage pulse or spike only when it crosses a flux transition. When the transition changes from positive to negative, the pulse that the head detects is a negative voltage. When the transition changes from negative to positive, the pulse is a positive voltage spike. This effect occurs because current is only generated in a conductor when passing through lines of magnetic force at an angle. Since the head moves parallel to the magnetic fields it created on the media, the only time the head will generate voltage when reading is when passing through a polarity or flux transition (flux reversal).

In essence, while reading from the medium, the head becomes a flux transition detector, emitting voltage pulses whenever it crosses a transition. Areas of no transition generate no pulse. Figure 9.4 shows the relationship between the read and write waveforms and the flux transitions recorded on a storage medium.

You can think of the write pattern as being a square waveform that is at a positive or negative voltage level. When the voltage is positive, a field is generated in the head, which polarizes the magnetic media in one direction. When the voltage changes to negative, the magnetic field induced in the media also changes direction. Where the waveform actually transitions from positive to negative voltage, or vice versa, the magnetic flux on the disk also changes polarity. During a read, the head senses these flux transitions and generates a pulsed positive or negative waveform, rather than the continuously positive or negative waveform used during the original

recording. In other words, the signal when reading is zero volts unless the head detects a magnetic flux transition, in which case it generates a positive or negative pulse accordingly. Pulses appear only when the head is passing over flux transitions on the medium. By knowing the clock timing the drive uses, the controller circuitry can determine whether a pulse (and therefore a flux transition) falls within a given transition cell time period.

Figure 9.4 Magnetic write and read processes.

The electrical pulse currents that are generated in the head while it is passing over the storage medium in read mode are very weak and can contain significant noise. Sensitive electronics in the drive and controller assembly amplify the signal above the noise level and decode the train of weak pulse currents back into binary data that is (theoretically) identical to the data originally recorded.

As you can see, hard disk drives and other storage devices read and write data by means of basic electromagnetic principles. A drive writes data by passing electrical currents through an electromagnet (the drive head), generating a magnetic field that is stored on the medium. The drive reads data by passing the head back over the surface of the medium. As the head encounters changes in the stored magnetic field, it generates a weak electrical current that indicates the presence or absence of flux transitions in the signal as it was originally written.

Magneto-Resistive (MR) Heads

A more recent development in magnetic recording, or more specifically, the read phase of magnetic recording, is the magneto-resistive head. All heads are detectors, that is they are designed to detect the flux transitions in the media and convert them back to an electrical signal that can be interpreted as data. One problem with magnetic recording is the ever increasing desire for more and more density, which is putting more information (flux transitions) in a smaller and smaller space. As the magnetic domains on the disk get smaller, the signal from the heads during reading operations becomes weaker; it becomes difficult to distinguish the true signal from the random noise or stray fields present. What is needed is a more efficient read head, which is a more efficient way to detect these transitions on the disk.

Long ago another effect of magnetism on a wire was discovered. When a wire was passed through a magnetic field, not only did the wire generate a small current, but the resistance of the wire also changed. Standard read heads use the head as a tiny generator, relying on the fact that the heads will generate a pulsed current when passed over magnetic flux transitions. A newer type of head design pioneered by IBM instead relies on the fact that the resistance in the head wires will also change.

Rather than use the head to generate tiny currents, which must then be filtered, amplified, and decoded, a magnetoresistive (MR) head uses the head as a resistor. A circuit passes a voltage through the head and watches for the voltage to change, which will occur when the resistance of the head changes as it passes through the flux reversals on the media. This mechanism for using the head results in a much stronger and clearer signal of what was on the media, and makes it possible for density to be increased.

Note that the MR scheme only works for reading—any time an MR read head is employed there is a separate standard inductive head used for writing the data. By incorporating separate read and write heads, they can both be optimized for their purpose and made to work much more efficiently than a single head that does both. In the last few years, virtually all modern hard disks have converted to using MR heads for reading. MR heads are capable of increasing density four times over the previous inductive-only heads. IBM introduced the first drive with MR heads in 1991, with their 1GB 3.5-inch models.

In the quest for even more density, a new type of MR head was introduced by IBM in 1997. Called giant magnetoresistive (GMR) heads, they are physically smaller than standard MR heads, but are so named for the GMR effect on which they are based.

The GMR effect was first discovered in 1988 in crystal samples exposed to very high-powered magnetic fields (1,000 times the fields used in HDDs). It was discovered that there were very large resistance changes occurring in materials comprised of alternating very thin layers of various metallic elements. The key structure in GMR materials is a spacer layer of a non-magnetic metal between two magnetic metals. Magnetic materials tend to align themselves in the same direction. So if the spacer layer is thin enough, changing the orientation of one of the magnetic layers can cause the next one to align itself in the same direction. What was determined was that the magnetic alignment of the magnetic layers periodically swung back and forth from being aligned in

the same magnetic direction to being aligned in opposite magnetic directions. The overall resistance is relatively low when the layers were in the same alignment and relatively high when in opposite alignment.

When a weak magnetic field, such as that from a bit on a hard disk, passes beneath a GMR head, the magnetic orientation of one of the magnetic layers rotates relative to that of the other, generating a significant change in electrical resistance due to the GMR effect. Since the physical nature of the resistance change was determined to be caused by the relative spin of the electrons in the different layers, GMR heads are often referred to as *spin-valve heads*.

In December 1997, IBM announced a 16.8GB 3.5-inch HDD product using GMR heads for the high-performance desktop market—the industry’s first GMR storage product. Currently GMR heads are found in many drives, and GMR will become the dominant head technology for the year 2000 and beyond.

Data Encoding Schemes

Magnetic storage is essentially an analog medium. The data that a PC stores on it, however, is digital information—that is, ones and zeros. When the drive sends digital information to a magnetic recording head, the head creates magnetic domains on the storage medium with specific polarities corresponding to the positive and negative voltages that the drive applies to the head. It is the flux reversals that form the boundaries between the areas of positive and negative polarity that the drive controller uses to encode the digital data onto the analog medium. During a read operation, each flux reversal that the drive detects generates a positive or negative pulse that the device uses to reconstruct the original binary data.

To optimize the placement of flux transitions during magnetic storage, the drive passes the raw digital input data through a device called an encoder/decoder (endec), which converts the raw binary information to a waveform that is designed to optimally place the flux transitions (pulses) on the media. During a read operation, the endec reverses the process and decodes the pulse train back into the original binary data. Over the years, several different schemes for encoding data in this manner have been developed; some are better or more efficient than others, which you see later in this section.

Other descriptions of the data encoding process may be much simpler, but they omit the facts that make some of the issues related to hard drive reliability so critical—namely, timing. Engineers and designers are constantly “pushing the envelope” to stuff more and more bits of information into the limited quantity of magnetic flux reversals per inch. What they came up with, essentially, is a design in which the bits of information are not only decoded from the presence or absence of flux reversals, but from the timing between them. The more accurately they can time the reversals, the more information that can be encoded (and subsequently decoded) from that timing information.

In any form of binary signaling, the use of timing is significant. When interpreting a read or write waveform, the timing of each voltage transition event is critical. Timing is what defines a particular bit or transition cell, that is the time window within which the drive is either writing

or reading a transition. If the timing is off, a given voltage transition may be recognized at the wrong time as being in a different cell, which would throw the conversion or encoding off, resulting in bits being missed, added, or misinterpreted. To ensure that the timing is precise, the transmitting and receiving devices must be in perfect synchronization. For example, if recording a zero is done by placing no transition on the disk for a given time period or cell, imagine recording 10 zero bits in a row—you would have a long period of 10 time periods or cells with no transitions.

Imagine now that the clock on the encoder was slightly off when reading from when the data was actually written. If it were fast, it might think that during this long stretch of 10 cells with no transitions only nine cells had elapsed. Or if it were slow, it might think that 11 cells had elapsed instead. In either case this would result in a read error, meaning the same bits would not be read as they were written. To prevent timing errors in drive encoding/decoding, perfect synchronization is necessary between the reading and writing processes. This synchronization is often accomplished by adding a separate timing signal, called a *clock signal*, to the transmission between the two devices. It is also possible for the clock and data signals to be combined and transmitted as a single signal. Most magnetic data encoding schemes use this type of combination of clock and data signals.

Adding a clock signal to the data ensures that the communicating devices can accurately interpret the individual bit cells. Each bit cell is bounded by two other cells containing the clock transitions. By sending clock information along with the data, the clocks remain in synch, even if the medium contains a long string of identical zero bits. Unfortunately, the transition cells that are used solely for timing take up space on the medium that could otherwise be used for data.

Because the number of flux transitions that a drive can record in a given space on a particular medium is limited by the physical nature or density of the medium and the head technology, drive engineers have developed various ways of encoding the data by using a minimum number of flux reversals (taking into consideration the fact that some flux reversals used solely for clocking are required). Signal encoding enables the system to make the maximum use of a given drive hardware technology.

Although various encoding schemes have been tried, only a few are popular today. Over the years, these three basic types have been the most popular:

- Frequency Modulation (FM)
- Modified Frequency Modulation (MFM)
- Run Length Limited (RLL)

The following sections examine these codes, discuss how they work, where they are used, and any advantages or disadvantages that apply to them. It will help to refer to Figure 9.5 (later in the chapter) as you read the descriptions of each of these encoding schemes, as this figure depicts how each of these schemes would store an “X” on the same media.

FM Encoding

One of the earliest techniques for encoding data for magnetic storage is called Frequency Modulation (FM) encoding. This encoding scheme, sometimes called Single Density encoding, was used in the earliest floppy disk drives installed in PC systems. The original Osborne portable computer, for example, used these Single-Density floppy disk drives, which stored about 80KB of data on a single disk. Although it was popular until the late 1970s, FM encoding is no longer used.

MFM Encoding

Modified Frequency Modulation (MFM) encoding was devised to reduce the number of flux reversals used in the original FM encoding scheme and, therefore, to pack more data onto the disk. MFM encoding minimizes the use of clock transitions, leaving more room for the data. MFM records clock transitions only when a stored zero bit is preceded by another zero bit; in all other cases, a clock transition is not required. Because MFM minimizes the use of clock transitions, it can double the clock frequency used by FM encoding, enabling it to store twice as many data bits in the same number of flux transitions.

Because it is twice as efficient as FM encoding, MFM encoding also has been called Double-Density recording. MFM is used in virtually all PC floppy disk drives today and was used in nearly all PC hard disks for a number of years. Today, virtually all hard disks use RLL (Run Length Limited) encoding, which provides even greater efficiency than MFM.

Because MFM encoding writes twice as many data bits by using the same number of flux reversals as FM, the clock speed of the data is doubled, so the drive actually sees the same number of total flux reversals as with FM. This means that a drive using MFM encoding reads and writes data at twice the speed of FM, even though the drive sees the flux reversals arriving at the same frequency as in FM.

The only caveat is that MFM encoding requires improved disk controller and drive circuitry, because the timing of the flux reversals must be more precise than in FM. These improvements were not difficult to achieve, and MFM encoding became the most popular encoding scheme for many years.

Table 9.1 shows the data bit to flux reversal translation in MFM encoding.

Table 9.1 MFM Data to Flux Transition Encoding

Data Bit Value	Flux Encoding
1	NT
0 preceded by 0	TN
0 preceded by 1	NN

T = Flux transition

N = No flux transition

RLL Encoding

Today's most popular encoding scheme for hard disks, called RLL (Run Length Limited), packs up to two times more information on a given disk than MFM does and three times as much information as FM. In RLL encoding, the drive combines groups of bits into a unit to generate specific patterns of flux reversals. By combining the clock and data signals in these patterns, the clock rate can be further increased while maintaining the same basic distance between the flux transitions on the storage medium.

IBM invented RLL encoding and first used the method in many of its mainframe disk drives. During the late 1980s, the PC hard disk industry began using RLL encoding schemes to increase the storage capabilities of PC hard disks. Today, virtually every drive on the market uses some form of RLL encoding.

Instead of encoding a single bit, RLL normally encodes a group of data bits at a time. The term *Run Length Limited* is derived from the two primary specifications of these codes, which are the minimum number (the run length) and maximum number (the run limit) of transition cells allowed between two actual flux transitions. Several variations of the scheme are achieved by changing the length and limit parameters, but only two have achieved any real popularity: RLL 2,7 and RLL 1,7.

You can even express FM and MFM encoding as a form of RLL. FM can be called RLL 0,1, because there are as few as zero and as many as one transition cells separating two flux transitions. MFM can be called RLL 1,3, because there are as few as one and as many as three transition cells separating two flux transitions. (Although these codes can be expressed as variations of RLL form, it is not common to do so.)

RLL 2,7 was initially the most popular RLL variation because it offers a high-density ratio with a transition detection window that is the same relative size as that in MFM. This method provides high storage density and fairly good reliability. In very high-capacity drives, however, RLL 2,7 did not prove to be reliable enough. Most of today's highest capacity drives use RLL 1,7 encoding, which offers a density ratio 1.27 times that of MFM and a larger transition detection window relative to MFM. Because of the larger relative timing window or cell size within which a transition can be detected, RLL 1,7 is a more forgiving and more reliable code, which is important when media and head technology are being pushed to their limits.

Another little-used RLL variation called RLL 3,9—sometimes called ARLL (Advanced RLL)—allows an even higher density ratio than RLL 2,7. Unfortunately, reliability suffered too greatly under the RLL 3,9 scheme; the method was used by only a few now-obsolete controllers and has all but disappeared.

It is difficult to understand how RLL codes work without looking at an example. Within a given RLL variation such as RLL 2,7 or 1,7, you can construct many different flux transition encoding tables to demonstrate how particular groups of bits are encoded into flux transitions.

In the conversion table shown in Table 9.2, specific groups of data bits 2, 3, and 4 bits long are translated into strings of flux transitions 4, 6, and 8 transition cells long, respectively. The

selected transitions for a particular bit sequence are designed to ensure that flux transitions do not occur too close together or too far apart.

It is necessary to limit how close two flux transitions can be because of the fixed resolution capabilities of the head and the storage medium. Limiting how far apart two flux transitions can be ensures that the clocks in the devices remain in sync.

Table 9.2 RLL 2,7 Data to Flux Transition Encoding

Data Bit Values	Flux Encoding
10	NTNN
11	TNNN
000	NNNTNN
010	TNNTNN
011	NNTNNN
0010	NNTNNTNN
0011	NNNNTNNN

T = Flux transition

N = No flux transition

In studying this table, you might think that encoding a byte value such as 00000001b would be impossible because no combinations of data bit groups fit this byte. Encoding this type of byte is not a problem, however, because the controller does not transmit individual bytes; instead, the controller sends whole sectors, making it possible to encode such a byte by including some of the bits in the following byte. The only real problem occurs in the last byte of a sector, if additional bits are needed to complete the final group sequence. In these cases, the endec in the controller adds excess bits to the end of the last byte. These excess bits are truncated during any reads so the controller always decodes the last byte correctly.

Encoding Scheme Comparisons

Figure 9.5 shows an example of the waveform written to store the ASCII character X on a hard disk drive by using three different encoding schemes.

In each of these encoding scheme examples, the top line shows the individual data bits (01011000b, for example) in their bit cells separated in time by the clock signal, which is shown as a period (.). Below that line is the actual write waveform, showing the positive and negative voltages as well as head voltage transitions that result in the recording of flux transitions. The bottom line shows the transition cells, with T representing a transition cell that contains a flux transition and N representing a transition cell that is empty.

The FM encoding example shown in Figure 9.5 is easy to explain. Each bit cell has two transition cells: one for the clock information and one for the data itself. All the clock transition cells contain flux transitions, and the data transition cells contain a flux transition only if the data is a 1 bit. No transition is present when the data is a 0 bit. Starting from the left, the first data bit is 0, which decodes as a flux transition pattern of TN. The next bit is a 1, which decodes as TT. The next bit is 0, which decodes as TN, and so on.

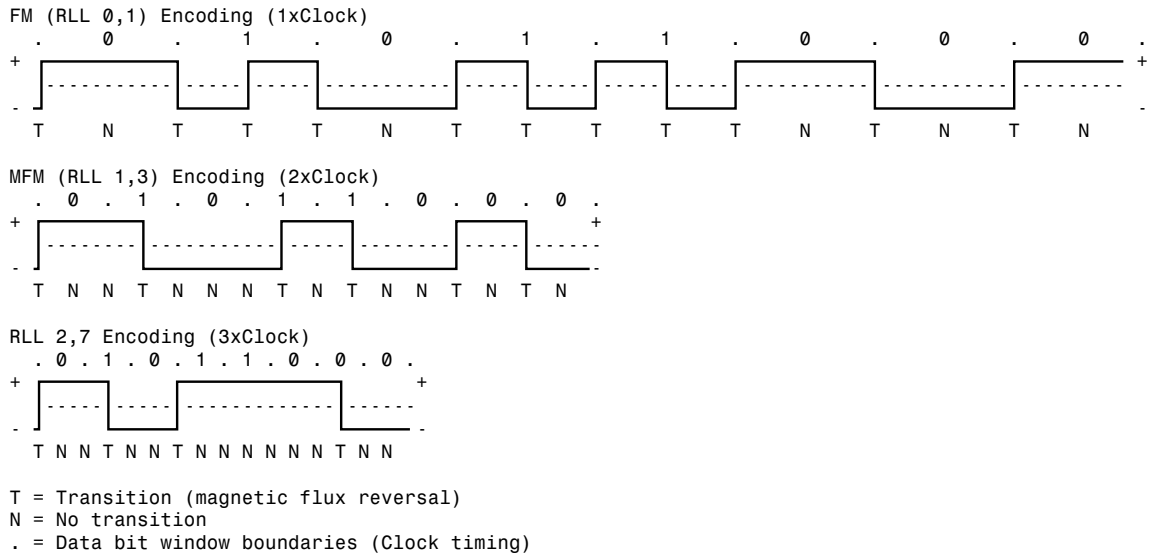

Figure 9.5 ASCII character “X” write waveforms using FM, MFM, and RLL 2,7 encoding.

The MFM encoding scheme also has clock and data transition cells for each data bit to be recorded. As you can see, however, the clock transition cells carry a flux transition only when a zero bit is stored after another zero bit. Starting from the left, the first bit is a 0, and the preceding bit is unknown (assume 0), so the flux transition pattern is TN for that bit. The next bit is a 1, which always decodes to a transition-cell pattern of NT. The next bit is 0, which was preceded by 1, so the pattern stored is NN. By using Table 9.1 (shown earlier), you can easily trace the MFM encoding pattern to the end of the byte. You can see that the minimum and maximum number of transition cells between any two flux transitions are one and three, respectively, which explains why MFM encoding can also be called RLL 1,3.

The RLL 2,7 pattern is more difficult to see because it encodes groups of bits rather than individual bits. Starting from the left, the first group that matches the groups listed in Table 9.2 are the first three bits, 010. These bits are translated into a flux transition pattern of TNNTNN. The next two bits, 11, are translated as a group to TNNN; and the final group, 000 bits, is translated to NNNTNN to complete the byte. As you can see in this example, no additional bits were needed to finish the last group.

Notice that the minimum and maximum number of empty transition cells between any two flux transitions in this example are 2 and 6, although a different example could show a maximum of seven empty transition cells. This is where the RLL 2,7 designation comes from. Because even fewer transitions are recorded than in MFM, the clock rate can be increased to three times that of FM or 1.5 times that of MFM, thus storing more data in the same space. Notice, however, that the resulting write waveform itself looks exactly like a typical FM or MFM waveform in terms of the number and separation of the flux transitions for a given physical portion of the disk. In other words, the physical minimum and maximum distances between any two flux transitions remain the same in all three of these encoding scheme examples.

PRML (Partial-Response, Maximum-Likelihood) Decoders

Another feature in high-end hard disk drives involves the disk read circuitry. Read channel circuits using Partial-Response, Maximum-Likelihood (PRML) technology enable disk drive manufacturers to increase the amount of data stored on a disk platter by up to 40 percent. PRML replaces the standard “detect one peak at a time” approach of traditional analog peak-detect, read/write channels with digital signal processing.

As the data density of hard drives increase, the drive must necessarily record the flux reversals closer together on the medium. This makes it more difficult to read the data on the disk, because the adjacent magnetic peaks can begin to interfere with each other. PRML modifies the way that the drive reads the data from the disk. The controller analyzes the analog data stream it receives from the heads by using digital signal sampling, processing, and detection algorithms (this is the partial response element) and predicts the sequence of bits that the data stream is most likely to represent (the maximum likelihood element). PRML technology can take an analog waveform, which might be filled with noise and stray signals, and produce an accurate reading from it.

This may not sound like a very precise method of reading data that must be bit-perfect to be usable, but the aggregate effect of the digital signal processing filters out the noise efficiently enough to enable the drive to place the flux change pulses much closer together on the platter, thus achieving greater densities. Most modern drives now use PRML technology in their endec circuits.

Capacity Measurements

The industry standard abbreviations for the units used to measure the capacity of magnetic (and other) drives are shown in Table 9.3.

Table 9.3 Standard Abbreviations and Meanings

Abbreviation	Description	Decimal Power	Decimal Value	Binary Power	Binary Value
Kbit or Kb	Kilobit	10^3	1,000	2^{10}	1,024
K or KB	Kilobyte	10^3	1,000	2^{10}	1,024
Mbit or Mb	Megabit	10^6	1,000,000	2^{20}	1,048,576
M or MB	Megabyte	10^6	1,000,000	2^{20}	1,048,576
Gbit or Gb	Gigabit	10^9	1,000,000,000	2^{30}	1,073,741,824
G or GB	Gigabyte	10^9	1,000,000,000	2^{30}	1,073,741,824
Tbit or Tb	Terabit	10^{12}	1,000,000,000,000	2^{40}	1,099,511,627,776
T or TB	Terabyte	10^{12}	1,000,000,000,000	2^{40}	1,099,511,627,776

As you can see, each of these units of measurement has two possible values: a decimal (or metric) and a binary. Unfortunately, there are no differences in the abbreviations used to indicate these two types of values. In other words, M can indicate both “millions of bytes” and megabytes. In

general, memory values are expressed by using the binary values, although disk capacities can go either way. This often leads to confusion in reporting disk capacities, because many manufacturers tend to use whichever value makes their products look better. Note also that when bits and bytes are used as part of some other measurement, the difference between bits and bytes is often distinguished by the use of a lower- or uppercase B. For example, megabits are typically abbreviated with a lowercase b, resulting in the abbreviation Mbps for megabits per second, while MBps indicates megabytes per second.

I hope that this examination of the basic principles of magnetic storage and the different encoding schemes that magnetic devices use has taken some of the mystery out of the way data is recorded on a drive.

Hard Disk Storage

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Definition of a Hard Disk

Areal Density

Hard Disk Drive Operation

Basic Hard Disk Drive Components

Hard Disk Features

Definition of a Hard Disk

To many users, the hard disk drive is the most important and yet the most mysterious part of a computer system. A *hard disk drive* is a sealed unit that a PC uses for nonvolatile data storage. *Nonvolatile*, or permanent storage, in this case, means that the storage device retains the data even when there is no power supplied to the computer. Because the hard disk drive is expected to retain its data until a user deliberately erases it, the PC uses it to store its most crucial programming and data. As a result, when the hard disk fails, the consequences are usually very serious. To maintain, service, and expand a PC system properly, you must understand how the hard disk unit functions.

Most computer users want to know how hard disk drives work and what to do when a problem occurs. However, few books about hard disks cover this subject in the detail necessary for the PC technician or sophisticated user. This section corrects that situation by thoroughly describing the hard disk drive from a physical, mechanical, and electrical point of view.

A hard disk drive contains rigid, disk-shaped platters, usually constructed of aluminum or glass. Unlike floppy disks, the platters cannot bend or flex—hence the term hard disk. In most hard disk drives, you cannot remove the platters, which is why they are sometimes called fixed disk drives. Removable hard disk drives are also available. Sometimes this term refers to a device in which the entire drive unit (that is, the disk and the drive) is removable, but it is more commonly used to refer to cartridge drives, such as the Iomega Zip and Jaz drives, that have removable storage media.

Figure 10.1 Hard disk heads and platters.

Note

Hard disk drives were at one time called *Winchester drives*. This term dates back to the 1960s, when IBM developed a high-speed hard disk drive that had 30MB of fixed-platter storage and 30MB of removable-platter storage. That drive soon received the nickname Winchester after the famous Winchester 30-30 rifle. For a time after that, all drives that used a high-speed spinning platter with a floating head were known colloquially as Winchester drives.

Hard Drive Advancements

In the 15 or more years that hard disks have commonly been used in PC systems, they have undergone tremendous changes. To give you an idea of how far hard drives have come in that time, I've outlined some of the more profound changes in PC hard disk storage:

- Maximum storage capacities have increased from the 10MB 5 1/4-inch full-height drives available in 1982 to 40GB or more for small 3 1/2-inch half-height drives, and 20GB or more for notebook system 2 1/2-inch drives. Hard drives smaller than 4GB are rare in today's personal computers.
- Data transfer rates from the media (sustained transfer rates) have increased from 85 to 102KBytes/sec for the original IBM XT in 1983 to 30MBytes/sec or more for some of the fastest drives today.
- Average seek times have decreased from more than 85ms (milliseconds) for the 10MB XT hard disk in 1983 to 5ms or less for some of the fastest drives today.
- In 1982, a 10MB drive cost more than \$1,500 (\$150 per megabyte). Today, the cost of hard drives has dropped to between 1 and 2 cents per megabyte or less!

Areal Density

Areal density is often used as a technology growth-rate indicator for the hard disk drive industry. *Areal density* is defined as the product of the linear bits per inch (BPI), measured along the length of the tracks around the disk, multiplied by the number of tracks per inch (TPI), measured radially on the disk. The results are expressed in units of megabits or gigabits per square inch (Mbit/sq.-inch or Gbit/sq.-inch) and are used as a measure of efficiency in drive recording technology. Current high-end 3 1/2-inch drives record at areal densities of nearly 6Gbit/sq.-inch. Prototype drives with densities as high as 20Gbit/sq.-inch now exist, providing capacities of more than 10GB on a single 2 1/2-inch platter.

During 1998, IBM introduced a drive they call the MicroDrive, which can store 340MB on a single platter the size of a quarter! This type of drive can be used in information appliances, digital cameras, and anywhere else that flash memory cards have been used.

Areal density (and, therefore, drive capacity) has been doubling approximately every two to three years, which will soon enable manufacturers to build 20 or 30GB drives that fit in the palm of your hand. Companies are also developing new media and head technologies to support these higher areal densities, such as ceramic or glass platters, MR (Magneto-Resistive) heads, pseudo-contact recording, and PRML (Partial-Response, Maximum-Likelihood) electronics. The primary challenge in achieving higher densities is manufacturing drive heads and disks to operate at closer tolerances. To fit more data on a platter of a given size, the tracks must be placed closer together, and the heads must be capable of achieving greater precision in their placement over the tracks. This means that as hard disk capacities increase, heads must ride ever closer to the disk surface.

Figure 10.2 Areal density, combining tracks per inch and bits per inch.

Hard Disk Drive Operation

The basic physical construction of a hard disk drive consists of spinning disks with heads that move over the disks and store data in tracks and sectors. The heads read and write data in concentric rings called tracks, which are divided up into segments called sectors, which normally store 512 bytes each (see Figure 10.3).

Hard disk drives usually have multiple disks, called platters, that are stacked on top of each other and spin in unison, each with two sides on which the drive stores data. Most drives have at least two or three platters, resulting in four or six sides, and some drives have up to 11 or more platters. The identically positioned tracks on each side of every platter together make up a cylinder (see Figure 10.4). A hard disk drive normally has one head per platter side, with all the heads mounted on a common carrier device or rack. The heads move radially in and out across the disk in unison; they cannot move independently, because they are mounted on the same rack.

Figure 10.3 The tracks and sectors on a disk.

Originally, most hard disks spun at 3,600 rpm—approximately 10 times faster than a floppy disk drive. Until recently, 3,600rpm was pretty much a constant among hard drives. Now, however, quite a few hard drives spin the disks even faster. The Toshiba 3.3G drive in one of my notebook computers spins at 4,852rpm; other drives spin as fast as 5,400, 5,600, 6,400, 7,200, and even 10,000rpm. High rotational speeds combined with a fast head-positioning mechanism and more sectors per track are what make one hard disk faster than another.

The heads in most hard disk drives do not (and should not!) touch the platters during normal operation. When the heads are powered off, however, in most drives they land on the platters as they stop spinning. While the drive is running, a very thin cushion of air keeps each head suspended a short distance above or below the platter. If the air cushion is disturbed by a particle of dust or a shock, the head may come into contact with the platter while it is spinning at full speed. When contact with the spinning platters is forceful enough to do damage, the event is called a *head crash*. The result of a head crash can be anything from a few lost bytes of data to a completely ruined drive. Most drives have special lubricants on the platters and hardened surfaces that can withstand the daily “takeoffs and landings” as well as more severe abuse.

Figure 10.4 Cylinders.

Because the platter assemblies are sealed and non-removable, the track densities on the disk can be very high. Hard drives today have up to 20,000 or more TPI (tracks per inch) recorded on the media. Head Disk Assemblies (HDAs), which contain the platters, are assembled and sealed in clean rooms under absolutely sanitary conditions. Because few companies repair HDAs, repair or replacement of the parts inside a sealed HDA can be expensive. Every hard disk ever made eventually fails. The only questions are when the failure will occur and whether your data is backed up.

Caution

It is strongly recommended that you do not even attempt to open a hard disk drive's HDA unless you have the equipment and the expertise to make repairs inside. Most manufacturers deliberately make the HDA difficult to open, to discourage the intrepid do-it-yourselfer. Opening the HDA almost certainly voids the drive's warranty.

Many PC users think that hard disks are fragile, and comparatively speaking, they are one of the more fragile components in your PC. In my weekly PC Hardware and Troubleshooting or Data Recovery seminars, however, I have run various hard disks for days with the lids off, and have even removed and installed the covers while the drives were operating. Those drives continue to store data perfectly to this day with the lids either on or off. Of course, I do not recommend that you try this test with your own drives, nor would I do this with my larger, more expensive drives.

The Ultimate Hard Disk Drive Analogy

There is an old analogy that compares the interaction of the heads and the medium in a typical hard disk drive as being similar in scale to a 747 flying a few feet off the ground at cruising speed (500+ mph). I have heard this analogy used over and over again for years, and I've even used it in my seminars many times without checking to see whether the analogy is technically accurate with respect to modern hard drives. It isn't.

One highly inaccurate aspect of the 747 analogy has always bothered me—the use of an airplane of any type to describe the head-and-platter interaction. This analogy implies that the heads fly very low over the surface of the disk, but technically, this is not true. The heads do not fly at all in the traditional aerodynamic sense; instead, they float on a cushion of air that's being dragged around by the platters.

A much better analogy would use a hovercraft instead of an airplane; the action of a hovercraft much more closely emulates the action of the heads in a hard disk drive. Like a hovercraft, the drive heads rely somewhat on the shape of the bottom of the head to capture and control the cushion of air that keeps them floating over the disk. By nature, the cushion of air on which the heads float forms only in very close proximity to the platter, and is often called an *air bearing* by the disk drive industry.

I thought it was time to come up with a new analogy that more correctly describes the dimensions and speeds at which a hard disk drive operates today. I looked up the specifications on a specific hard disk drive, and then magnified and rescaled all the dimensions involved to make the head floating height equal to 1 inch. For my example, I used a Seagate model ST-12550N Barracuda 2 drive, which is a 2GB (formatted capacity), 3 1/2-inch SCSI-2 drive, hardly state of the art by today's rapidly changing standards. Table 10.1 shows the specifications of the Barracuda drive, as listed in the technical documentation.

Table 10.1 Seagate ST-12550N Barracuda 2, 3 1/2-inch, SCSI-2 Drive Specifications

Specification	Value	Unit of Measure
Linear density	52,187	Bits per inch (BPI)
Bit spacing	19.16	Micro-inches (μ -in)
Track density	3,047	Tracks per inch (TPI)
Track spacing	328.19	Micro-inches (μ -in)
Total tracks	2,707	Tracks
Rotational speed	7,200	Revolutions per minute (rpm)
Average head linear speed	53.55	Miles per hour (mph)
Head slider length	0.08	Inches
Head slider height	0.02	Inches
Head floating height	5	Micro-inches (μ -in)
Average seek time	8	Milliseconds (ms)

By interpreting these specifications, you can see that in this drive, the head sliders are about 0.08-inch long and 0.02-inch high. The heads float on a cushion of air about 5μ -in (millionths of an inch) from the surface of the disk while traveling at an average speed of 53.55mph (figuring an average track diameter of 2 1/2-inches). These heads read and write individual bits spaced only 19.16μ -in apart on tracks separated by only 328.19μ -in. The heads can move from one track to another in only 8ms during an average seek operation.

To create my analogy, I magnified the scale to make the head floating height equal to 1 inch. Because 1 inch is 200,000 times greater than 5μ -in, I scaled up everything else by the same amount.

Magnified to such a scale, the heads of this typical hard disk in my analogy would be more than 1,300 feet long and 300 feet high (about the size of the Sears Tower lying sideways!) The heads would float on a cushion of air that travels at a speed of more than 10.7 million mph (2,975 miles per second), only 1 inch above the ground and reads data bits spaced a mere 3.83 inches apart on tracks separated by only 5.47 feet.

Because the average seek time of 8ms (.008 seconds) is defined as the time it takes to move the heads over one-third of the total tracks (about 902, in this case), each skyscraper-size head could move sideways to any track within a distance of 0.93 miles ($902 \text{ tracks} \times 5.47 \text{ feet}$). This results in an average sideways velocity of more than 420,000 mph (116 miles per second)!

The forward speed of this imaginary head is difficult to comprehend, so I'll elaborate. The diameter of the Earth at the equator is 7,926 miles, which means a circumference of about 24,900 miles. At 2,975 miles per second, this imaginary head would circle the Earth about once every 8 seconds!

This analogy should give you a new appreciation of the technological marvel that the modern hard disk drive actually represents. It makes the 747 analogy look rather archaic (not to mention totally inaccurate), doesn't it?

Tracks and Sectors

A *track* is a single ring of data on one side of a disk. A disk track is too large to manage data effectively as a single storage unit. Many disk tracks can store 100,000 or more bytes of data, which would be very inefficient for storing small files. For that reason, tracks are divided into several numbered divisions known as sectors. These sectors represent slices of the track.

Various types of disk drives split their disk tracks into different numbers of sectors, depending on the density of the tracks. For example, floppy disk formats use 8–36 sectors per track, although hard disks usually store data at a higher density and can use 17–100 or more sectors per track. The sectors created by the standard formatting procedure on a PC system have a capacity of 512 bytes, which has been one constant throughout the history of the PC.

The sectors on a track are numbered starting with 1, unlike the heads or cylinders that are numbered starting with 0. For example, a 1.44MB floppy disk contains 80 cylinders numbered from 0–79 and two heads numbered 0 and 1, while each track on each cylinder has 18 sectors numbered from 1–18.

When a disk is formatted, the formatting program creates ID areas before and after each sector's data that the disk controller uses for sector numbering and for identifying the start and end of each sector. These areas precede and follow each sector's data area, and consume some of the disk's total storage capacity. This accounts for the difference between a disk's unformatted and formatted capacities. Note that most modern hard drives are sold preformatted and only advertise the formatted capacity. The unformatted capacity is usually not mentioned anymore. Another interesting development is that IBM and others now make drives with ID-less recording, which means that the sectors are recorded without ID marks before and after each sector. This means that more of the disk can be used for actual data.

Each sector on a disk has a prefix portion, or header, that identifies the start of the sector and contains the sector number, as well as a suffix portion, or trailer, that contains a checksum (which helps ensure the integrity of the data contents). Each sector also contains 512 bytes of data. The low-level formatting process normally fills the data bytes with some specific value, such as F6h (hex), or some other test pattern used by the drive manufacturer. Some patterns are more difficult for the drive to encode/decode, so these patterns are normally used when the manufacturer is testing the drive during initial formatting. A special test pattern might cause errors to surface that a normal data pattern would not show. This way, the manufacturer can more accurately identify marginal sectors during testing.

Note

The type of disk formatting discussed here is a physical or low-level format, not the high-level format that you perform when you use the Windows 9x Explorer or the DOS FORMAT program on a disk. See the "Disk Formatting" section later in this chapter to learn about the difference between these two types of formatting.

The sector headers and trailers are independent of the operating system, the file system, and the files stored on the drive. In addition to the headers and trailers, there are gaps within the sectors, between the sectors on each track, and also between tracks, but none of these gaps contain usable

data space. The gaps are created during the low-level format process when the recording is turned off momentarily. They serve some of the same function as having gaps of no sound between the songs recorded on a cassette tape. The prefix, suffix, and gaps account for the lost space between the unformatted capacity of a disk and the formatted capacity. For example, a 4MB floppy disk (3 1/2-inch) has a capacity of 2.88MB when it is formatted, a 2MB floppy has a formatted capacity of 1.44MB, and an older 38MB hard disk has a capacity of only 32MB when it is formatted. Because the IDE and SCSI hard drives you purchase today are low-level formatted at the factory, the manufacturers now only advertise the formatted capacity. Even so, nearly all drives use some reserved space for managing the data that will be stored on the drive.

Thus, while I stated earlier that each disk sector is 512 bytes in size, this statement is technically not true. Each sector does allow for the storage of 512 bytes of data, but the data area is only a portion of the sector. Each sector on a disk typically occupies 571 bytes of the disk, of which only 512 bytes are available for the storage of user data. The actual number of bytes required for the sector header and trailer can vary from drive to drive, but this figure is typical. A few modern drives now use an ID-less recording scheme that virtually eliminates the storage overhead of the sector header information. In an ID-less recording, virtually all the space on the track is occupied by data.

You might find it helpful to think of each disk sector as being a page in a book. In a book, each page contains text, but the entire page is not filled with text; rather, each page has top, bottom, left, and right margins. Information such as chapter titles (track and cylinder numbers) and page numbers (sector numbers) is placed in the margins. The “margin” areas of a sector are created and written to during the low-level formatting process. Formatting also fills the data area of each sector with dummy values. After you perform a high-level format on the disk, the PC’s file system can write to the data area of each sector, but the sector header and trailer information cannot be altered during normal write operations unless the disk is low-level formatted again.

Table 10.2 shows the format for each track and sector on a typical hard disk drive with 17 sectors per track.

Table 10.2 Typical Disk Sector Format

Bytes	Name	Description
16	POST INDEX GAP	All 4Eh, at the track beginning after the Index mark.
The following sector data (shown between the lines in this table) is repeated as many times as there are sectors on the track, which is 17 for an MFM encoded track.		
13	ID VFO LOCK	All 00h; synchronizes the VFO for the sector ID.
1	SYNC BYTE	A 1h; notifies the controller that data follows.
1	ADDRESS MARK	FEh; defines that ID field data follows.
2	CYLINDER NUMBER	A value that defines the head actuator position.
1	HEAD NUMBER	A value that defines the particular head selected.
1	SECTOR NUMBER	A value that defines the sector.
2	CRC	Cyclic Redundancy Check to verify ID data.
3	WRITE TURN-ON GAP	00h written by format to isolate the ID from DATA.

Bytes	Name	Description
13	DATA SYNC VFO LOCK	All 00h; synchronizes the VFO for the DATA.
1	SYNC BYTE	A1h; notifies the controller that data follows.
1	ADDRESS MARK	F8h; defines that user DATA field follows.
512	DATA	The area for user DATA.
2	CRC	Cyclic Redundancy Check to verify DATA.
3	WRITE TURN-OFF GAP	00h; written by DATA update to isolate DATA.
15	INTER-RECORD GAP	All 00h; a buffer for spindle speed variation.
693	PRE-INDEX GAP	All 4Eh, at track end before Index mark.

571 = Total bytes per sector

512 = Data bytes per sector

10,416 = Total bytes per track

8,704 = Data bytes per track

Note: All XXh indicates that field will be filled with XXh bytes.

This table refers to a hard disk track with 17 sectors, although the same basic sector and track structure applies to newer drives as well, except they would have more sectors per each track. Although this capacity was typical during the mid-1980s, modern hard disks place as many as 150 or more sectors per track, and the specific formats of those sectors may differ slightly from this example. As you can see, the usable space for data on each track is about 16 percent less than its total unformatted capacity. This is true for most disks, although the percentage may vary slightly. The following paragraphs detail each piece of the sector data listed in Table 10.2.

The POST INDEX GAP provides a head-switching recovery period, so when switching from one track to another, the heads can read sequential sectors without waiting for an additional revolution of the disk. Because the disk is continuously spinning and the heads take some small amount of time to move radially from track to track, it is not possible to read consecutive sectors on two different tracks one right after the other. By the time the head moves to the new track, the beginning of the second sector has already spun past it. Leaving a gap between sectors provides the heads with time to move to another track.

In some drives, this gap does not provide sufficient time for the heads to move. When this is the case, it is possible for a drive to gain additional time by skewing the sectors on different tracks so the arrival of the first sector is delayed. In other words, the low-level formatting process offsets the sector numbering, so instead of the same numbered sectors on each track being adjacent to each other, Sector 9 on one track may be next to Sector 8 of the next track, which is next to Sector 7 on the next, and so forth. The optimum skew value is based on the rotational speed of the disk as compared to the lateral speed of the heads.

Note

At one time, the head skew was a parameter that you could set yourself while low-level formatting a drive. Today's IDE and SCSI drives are low-level formatted at the factory with the optimum skew values.

The Sector ID data consists of the Cylinder, Head, and Sector Number fields, as well as a CRC field used to verify the ID data. Most controllers use bit 7 of the Head Number field to mark a sector as bad during a low-level format or surface analysis. This convention is not absolute, however. Some controllers use other methods to mark a bad sector, but usually the mark involves one of the ID fields.

The WRITE TURN-ON GAP follows the ID field's CRC bytes and provides a pad to ensure a proper recording of the user data area that follows, as well as to allow full recovery of the ID CRC.

The user DATA field consists of all 512 bytes of data stored in the sector. This field is followed by a CRC field to verify the data. Although many controllers use two bytes of CRC here, the controller may implement a longer Error Correction Code (ECC) that requires more than two CRC bytes to store. The ECC data stored here provides the possibility of correcting errors in the DATA field as well as detecting them. The correction/detection capabilities depend on the ECC code the drive uses and its implementation by the controller. The WRITE TURN-OFF GAP is a pad that enables the ECC (CRC) bytes to be fully recovered.

The INTER-RECORD GAP provides a means to accommodate variances in drive spindle speeds. A track may have been formatted while the disk was running slightly slower than normal, and then written to while the disk was running slightly faster than normal. In such cases, this gap prevents the accidental overwriting of any information in the next sector. The actual size of this padding varies, depending on the speed of the DATA disk's rotation when the track was formatted and each time the DATA field is updated.

The PRE-INDEX GAP allows for speed tolerance over the entire track. This gap varies in size, depending on the variances in disk rotation speed and write-frequency tolerance at the time of formatting.

This sector prefix information is extremely important, because it contains the numbering information that defines the cylinder, head, and sector. So this information—except the DATA field, DATA CRC bytes, and WRITE TURN-OFF GAP—is written only during a low-level format.

Disk Formatting

There are two formatting procedures required before you can write user data to a disk:

- Physical, or low-level formatting
- Logical, or high-level formatting

When you format a blank floppy disk, the Windows 9x Explorer or the DOS `FORMAT` command performs both kinds of formats simultaneously. If the floppy was already formatted, DOS and Windows will default to doing only a high-level format.

A hard disk, however, requires two separate formatting operations. Moreover, a hard disk requires a third step, between the two formatting procedures, to write the partitioning information to the disk. Partitioning is required because a hard disk is designed to be used with more than one operating system. It is possible to use multiple operating systems on one hard drive by separating the physical formatting into a procedure that is always the same, regardless of the operating system

used and the high-level format (which is different for each operating system). Partitioning enables a single hard disk drive to run more than one type of operating system or it can enable a single operating system to use the disk as several volumes or logical drives. A volume or logical drive is any section of the disk to which the operating system assigns a drive letter or name.

Consequently, preparing a hard disk drive for data storage involves three steps:

1. Low-level formatting (LLF)
2. Partitioning
3. High-level formatting (HLF)

Low-Level Formatting

During a low-level format, the formatting program divides the disk's tracks into a specific number of sectors, creating the intersector and intertrack gaps and recording the sector header and trailer information. The program also fills each sector's data area with a dummy byte value or a pattern of test values. For floppy disks, the number of sectors recorded on each track depends on the type of disk and drive. For hard disks, the number of sectors per track depends on the drive and the controller interface.

Originally, PC hard disk drives used a separate controller that took the form of an expansion card or was integrated into the motherboard. Because the controller could be used with various disk drives and might even have been made by a different manufacturer, there had to be some uniformity in the communications between the controller and the drive. For this reason, the number of sectors written to a track tended to be relatively consistent.

The original ST-506/412 MFM controllers always placed 17 sectors per track on a disk, although ST-506/412 controllers with RLL encoding increased the number of sectors to 25 or 26 per track; ESDI drives had 32 or more sectors per track. The IDE and SCSI drives found in PCs today can have anywhere from 17 to 100 or more sectors per track because these drives have the controller integrated into the drive unit. This is what Integrated Drive Electronics (IDE) means. A SCSI drive is basically the same as an IDE, except for the addition of a SCSI bus adapter circuit. Because the drive and the controller are a matched set, there is no need for manufacturers to maintain any uniformity in the communications between them, and they can use any number of sectors per track they want.

Virtually all IDE and SCSI drives use a technique called *zoned recording*, which writes a variable number of sectors per track. Without zoned recording, the number of sectors, and therefore bits, on each track is a constant. This means the actual number of bits per inch will vary. There will be more bits per inch on the inner tracks and less on the outer. The data rate and rotational speed will remain constant, as is the number of bits per track. The following figure shows a drive recorded with the same number of sectors per track.

A standard recording wastes capacity on the outer tracks, because it is longer and yet holds the same amount of data (more loosely spaced) as the inner tracks. One way to increase the capacity of a hard drive during the low-level format is to create more sectors on the disks' outer cylinders

than on the inner ones. Because they have a larger circumference, the outer cylinders can hold more data. Drives without zoned bit recording store the same amount of data on every cylinder, even though the tracks of the outer cylinders might be twice as long as those of the inner cylinders. The result is wasted storage capacity, because the disk medium must be capable of storing data reliably at the same density as on the inner cylinders. When the number of sectors per track is fixed, as in older controllers, the drive capacity is limited by the density of the innermost (shortest) track.

Figure 10.5 Standard recording, where the same number of sectors comprise every track.

Drives that use zoned bit recording split the cylinders into groups called zones, with each successive zone having more sectors per track as you move outward from the center of the disk. All the cylinders in a particular zone have the same number of sectors per track. The number of zones varies with specific drives, but most drives have 10 or more zones.

Figure 10.6 shows a drive with a zoned recording.

Figure 10.6 Zoned recording, where the number of sectors per track increases within each zone moving out from the center.

Another effect of zoned bit recording is that transfer speeds vary depending on what zone the heads are in. A drive with a zoned recording still spins at a constant speed, however, because there are more sectors per track in the outer zones, data transfer will be fastest there. Consequently, data transfer will be slowest when reading or writing to the inner zones. That is why virtually all drives today report minimum and maximum sustained transfer rates, which depend on where on the drive you are reading from or writing to.

As an example, see Table 10.3, which shows the zones defined for one particular 3.8GB Quantum drive, the sectors per track for each zone, and its data transfer rate.

Table 10.3 Zoned Bit Recording Information for the Quantum Fireball 3.8GB Hard Disk Drive

Zone	Tracks in Zone	Sectors Per Track	Data Transfer Rate (Mbit/s)
0	454	232	92.9
1	454	229	91.7
2	454	225	90.4
3	454	225	89.2
4	454	214	85.8
5	454	205	82.1
6	454	195	77.9
7	454	185	74.4
8	454	180	71.4
9	454	170	68.2
10	454	162	65.2
11	454	153	61.7
12	454	142	57.4
13	454	135	53.7
14	454	122	49.5

This drive has a total of 6,810 tracks on each platter surface and, as you can see, the tracks are divided into 15 zones of 454 tracks each. It is not essential for all the zones to be the same size; this is simply how this drive is arranged. Zone 0 consists of the outermost 454 tracks, which are the longest and contain the most sectors: 232. Each track in this zone can therefore provide 118,784 bytes or 116KB of user data storage, although the 122 sector tracks in zone 14 can hold only 62,464 bytes, or 61KB.

Thus, with zoned bit recording, each platter surface in this disk drive contains 1,259,396 sectors, for a storage capacity of 644,810,752 bytes or 614.94MB. Without zoned bit recording, the number of sectors per track would be limited to 122 over the entire surface of each platter, for a total of 830,820 sectors, storing 425,379,840 bytes or 405.67MB. Zoned bit recording, therefore, provides a 51.59 percent increase in the storage capacity of this particular drive.

Notice also the difference in the data transfer rates for each of the zones. The tracks in the outermost zone (0) yield a transfer rate of 92.9Mbit/sec, which is 87.67 percent higher than the 49.5Mbit/sec of the innermost zone (14). This is one reason why you might notice huge discrepancies in the results produced by disk drive benchmark programs. A test that reads or writes files on the outer tracks of the disk naturally yields far better results than one conducted on the inner tracks. It may appear as though your drive is running slower, when the problem is actually that the test results you are comparing result from disk activity on different zones.

Drives with separate controllers used in the past could not handle zoned bit recording because there was no standard way to communicate information about the zones from the drive to the controller.

With SCSI and IDE disks, however, it became possible to format individual tracks with different numbers of sectors, because these drives have the disk controller built in. The built-in controllers on these drives are fully aware of the zoning algorithm, and can translate the physical Cylinder, Head, and Sector numbers to logical Cylinder, Head, and Sector numbers so the drive appears to have the same number of sectors on each track. Because the PC BIOS is designed to handle only a single number of sectors per track throughout the entire drive, a zoned drive must run by using a sector translation scheme.

The use of zoned bit recording enables drive manufacturers to increase the capacity of their hard drives by 20–50 percent compared with a fixed-sector-per-track arrangement. Virtually all IDE and SCSI drives today use zoned bit recording.

Partitioning

Creating a partition on a hard disk drive enables it to support separate file systems, each in its own partition.

Each file system can then use its own method to allocate file space in logical units called clusters or allocation units. Every hard disk drive must have at least one partition on it and can have up to four partitions, each of which can support the same or different type file systems. There are three common file systems used by PC operating systems today:

- **FAT (File Allocation Table).** The standard file system supported by DOS, Windows 9x, and Windows NT. FAT partitions support filenames of 11 characters maximum (8+3 character extension) under DOS, and 255 characters under Windows 9x or Windows NT 4.0 (or later). The standard FAT file system uses 12- or 16-bit numbers to identify clusters, resulting in a maximum volume size of 2GB.

Using FDISK, you can create only two physical FAT partitions on a hard disk drive—primary and extended—but you can subdivide the extended partition into as many as 25 logical volumes. Alternative partitioning programs such as Partition Magic can create up to four primary partitions or three primary and one extended.

- **FAT32 (File Allocation Table, 32-bit).** An optional file system supported by Windows 95 OSR2 (OEM Service Release 2), Windows 98, and Windows 2000.

FAT32 uses 32-bit numbers to identify clusters, resulting in a maximum single volume size of 2TB or 2,048GB in size.

- **NTFS (Windows NT File System).** The native file system for Windows NT that supports filenames up to 256 characters long and partitions up to (a theoretical) 16 exabytes. NTFS also provides extended attributes and file system security features that do not exist in the FAT file system. Of these three file systems, the FAT file system still is by far the most popular and is accessible by nearly every operating system, which makes it the most compatible as well. FAT32 and NTFS provide additional features but are not universally accessible by other operating systems.

Partitioning is accomplished by running the FDISK program that comes with your operating system. FDISK allows you to select the amount of space on the drive to use for a partition, from a single megabyte or one percent of the drive up to the entire capacity of the drive, or as much as the particular file system will allow. Normally it is recommended to have as few partitions as possible, and many people (myself included) try to stick with only one or two at the most. This was more difficult before FAT32, as the maximum partition size for a FAT16 partition was only 2GB. With FAT32, the maximum partition size can be up to 2,048GB.

Once a drive is partitioned, each partition must then be high-level formatted by the operating system that will use it.

High-Level Formatting

During the high-level format, the operating system (such as Windows 9x, Windows NT, or DOS) writes the structures necessary for managing files and data on the disk. FAT partitions have a Volume Boot Sector (VBS), two copies of a file allocation table (FAT), and a root directory on each formatted logical drive. These data structures enable the operating system to manage the space on the disk, keep track of files, and even manage defective areas so they do not cause problems.

High-level formatting is not really a physical formatting of the drive, but rather the creation of a table of contents for the disk. In low-level formatting, which is the real physical formatting process, tracks and sectors are written on the disk. As mentioned, the DOS `FORMAT` command can perform both low-level and high-level format operations on a floppy disk, but it performs only the high-level format for a hard disk. Low-level formats of IDE and SCSI hard disk drives are performed by the manufacturer, and should almost never be performed by the end user. The only time I low-level IDE or SCSI drives is when I am attempting to repair a format that has become damaged (parts of the disk become unreadable), or in some cases when I want to wipe away all data on the drive.

Basic Hard Disk Drive Components

Many types of hard disk drives are on the market, but nearly all share the same basic physical components. There might be some differences in the implementation of these components (and in the quality of the materials used to make them), but the operational characteristics of most drives are similar. The basic components of a typical hard disk drive (see Figure 10.5) are as follows:

- Disk platters
- Logic board
- Read/write heads
- Cables and connectors
- Head actuator mechanism
- Configuration items (such as jumpers or switches)
- Spindle motor

The platters, spindle motor, heads, and head actuator mechanisms are usually contained in a sealed chamber called the Head Disk Assembly (HDA). The HDA is usually treated as a single component; it is rarely opened. Other parts external to the drive's HDA, such as the logic boards, bezel, and other configuration or mounting hardware, can be disassembled from the drive.

Hard Disk Platters (Disks)

A typical hard disk drive has one or more platters, or disks. Hard disks for PC systems have been available in a number of form factors over the years. Normally, the physical size of a drive is expressed as the size of the platters. Following are the platter sizes that have been associated with PC hard disk drives:

- 5 1/4-inch (actually 130mm, or 5.12 inches)
- 3 1/2-inch (actually 95mm, or 3.74 inches)
- 2 1/2-inch
- 1.8-inch
- 1-inch (MicroDrive)

Larger hard disk drives that have 8-inch, 14-inch, or even larger platters are available, but these drives are not used with PC systems. Currently, the 3 1/2-inch drives are the most popular for desktop and some portable systems, while the 2 1/2-inch and smaller drives are very popular in portable or notebook systems. These little drives are quite amazing, with current capacities typically in the 4GB–14GB range, and capacities of 20GB or more expected by the year 2000. Figure 10.7 shows an expanded view of a typical, 3 1/2-inch hard drive.

Most hard disk drives have two or more platters, although some of the smaller drives have only one. The number of platters that a drive can have is limited by the drive's vertical physical size. The maximum number of platters I have seen in any 3 1/2-inch drive is 11.

Platters have traditionally been made from an aluminum alloy, which provides both strength and light weight. However, manufacturers' desire for higher and higher densities and smaller drives has led to the use of platters made of glass (or, more technically, a glass-ceramic composite). One such material, produced by the Dow Corning Corporation, is called MemCor. MemCor is composed of glass with ceramic implants, enabling it to resist cracking better than pure glass. Glass platters offer greater rigidity than metal (because metal can be bent and glass cannot) and can therefore be machined to one-half the thickness of conventional aluminum disks—sometimes less. Glass platters are also much more thermally stable than aluminum platters, which means that they do not expand or contract very much with changes in temperature. Several hard disk drives made by companies such as IBM, Seagate, Toshiba, Areal Technology, and Maxtor currently use glass or glass-ceramic platters. For most manufacturers, glass disks will probably replace the standard aluminum substrate over the next few years, especially in high-performance 2 1/2- and 3 1/2-inch drives.

Figure 10.7 Hard disk drive components.

Recording Media

No matter what substrate is used, the platters are covered with a thin layer of a magnetically retentive substance, called the medium, on which magnetic information is stored. Two popular types of magnetic media are used on hard disk platters:

- Oxide media
- Thin-film media

The oxide medium is made of various compounds, containing iron oxide as the active ingredient. The magnetic layer is created on the disk by coating the aluminum platter with a syrup containing iron-oxide particles. This syrup is spread across the disk by spinning the platters at high speed; centrifugal force causes the material to flow from the center of the platter to the outside, creating an even coating of the material on the platter. The surface is then cured and polished. Finally, a layer of material that protects and lubricates the surface is added and burnished smooth. The oxide coating is normally about 30 millionths of an inch thick. If you could peer into a drive with oxide-coated platters, you would see that the platters are brownish or amber.

As drive density increases, the magnetic media needs to be thinner and more perfectly formed. The capabilities of oxide coatings have been exceeded by most higher capacity drives. Because the oxide medium is very soft, disks that use it are subject to head-crash damage if the drive is jolted during operation. Most older drives, especially those sold as low-end models, use oxide media on the drive platters. Oxide media, which have been used since 1955, remained popular because of their relatively low cost and ease of application. Today, however, very few drives use oxide media.

The thin-film media is thinner, harder, and more perfectly formed than oxide media. Thin film was developed as a high-performance medium that enabled a new generation of drives to have lower head floating heights, which in turn made increases in drive density possible. Originally, thin-film media were used only in higher capacity or higher quality drive systems, but today, virtually all drives use thin-film media.

The thin-film media is aptly named. The coating is much thinner than can be achieved by the oxide-coating method. Thin-film media are also known as plated, or sputtered, media because of the various processes used to deposit the thin film on the platters.

Thin-film plated media are manufactured by depositing the magnetic medium on the disk with an electroplating mechanism, in much the same way that chrome plating is deposited on the bumper of a car. The aluminum platter is immersed in a series of chemical baths that coat the platter with several layers of metallic film. The magnetic medium layer itself is a cobalt alloy about 3 μ -in. thick.

Thin-film sputtered media are created by first coating the aluminum platters with a layer of nickel phosphorus, and then applying the cobalt-alloy magnetic material in a continuous vacuum-deposition process called *sputtering*. This process deposits magnetic layers as thin as 1 or 2 μ -in. on the disk, in a fashion similar to the way that silicon wafers are coated with metallic films in the semiconductor industry. The same sputtering technique is then used again to lay down an extremely hard, 1 μ -in. protective carbon coating. The need for a near-perfect vacuum makes sputtering the most expensive of the processes described here.

The surface of a sputtered platter contains magnetic layers as thin as 1 μ -in. Because this surface also is very smooth, the head can float closer to the disk surface than was possible previously. Floating heights as small as 3 μ -in. above the surface are possible. When the head is closer to the platter, the density of the magnetic flux transitions can be increased to provide greater storage capacity. Additionally, the increased intensity of the magnetic field during a closer-proximity read provides the higher signal amplitudes needed for good signal-to-noise performance.

Both the sputtering and plating processes result in a very thin, hard film of magnetic media on the platters. Because the thin-film media is so hard, it has a better chance of surviving contact with the heads at high speed. In fact, modern thin-film media are virtually uncrashable. If you could open a drive to peek at the platters, you would see that platters coated with the thin-film media look like the silver surfaces of mirrors.

The sputtering process results in the most perfect, thinnest, and hardest disk surface that can be produced commercially, which is why it has largely replaced plating as the preferred method of creating thin-film media. Having a thin-film media surface on a drive results in increased storage capacity in a smaller area with fewer head crashes and a drive that typically will provide many years of trouble-free use.

Read/Write Heads

A hard disk drive usually has one read/write head for each platter surface (meaning that each platter has two sets of read/write heads—one for the top side and one for the bottom side). These heads are connected, or ganged, on a single movement mechanism. The heads, therefore, move across the platters in unison.

Mechanically, read/write heads are simple. Each head is on an actuator arm that is spring-loaded to force the head into contact with a platter. Few people realize that each platter actually is “squeezed” by the heads above and below it. If you could open a drive safely and lift the top head with your finger, the head would snap back down into the platter when you released it. If you could pull down on one of the heads below a platter, the spring tension would cause it to snap back up into the platter when you released it.

Figure 10.8 shows a typical hard disk head-actuator assembly from a voice coil drive.

Figure 10.8 Read/write heads and rotary voice coil actuator assembly.

When the drive is at rest, the heads are forced into direct contact with the platters by spring tension, but when the drive is spinning at full speed, air pressure develops below the heads and lifts them off the surface of the platter. On a drive spinning at full speed, the distance between the heads and the platter can be anywhere from 3 to 20 μ -in. or more.

In the early 1960s, hard disk drive recording heads operated at floating heights as large as 200–300 μ -in.; today's drive heads are designed to float as low as 3–5 μ -in. above the surface of the disk. To support higher densities in future drives, the physical separation between the head and disk is expected to be as little as 0.5 μ -in. by the end of the century.

Caution

The small size of the gap between the platters and the heads is why you should never open the disk drive's HDA except in a clean-room environment. Any particle of dust or dirt that gets into this mechanism could cause the heads to read improperly, or possibly even to strike the platters while the drive is running at full speed. The latter event could scratch the platter or the head.

To ensure the cleanliness of the interior of the drive, the HDA is assembled in a class-100 or better clean room. This specification means that a cubic foot of air cannot contain more than 100 particles that measure up to 0.5 microns (19.7 μ -in.). A single person breathing while standing motionless spews out 500 such particles in a single minute! These rooms contain special air-filtration systems that continuously evacuate and refresh the air. A drive's HDA should not be opened unless it is inside such a room.

Although maintaining a clean-room environment may seem to be expensive, many companies manufacture tabletop or bench-size clean rooms that sell for only a few thousand dollars. Some of these devices operate like a glove box; the operator first inserts the drive and any tools required, and then closes the box and turns on the filtration system. Inside the box, a clean-room environment is maintained, and a technician can use the built-in gloves to work on the drive.

In other clean-room variations, the operator stands at a bench where a forced-air curtain maintains a clean environment on the bench top. The technician can walk in and out of the clean-room field by walking through the air curtain. This air curtain is much like the curtain of air used in some stores and warehouses to prevent heat from escaping in the winter while leaving a passage wide open.

Because the clean environment is expensive to produce, few companies, except those that manufacture the drives, are properly equipped to service hard disk drives.

Read/Write Head Designs

As disk drive technology has evolved, so has the design of the read/write head. The earliest heads were simple iron cores with coil windings (electromagnets). By today's standards, the original head designs were enormous in physical size and operated at very low recording densities. Over the years, head designs have evolved from the first simple Ferrite Core designs into the several types and technologies available today. This section discusses the different types of heads found in PC hard disk drives, including the applications and relative strengths and weaknesses of each.

Four types of heads have been used in hard disk drives over the years:

- Ferrite
- Metal-In-Gap (MIG)
- Thin Film (TF)
- Magneto-Resistive (MR)

Ferrite

Ferrite heads, the traditional type of magnetic-head design, evolved from the original IBM 30-30 Winchester drive. These heads have an iron-oxide core wrapped with electromagnetic coils. The drive produces a magnetic field by energizing the coils or by passing a magnetic field near them. This gives the heads full read/write capability. Ferrite heads are larger and heavier than thin-film heads and therefore require a larger floating height to prevent contact with the disk while it is spinning.

Manufacturers have made many refinements to the original (monolithic) ferrite head design. One type of ferrite head called a composite ferrite head has a smaller ferrite core bonded with glass in a ceramic housing. This design permits a smaller head gap, which allows higher track densities. These heads are less susceptible to stray magnetic fields than the older monolithic design heads.

During the 1980s, composite ferrite heads were popular in many low-end drives, such as the Seagate ST-225. As density demands grew, the competing MIG and thin-film head designs came to be used in place of ferrite heads, which are virtually obsolete today. Ferrite heads cannot write to the higher coercivity media needed for high-density disk designs and have poor frequency response with higher noise levels. The main advantage of ferrite heads is that they are the cheapest type available.

Metal-In-Gap

Metal-In-Gap (MIG) heads are a specially enhanced version of the composite ferrite design. In MIG heads, a metal substance is applied to the head's recording gap. Two versions of MIG heads are available: single-sided and double-sided. Single-sided MIG heads are designed with a layer of magnetic alloy placed along the trailing edge of the gap. Double-sided MIG designs apply the layer to both sides of the gap. The metal alloy is applied through a vacuum-deposition process called sputtering, which was discussed in the previous section on recording media.

This magnetic alloy has twice the magnetization capability of raw ferrite and enables the head to write to the higher coercivity thin-film media needed at the higher densities. MIG heads also produce a sharper gradient in the magnetic field for a better-defined magnetic pulse. Double-sided MIG heads offer even higher coercivity capability than the single-sided designs.

Because of these increases in capabilities through improved designs, MIG heads were for a time the most popular head design, and were used in all but very high-capacity drives. Due to market pressures demanding higher and higher densities, however, MIG heads have been largely displaced in favor of thin-film heads.

Thin Film

Thin-film (TF) heads are manufactured much the same way as a semiconductor chip—through a photolithographic process. This process creates many thousands of heads on a single circular wafer and produces a very small, high-quality product.

TF heads have an extremely narrow and controlled head gap that is created by sputtering a hard aluminum material. Because this material completely encloses the gap, the area is very well protected, minimizing the chance of damage from contact with the spinning disk. The core is a combination of iron and nickel alloy that has two to four times more magnetic power than a ferrite head core.

TF heads produce a sharply defined magnetic pulse that enables them to write at extremely high densities. Because they do not have a conventional coil, TF heads are more immune to variations in coil impedance. These small, lightweight heads can float at a much lower height than the ferrite and MIG heads; in some designs, the floating height is 2 μ -in. or less. Because the reduced height enables the heads to pick up and transmit a much stronger signal from the platters, the signal-to-noise ratio increases, improving accuracy. At the high track and linear densities of some drives, a standard ferrite head would not be capable of picking out the data signal from the background noise. Another advantage of TF heads is that their small size enables the platters to be stacked closer together, making it possible to fit more platters into the same space.

Until the past few years, TF heads were relatively expensive compared with older technologies, such as ferrite and MIG. Better manufacturing techniques and the need for higher densities, however, have driven the market to TF heads. The widespread use of these heads has also made them cost-competitive with, if not cheaper than, MIG heads.

Many of the drives in the 100MB to 1,000MB range manufactured today use TF heads, especially in the smaller form factors. TF heads displaced MIG heads as the most popular head design, but they are now themselves being displaced by newer technologies, such as magneto-resistive heads.

Magneto-Resistive

Magneto-Resistive (MR) heads are the latest technology. Invented and pioneered by IBM, MR heads currently offer the highest performance available. Most 3 1/2-inch drives with capacities in excess of 1GB currently use MR heads. As areal densities continue to increase, the MR head eventually will become the head of choice for nearly all hard drives, displacing the popular MIG and TF head designs.

MR heads rely on the fact that the resistance of a conductor changes slightly when an external magnetic field is present. Rather than put out a voltage by passing through a magnetic-field flux reversal, as a normal head would, the MR head senses the flux reversal and changes resistance. A small current flows through the heads, and this sense current measures the change in resistance. This design provides an output that is three or more times more powerful than a TF head during a read. In effect, MR heads are power-read heads, acting more like sensors than generators.

MR heads are more costly and complex to manufacture than other types of heads, because several special features or steps must be added. Among them are

- Additional wires must be run to and from the head to carry the sense current.
- Four to six more masking steps are required.
- Because MR heads are so sensitive, they are very susceptible to stray magnetic fields and must be shielded.

Because the MR principle can only read data and is not used for writing, MR heads really are two heads in one. The assembly includes a standard inductive TF head for writing data and an MR head for reading. Because two separate heads are built into one assembly, each head can be optimized for its task. Ferrite, MIG, and TF heads are known as single-gap heads because the same gap is used for both reading and writing, while the MR head uses a separate gap for each operation.

The problem with single-gap heads is that the gap length is always a compromise between what is best for reading and what is best for writing. The read function needs a thin gap for higher resolution; the write function needs a thicker gap for deeper flux penetration to switch the medium. In a dual-gap MR head, the read and write gaps can be optimized for both functions independently. The write (TF) gap writes a wider track than the read (MR) gap reads. Thus, the read head is less likely to pick up stray magnetic information from adjacent tracks.

Drives with MR heads require better shielding from stray magnetic fields, which can affect these heads more easily than they do the other head designs. All in all, however, the drawback is minor compared with the advantages that the MR heads offer.

More recently, improved MR designs called giant Magneto-Resistive or spin valve heads have been introduced. These use the effect of a magnetic field capable of changing the direction of electron spin in certain materials to alter the resistance of the material. This results in a Magneto-Resistive effect that is even more sensitive, and which can be used to read even higher density recordings.

Head Sliders

The term *slider* is used to describe the body of material that supports the actual drive head itself. The slider is what actually floats or slides over the surface of the disk, carrying the head at the correct distance from the medium for reading and writing. Most sliders resemble a trimaran, with two outboard pods that float along the surface of the disk media and a central “hull” portion that actually carries the head and the read/write gap. The following figure shows a typical slider. Note the actual head, with the read/write gap, is on the trailing end of the slider.

The trend toward smaller and smaller form factor drives has forced sliders to become smaller and smaller as well. The typical mini-Winchester slider design is about .160×.126×.034 inches in size. Most head manufacturers have now shifted to 50 percent smaller nanosliders, which have dimensions of about .08×.063×.017 inches. The nanoslider is being used in both high-capacity and small form-factor drives. The next evolution in slider design, called the picoslider, is smaller still—70 percent smaller than the original design. Picosliders are assembled by using flex interconnect cable (FIC) and chip on ceramic (COC) technology that enables the process to be completely automated.

Figure 10.9 The underside of a typical head slider.

Smaller sliders reduce the mass carried at the end of the head actuator arms, providing increased acceleration and deceleration, leading to faster seek times. The smaller sliders also require less area for a landing zone, thus increasing the usable area of the disk platters. Further, the smaller slider contact area reduces the slight wear on the platter surface that occurs during normal startup and spindown of the drive platters.

The newer nanoslider designs also have specially modified surface patterns that are designed to maintain the same floating height above the disk surface, whether the slider is positioned above the inner or outer cylinders. Conventional sliders increase or decrease their floating height considerably, according to the velocity of the disk surface traveling beneath them. Above the outer cylinders, the velocity and floating height are higher. This arrangement is undesirable in newer drives that use zoned bit recording, in which the bit density is the same on all the cylinders. When the bit density is uniform throughout the drive, the head floating height should be relatively constant as well for maximum performance. Special textured surface patterns and manufacturing techniques enable the nanosliders to float at a much more consistent height, making them ideal for zoned bit recording drives.

Head Actuator Mechanisms

Possibly more important than the heads themselves is the mechanical system that moves them: the head actuator. This mechanism moves the heads across the disk and positions them accurately above the desired cylinder. There are many variations on head actuator mechanisms in use, but all fall into one of two basic categories:

- Stepper motor actuators
- Voice coil actuators

The use of one or the other type of actuator has profound effects on a drive's performance and reliability. The effects are not limited to speed; they also include accuracy, sensitivity to temperature, position, vibration, and overall reliability. The head actuator is the single most important specification in the drive, and the type of head actuator mechanism in a drive tells you a great deal about the drive's performance and reliability characteristics. Table 10.4 shows the two types of hard disk drive head actuators and the affected performance characteristics.

Table 10.4 Characteristics of Stepper Motor Versus Voice Coil Drives

Characteristic	Stepper Motor	Voice Coil
Relative access speed	Slow	Fast
Temperature sensitive	Yes (very)	No
Positionally sensitive	Yes	No
Automatic head parking	Not usually	Yes
Preventive maintenance	Periodic format	None required
Relative reliability	Poor	Excellent

Generally, a stepper motor drive has a slower average access rating, is temperature-sensitive during read and write operations, is sensitive to physical orientation during read and write operations, does not automatically park its heads above a save zone during power-down, and usually requires annual or biannual reformats to realign the sector data with the sector header information due to mistracking. To put it bluntly, a drive equipped with a stepper motor actuator is much less reliable (by a large margin) than a drive equipped with a voice coil actuator.

Floppy disk drives position their heads by using a stepper motor actuator. The accuracy of the stepper mechanism is suited to a floppy disk drive, because the track densities are usually nowhere near those of a hard disk. The track density of a 1.44MB floppy disk is 135 tracks per inch, while hard disk drives have densities of over 5,000 tracks per inch. Virtually all the hard disk drives being manufactured today use voice coil actuators, because stepper motors cannot achieve the degree of accuracy needed.

Stepper Motor Actuators

A stepper motor is an electrical motor that can “step,” or move from position to position, with mechanical detents or click-stop positions. If you were to grip the spindle of one of these motors and spin it manually, you would hear a clicking or buzzing sound as the motor passed each detent position with a soft click.

Stepper motors cannot position themselves between step positions; they can stop only at the predetermined detent positions. The motors are small (between 1 and 3 inches) and can be square, cylindrical, or flat. Stepper motors are outside the sealed HDA, although the spindle of the motor penetrates the HDA through a sealed hole.

Stepper motor mechanisms are affected by a variety of problems; the greatest problem is temperature. As the drive platters heat and cool, they expand and contract, and the tracks on the platters move in relation to a predetermined track position. The stepper mechanism cannot move in increments of less than a single track to correct for these temperature-induced errors. The drive positions the heads to a particular cylinder according to a predetermined number of steps from the stepper motor, with no room for nuance.

Figure 10.10 shows a common stepper motor design, where a split metal band is used to transfer the movement from the rotating motor shaft to the head actuator itself.

Figure 10.10 A stepper motor actuator.

Voice Coil Actuators

The voice coil actuators used in virtually all hard disk drives made today, unlike stepper motor actuators, use a feedback signal from the drive to accurately determine the head positions and adjust them, if necessary. This arrangement provides significantly greater performance, accuracy, and reliability than traditional stepper motor actuator designs.

A voice coil actuator works by pure electromagnetic force. The construction of the mechanism is similar to that of a typical audio speaker, from which the term voice coil is derived. An audio speaker uses a stationary magnet surrounded by a voice coil, which is connected to the speaker's paper cone. Energizing the coil causes it to move relative to the stationary magnet, which produces sound from the cone. In a typical hard disk drive's voice coil system, the electromagnetic coil is attached to the end of the head rack and placed near a stationary magnet. There is no physical contact between the coil and the magnet; instead, the coil moves by pure magnetic force. As the electromagnetic coils are energized, they attract or repulse the stationary magnet and move the head rack. Systems like these are extremely quick and efficient, and usually much quieter than systems driven by stepper motors.

Unlike a stepper motor, a voice coil actuator has no click-stops, or detent positions; rather, a special guidance system stops the head rack above a particular cylinder. Because it has no detents, the voice coil actuator can slide the heads in and out smoothly to any position desired. Voice coil actuators use a guidance mechanism called a *servo* to tell the actuator where the heads are in relation to the cylinders and to place the heads accurately at the desired positions. This positioning system often is called a *closed loop feedback mechanism*. It works by sending the index (or servo)

signal to the positioning electronics, which return a feedback signal that is used to position the heads accurately. The system is also called servo-controlled, which refers to the index or servo information that is used to dictate or control head-positioning accuracy.

A voice coil actuator with servo control is not affected by temperature changes, as a stepper motor is. When temperature changes cause the disk platters to expand or contract, the voice coil system compensates automatically because it never positions the heads in predetermined track positions. Rather, the voice coil system searches for the specific track, guided by the prewritten servo information, and then positions the head rack precisely above the desired track, wherever it happens to be. Because of the continuous feedback of servo information, the heads adjust to the current position of the track at all times. For example, as a drive warms up and the platters expand, the servo information enables the heads to “follow” the track. As a result, a voice coil actuator is sometimes called a *track following system*.

The two main types of voice-coil positioner mechanisms are

- Linear voice-coil actuators
- Rotary voice-coil actuators

The two types differ only in the physical arrangement of the magnets and coils.

A linear actuator (see Figure 10.11) moves the heads in and out over the platters in a straight line. The coil moves in and out on a track surrounded by the stationary magnets. The primary advantage of the linear design is that it eliminates the head *azimuth* variations that occur with rotary positioning systems. (Azimuth refers to the angular measurement of the head position relative to the tangent of a given cylinder.) A linear actuator does not rotate the head as it moves from one cylinder to another, thus eliminating this problem.

Although the linear actuator seems to be a good design, it has one fatal flaw: The devices are much too heavy. As drive performance has increased, the desire for lightweight actuator mechanisms has become very important. The lighter the mechanism, the faster it can accelerate and decelerate from one cylinder to another. Because they are much heavier than rotary actuators, linear actuators were popular only for a short time; they are virtually nonexistent in drives manufactured today.

Rotary actuators (refer to Figure 10.8) also use stationary magnets and a movable coil, but the coil is attached to the end of an actuator arm. As the coil moves relative to the stationary magnet, it swings the head arms in and out over the surface of the disk. The primary advantage of this mechanism is its light weight, which means that the heads can accelerate and decelerate very quickly, resulting in very fast average seek times. Because of the lever effect on the head arm, the heads move faster than the actuator, which also helps to improve access times. (Refer to Figure 10.8, which shows a rotary voice coil actuator.)

The disadvantage of a rotary system is that as the heads move from the outer to the inner cylinders, they rotate slightly with respect to the tangent of the cylinders. This rotation results in an azimuth error and is one reason why the area of the platter in which the cylinders are located is somewhat limited. By limiting the total motion of the actuator, the azimuth error is contained to within reasonable specifications. Virtually all voice coil drives today use rotary actuator systems.

Figure 10.11 A linear voice coil actuator.

Servo Mechanisms

Three servo mechanism designs have been used to control voice coil positioners over the years:

- Wedge servo
- Embedded servo
- Dedicated servo

The three designs are slightly different, but they accomplish the same basic task: They enable the head positioner to adjust continuously so it is precisely positioned above a given cylinder on the disk. The main difference between these servo designs is where the gray code information is actually written on the drive.

All servo mechanisms rely on special information that is written to the disk when it is manufactured. This information is usually in the form of a special code called a *gray code*. A gray code is a special binary notational system in which any two adjacent numbers are represented by a code that differs in only one bit place or column position. This system makes it easy for the head to read the information and quickly determine its precise position.

At the time of manufacture, a special machine called a servowriter writes the servo gray code on the disk. The servowriter is basically a jig that mechanically moves the heads to a given reference

position, and then writes the servo information at that position. Many servowriters are themselves guided by a laser-beam reference that calculates its own position by calculating distances in wavelengths of light. Because the servowriter must be capable of moving the heads mechanically, the process requires either that the lid of the drive be removed or that access be available through special access ports in the HDA. After the servowriting is complete, these ports are usually covered with sealing tape. You often see these tape-covered holes on the HDA, usually accompanied by warnings that you will void the warranty if you remove the tape. Because servowriting exposes the interior of the HDA, it requires a clean-room environment.

A servowriter is an expensive piece of machinery, costing up to \$50,000 or more, and often must be custom-made for a particular make or model of drive. Some drive-repair companies have servowriting capability, which means that they can rewrite the servo information on a drive if it becomes damaged. If a servowriter is not available, a drive with servo-code damage must be sent back to the drive manufacturer for the servo information to be rewritten.

Fortunately, it is impossible to damage the servo information through disk read and write processes. Drives are designed so the heads cannot overwrite the servo information, even during a low-level format. One myth that has been circulating (especially with respect to IDE drives) is that you can damage the servo information by improper low-level formatting. This is not true. An improper low-level format can compromise the performance of the drive, but the servo information is totally protected and cannot be overwritten. Even so, it is possible for the servo information on some drives to be damaged by a strong adjacent magnetic field or by jarring the drive while it is writing, causing the heads to move off track.

The track-following capabilities of a servo-controlled voice coil actuator eliminate the positioning errors that occur over time with stepper motor drives. Voice coil drives are not affected by conditions such as thermal expansion and contraction of the platters. In fact, many voice coil drives today perform a special thermal-recalibration procedure at predetermined intervals while they run. This procedure usually involves seeking the heads from cylinder 0 to some other cylinder one time for every head on the drive. As this sequence occurs, the control circuitry in the drive monitors how much the track positions have moved since the last time the sequence was performed, and a thermal-recalibration adjustment is calculated and stored in the drive's memory. This information is then used every time the drive positions the heads to ensure the most accurate positioning possible.

Most drives perform the thermal-recalibration sequence every five minutes for the first half-hour that the drive is powered on, and then once every 25 minutes after that. With some drives, this thermal-recalibration sequence is very noticeable; the drive essentially stops what it is doing, and you hear rapid ticking for a second or so. Some people think that this is an indication that their drive is having a problem reading something and perhaps is conducting a read retry, but this is not true. Most of the newer intelligent drives (IDE and SCSI) employ this thermal-recalibration procedure to maintain positioning accuracy.

As multimedia applications grew in popularity, thermal recalibration became a problem with some manufacturers' drives. The thermal-recalibration sequence sometimes interrupted the transfer of a large data file, such as an audio or video file, which resulted in audio or video playback

jitter. Some companies released special A/V (audio visual) drives that hide the thermal-recalibration sequences so they never interrupt a file transfer. Most of the newer IDE and SCSI drives are A/V capable, which means that the thermal-recalibration sequences will not interrupt a transfer such as a video playback.

While we are on the subject of automatic drive functions, most of the drives that perform thermal-recalibration sequences also automatically perform a function called a *disk sweep*. Also called *wear leveling* by some manufacturers, this procedure is an automatic head seek that occurs after the drive has been idle for a period of time. The disk-sweep function moves the heads to a cylinder in the outer portion of the platters, which is where the head float-height is highest (because the head-to-platter velocity is highest). Then, if the drive continues to remain idle for another period, the heads move to another cylinder in this area, and the process continues indefinitely as long as the drive is powered on.

The disk-sweep function is designed to prevent the head from remaining stationary above one cylinder in the drive for too long, where friction between the head and platter eventually would dig a trench in the medium. Although the heads are not in direct contact with the medium, they are so close that the constant air pressure from the head floating above a single cylinder could cause friction and excessive wear.

Wedge Servo

Some early servo-controlled drives used a technique called a *wedge servo*. In these drives, the gray-code guidance information is contained in a “wedge” slice of the drive in each cylinder immediately preceding the index mark. The index mark indicates the beginning of each track, so the wedge-servo information was written in the PRE-INDEX GAP, which is at the end of each track. This area is provided for speed tolerance and normally is not used by the controller. Figure 10.12 shows the servo-wedge information on a drive.

Some controllers had to be notified that the drive was using a wedge servo so they could shorten the sector timing to allow for the wedge-servo area. If they were not correctly configured, these controllers would not work properly with the drive.

Another problem was that the servo information appears only one time every revolution, which means that the drive often needed several revolutions before it could accurately determine and adjust the head position. Because of these problems, the wedge servo never was a popular design; it no longer is used in drives.

Figure 10.12 A wedge servo.

Embedded Servo

An embedded servo (see Figure 10.13) is an enhancement of the wedge servo. Instead of placing the servo code before the beginning of each cylinder, an embedded servo design writes the servo information before the start of each sector. This arrangement enables the positioner circuits to receive feedback many times in a single revolution, making the head positioning much faster and more precise. Another advantage is that every track on the drive has its own positioning information, so each head can quickly and efficiently adjust position to compensate for any changes in the platter or head dimensions, especially for changes due to thermal expansion or physical stress.

Figure 10.13 An embedded servo.

Most drives today use an embedded servo to control the positioning system. As in the wedge servo design, the embedded servo information is protected by the drive circuits, and any write operations are blocked whenever the heads are above the servo information. Thus, it is impossible to overwrite the servo information with a low-level format, as some people incorrectly believe.

Although the embedded servo works much better than the wedge servo because the servo feedback information is made available several times in a single disk revolution, a system that offered continuous servo feedback information would be better.

Dedicated Servo

A dedicated servo is a design in which the servo information is written continuously throughout the entire track, rather than just once per track or at the beginning of each sector. Unfortunately,

if this procedure were used on the entire drive, no room would be left for data. For this reason, a *dedicated servo* uses one side of one of the platters exclusively for the servo-positioning information. The term “dedicated” comes from the fact that this platter side is completely dedicated to the servo information and cannot contain any data.

When building a dedicated servo drive, the manufacturer deducts one side of one platter from normal read/write usage, and records a special set of gray-code data there that indicates the proper track positions. Because the head that rests above this surface cannot be used for normal reading and writing, the gray code can never be erased, and the servo information is protected, as in the other servo designs. No low-level format or other procedure can possibly overwrite the servo information. Figure 10.14 shows a dedicated servo mechanism. Normally the head on top or one in the center is dedicated for servo use.

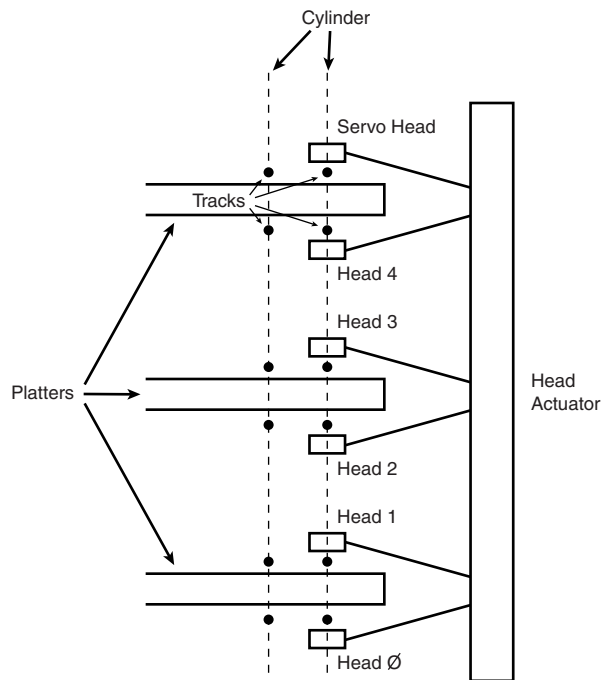

Figure 10.14 A dedicated servo, showing one entire head/side used for servo reading.

When the drive moves the heads to a specific cylinder, the internal drive electronics use the signals received by the servo head to determine the position of the read/write heads. As the heads move, the track counters are read from the dedicated servo surface. When the servo head detects the requested track, the actuator stops. The servo electronics then fine-tune the position so the heads are positioned precisely above the desired cylinder before any writing is permitted.

Although only one head is used for servo tracking, the other heads are attached to the same rack so if one head is above the desired cylinder, all the others will be as well.

One way of telling if a drive uses a dedicated servo platter is if it has an odd number of heads. For example, the Toshiba MK-538FB 1.2GB drive that I have on my computer has eight platters, but only 15 read/write heads. The drive uses a dedicated-servo positioning system, and the sixteenth head is the servo head. The advantage of the dedicated servo concept is that the servo information is continuously available to the drive, making the head positioning process faster and more precise. The drawback is that dedicating an entire platter surface to servo information can be wasteful. More drives today use embedded servo information than dedicated servo. Some drives combine a dedicated servo with an embedded servo, but this type of hybrid design is rare.

Of course, as mentioned earlier, today's IDE and SCSI drives have head, track, and sector-per-track parameters that are translated from the actual physical numbers. Therefore, it is not usually possible to tell from the published numbers exactly how many heads or platters are contained within a drive.

Automatic Head Parking

When you power off a hard disk drive, the spring tension in each head arm pulls the heads into contact with the platters. The drive is designed to sustain thousands of takeoffs and landings, but it is wise to ensure that the landing occurs at a spot on the platter that contains no data. Older drives required manual head parking; you had to run a program that positioned the drive heads to a landing zone, usually the innermost cylinder, before turning the system off. Modern drives automatically park the heads, so park programs are no longer needed.

Some amount of abrasion occurs during the landing and takeoff process, removing just a "micro puff" from the magnetic medium; but if the drive is jarred during the landing or takeoff process, real damage can occur.

One benefit of using a voice coil actuator is automatic head parking. In a drive that has a voice coil actuator, the heads are positioned and held by magnetic force. When the power to the drive is removed, the magnetic field that holds the heads stationary over a particular cylinder dissipates, enabling the head rack to skitter across the drive surface and potentially cause damage. In the voice coil design, the head rack is attached to a weak spring at one end and a head stop at the other end. When the system is powered on, the spring is overcome by the magnetic force of the positioner. When the drive is powered off, however, the spring gently drags the head rack to a park-and-lock position before the drive slows down and the heads land. On some drives, you can actually hear the "ting...ting...ting...ting" sound as the heads literally bounce-park themselves, driven by this spring.

On a drive with a voice coil actuator, you activate the parking mechanism by turning off the computer; you do not need to run a program to park or retract the heads. In the event of a power outage, the heads park themselves automatically. (The drives unpark automatically when the system is powered on.)

Air Filters

Nearly all hard disk drives have two air filters. One filter is called the recirculating filter, and the other is called either a barometric or breather filter. These filters are permanently sealed inside

the drive and are designed never to be changed for the life of the drive, unlike many older main-frame hard disks that had changeable filters.

A hard disk on a PC system does not circulate air from inside to outside the HDA or vice versa. The recirculating filter that is permanently installed inside the HDA is designed to filter only the small particles scraped off the platters during head takeoffs and landings (and possibly any other small particles dislodged inside the drive). Because PC hard disk drives are permanently sealed and do not circulate outside air, they can run in extremely dirty environments (see Figure 10.15).

Figure 10.15 Air circulation in a hard disk.

The HDA in a hard disk drive is sealed but not airtight. The HDA is vented through a barometric or breather filter element that allows for pressure equalization (breathing) between the inside and outside of the drive. For this reason, most hard drives are rated by the drive's manufacturer to run in a specific range of altitudes, usually from 1,000 feet below to 10,000 feet above sea level. In fact, some hard drives are not rated to exceed 7,000 feet while operating, because the air pressure would be too low inside the drive to float the heads properly. As the environmental air pressure changes, air bleeds into or out of the drive so internal and external pressures are identical. Although air does bleed through a vent, contamination usually is not a concern, because the barometric filter on this vent is designed to filter out all particles larger than 0.3 microns (about $12\mu\text{-in.}$) to meet the specifications for cleanliness inside the drive. You can see the vent holes on most drives, which are covered internally by this breather filter. Some drives use even finer grade filter elements to keep out even smaller particles.

I conducted a seminar in Hawaii several years ago, and several of the students were from the Mauna Kea astronomical observatory. They indicated that virtually all the hard disk drives they had tried to use at the observatory site had failed very quickly, if they worked at all. This was no surprise, because the observatory is at the 13,800-foot peak of the mountain, and at that altitude,

even people don't function very well! At the time, it was suggested that the students look into solid-state (RAM) disks, tape drives, or even floppy disk drives as their primary storage medium. Since this time, IBM's Adstar division (which produces all IBM hard drives) introduced a line of rugged 3 1/2-inch drives that are hermetically sealed (airtight), although they do have air inside the HDA. Because they carry their own internal air under pressure, these drives can operate at any altitude, and can also withstand extremes of shock and temperature. The drives are designed for military and industrial applications, such as systems used aboard aircraft and in extremely harsh environments.

Hard Disk Temperature Acclimation

Because hard drives have a filtered port to bleed air into or out of the HDA, moisture can enter the drive, and after some period of time, it must be assumed that the humidity inside any hard disk is similar to that outside the drive. Humidity can become a serious problem if it is allowed to condense—and especially if you power up the drive while this condensation is present. Most hard disk manufacturers have specified procedures for acclimating a hard drive to a new environment with different temperature and humidity ranges, and especially for bringing a drive into a warmer environment in which condensation can form. This situation should be of special concern to users of laptop or portable systems. If you leave a portable system in an automobile trunk during the winter, for example, it could be catastrophic to bring the machine inside and power it up without allowing it to acclimate to the temperature indoors.

The following text and Table 10.5 are taken from the factory packaging that Control Data Corporation (later Imprimis and eventually Seagate) used to ship with its hard drives:

If you have just received or removed this unit from a climate with temperatures at or below 50°F (10°C) do not open this container until the following conditions are met, otherwise condensation could occur and damage to the device and/or media may result. Place this package in the operating environment for the time duration according to the temperature chart.

Table 10.5 Hard Disk Drive Environmental Acclimation Table

Previous Climate Temperature	Acclimation Time
+40°F (+4°C)	13 hours
+30°F (-1°C)	15 hours
+20°F (-7°C)	16 hours
+10°F (-12°C)	17 hours
0°F (-18°C)	18 hours
-10°F (-23°C)	20 hours
-20°F (-29°C)	22 hours
-30°F (-34°C) or less	27 hours

As you can see from this table, you must place a hard disk drive that has been stored in a colder-than-normal environment into its normal operating environment for a specified amount of time to allow it to acclimate before you power it on.

Spindle Motors

The motor that spins the platters is called the spindle motor because it is connected to the spindle around which the platters revolve. Spindle motors in hard disk drives are always connected directly; there are no belts or gears involved. The motor must be free of noise and vibration; otherwise, it can transmit a rumble to the platters that can disrupt reading and writing operations.

The spindle motor must also be precisely controlled for speed. The platters in hard disk drives revolve at speeds ranging from 3,600 to 7,200rpm or more, and the motor has a control circuit with a feedback loop to monitor and control this speed precisely. Because the speed control must be automatic, hard drives do not have a motor-speed adjustment. Some diagnostics programs claim to measure hard drive rotation speed, but all these programs do is estimate the rotational speed by the timing at which sectors pass under the heads.

There is actually no way for a program to measure the hard disk drive's rotational speed; this measurement can be made only with sophisticated test equipment. Don't be alarmed if some diagnostics program tells you that your drive is spinning at an incorrect speed; most likely the program is wrong, not the drive. Platter rotation and timing information is not provided through the hard disk controller interface. In the past, software could give approximate rotational speed estimates by performing multiple sector read requests and timing them, but this was valid only when all drives had the same number of sectors per track and spun at the same speed. Zoned bit recording—combined with the many different rotational speeds used by modern drives, not to mention built-in buffers and caches—means that these calculation estimates cannot be performed accurately by software.

On most drives, the spindle motor is on the bottom of the drive, just below the sealed HDA. Many drives today, however, have the spindle motor built directly into the platter hub inside the HDA. By using an internal hub spindle motor, the manufacturer can stack more platters in the drive, because the spindle motor takes up no vertical space.

Note

Spindle motors, particularly on the larger form-factor drives, can consume a great deal of 12-volt power. Most drives require two to three times the normal operating power when the motor first spins the platters. This heavy draw lasts only a few seconds or until the drive platters reach operating speed. If you have more than one drive, you should try to sequence the start of the spindle motors so the power supply does not have to provide such a large load to all the drives at the same time. Most SCSI and IDE drives have a delayed spindle-motor start feature.

Logic Boards

All hard disk drives have one or more logic boards mounted on them. The logic boards contain the electronics that control the drive's spindle and head actuator systems and present data to the controller in some agreed-upon form. On IDE drives, the boards include the controller itself, while SCSI drives include the controller and the SCSI bus adapter circuit.

Many disk drive failures occur in the logic board not in the mechanical assembly. (This statement does not seem logical, but it is true.) Therefore, you can sometimes repair a failed drive by replacing the logic board rather than the entire drive. Replacing the logic board, moreover, enables you to regain access to the data on the drive—something that replacing the entire drive does not.

In many cases, logic boards plug into the drive and are easily replaceable. These boards are usually mounted with standard screw hardware. If a drive is failing and you have a spare, you might be able to verify a logic-board failure by taking the board off the known good drive and mounting it on the bad one. If your suspicions are confirmed, you can order a new logic board from the drive manufacturer, but unless you have data on the drive you need to recover, it may make more sense to buy a new drive, considering today's low disk drive costs.

To reduce costs further, many third-party vendors can also supply replacement logic-board assemblies. These companies often charge much less than the drive manufacturers for the same components. (See the Vendor List on the CD, for vendors of drive components, including logic boards.)

Cables and Connectors

Hard disk drives typically have several connectors for interfacing to the computer, receiving power, and sometimes grounding to the system chassis. Most drives have at least these three types of connectors:

- Interface connector(s)
- Power connector
- Optional ground connector (tab)

Of these, the interface connectors are the most important, because they carry the data and command signals between the system and the drive. In most cases, the drive interface cables can be connected in a daisy chain or bus-type configuration. Most interfaces support at least two devices, and SCSI (Small Computer System Interface) can support up to seven (Wide SCSI-2 can support up to 15) devices in the chain, in addition to the host adapter. Older interfaces, such as ST-506/412 or ESDI (Enhanced Small Device Interface), used separate cables for data and control signals, but today's SCSI and IDE (Integrated Drive Electronics) drives have a single connector.

◀◀ See "ATA I/O Connector," p. 514, and "SCSI Cables and Connectors," p. 541.

The power connector is usually the same four-pin type that is used in floppy disk drives, and the same power-supply connector plugs into it. Most hard disk drives use both 5- and 12-volt power, although some of the smaller drives designed for portable applications use only 5-volt power. In most cases, the 12-volt power runs the spindle motor and head actuator, and the 5-volt power runs the circuitry. Make sure that your power supply can supply adequate power for the hard disk drives installed in your system.

The 12-volt power consumption of a drive usually varies with the physical size of the unit. The larger the drive is, the faster it spins, and the more platters there are to spin, the more power that it requires. For example, most of the 3 1/2-inch drives on the market today use roughly one-half to one-fourth the power (in watts) of the older 5 1/4-inch drives. Some of the very small (2 1/2- or 1.8-inch) hard disks barely sip electrical power and actually use one watt or less!

A grounding tab provides a positive ground connection between the drive and the system's chassis. In most computers, the hard disk drive is mounted directly to the chassis using screws, so the ground wire is unnecessary. On some systems, the drives are installed on plastic or fiberglass rails,

which do not provide proper grounding. These systems must provide a grounding wire plugged into the drive at this grounding tab. Failure to ground the drive may result in improper operation, intermittent failure, or general read and write errors.

Configuration Items

To configure a hard disk drive for installation in a system, you usually must set several jumpers (and, possibly, terminating resistors) properly. These items vary from interface to interface and often from drive to drive as well. A complete discussion of the configuration settings for each interface appears in the section “Hard Disk Installation Procedures” later in this chapter.

The Faceplate or Bezel

Many hard disk drives offer as an option a front faceplate, or bezel (see Figure 10.16). A bezel usually is supplied as an option for the drive rather than as a standard item. In most cases today, the bezel is a part of the case and not the drive itself.

Figure 10.16 Typical 5 1/4- and 3 1/2-inch hard drives bezel shown from the front (as seen on the outside of the PC case) (top) and from the back (bottom) (the inside mounting and LED wiring).

Older systems had the drive installed so it was visible outside the system case. To cover the hole in the case, you would use an optional bezel or faceplate. Bezels often come in several sizes and colors to match various PC systems. Many faceplate configurations for 3 1/2-inch drives are available, including bezels that fit 3 1/2-inch drive bays as well as 5 1/4-inch drive bays. You even have a choice of colors (usually black, cream, or white).

Some bezels feature a light-emitting diode (LED) that flickers when your hard disk is in use. The LED is mounted in the bezel; the wire hanging off the back of the LED plugs into the drive. In some drives, the LED is permanently mounted on the drive, and the bezel has a clear or colored window so you can see the LED flicker while the drive is being accessed.

In systems in which the hard disk is hidden by the unit's cover, a bezel is not needed. In fact, using a bezel may prevent the cover from resting on the chassis properly, in which case the bezel will have to be removed. If you are installing a drive that does not have a proper bezel, frame, or rails to attach to the system, check Appendix C on the CD; several listed vendors offer these accessories for a variety of drives.

Hard Disk Features

To make the best decision in purchasing a hard disk for your system or to understand what differentiates one brand of hard disk from another, you must consider many features. This section examines some of the issues that you should consider when you evaluate drives:

- Reliability
- Shock mounting
- Speed
- Cost

Reliability

When you shop for a drive, you might notice a statistic called the Mean Time Between Failures (MTBF) described in the drive specifications. MTBF figures usually range from 20,000–500,000 hours or more. I usually ignore these figures because they are derived theoretically.

In understanding the MTBF claims, it is important to understand how the manufacturers arrive at them and what they mean. Most manufacturers have a long history of building drives and their drives have seen millions of hours of cumulative use. They can look at the failure rate for previous drive models with the same components and calculate a failure rate for a new drive based on the components used to build the drive assembly. For the electronic circuit board, they can also use industry standard techniques for predicting the failure of the integrated electronics. This enables them to calculate the predicted failure rate for the entire drive unit.

To understand what these numbers mean, it is important to know that the MTBF claims apply to a population of drives, not an individual drive. This means that if a drive claims to have a MTBF of 500,000 hours, you can expect a failure in that population of drives in 500,000 hours of total running time. If there are 1,000,000 drives of this model in service and all 1,000,000 are running at once, you can expect one failure out of this entire population every 1/2 hour. MTBF statistics are not useful for predicting the failure of any individual drive or a small sample of drives.

It is also important to understand the meaning of the word failure. In this sense, a failure is a fault that requires the drive to be returned to the manufacturer for repair, not an occasional failure to read or write a file correctly.

Finally, as some drive manufacturers point out, this measure of MTBF should really be called mean time to first failure. "Between failures" implies that the drive fails, is returned for repair, and then at some point fails again. The interval between repair and the second failure here would be the MTBF. Because in most cases, a failed hard drive that would need manufacturer repair is replaced rather than repaired, the whole MTBF concept is misnamed.

The bottom line is that I do not really place much emphasis on MTBF figures. For an individual drive, they are not accurate predictors of reliability. However, if you are an information systems manager considering the purchase of thousands of PCs or drives per year, or a system vendor building and supporting thousands of systems, it is worth your while to examine these numbers and study the methods used to calculate them by each vendor. If you can understand the vendor's calculations and compare the actual reliability of a large sample of drives, you can purchase more reliable drives and save time and money in service and support.

S.M.A.R.T.

S.M.A.R.T. (Self-Monitoring, Analysis and Reporting Technology) is an industry standard providing failure prediction for disk drives. When S.M.A.R.T. is enabled for a given drive, the drive monitors predetermined attributes that are susceptible to or indicative of drive degradation. Based on changes in the monitored attributes, a failure prediction can be made. If a failure is deemed likely to occur, S.M.A.R.T. makes a status report available so that the system BIOS or driver software can notify the user of the impending problems, perhaps allowing the user to back up the data on the drive before any real problems occur.

Predictable failures are the types of failures that S.M.A.R.T. will attempt to detect. These failures result from the gradual degradation of the drive's performance. According to Seagate, 60 percent of drive failures are mechanical, which are exactly the type of failures S.M.A.R.T. is designed to predict.

Of course, not all failures are predictable, and S.M.A.R.T. cannot help with unpredictable failures that happen without any advance warning. These can be caused by static electricity, improper handling or sudden shock, or circuit failure such as thermal-related solder problems or component failure.

S.M.A.R.T. was originally created by IBM in 1992. That year IBM began shipping 3 1/2-inch hard disk drives equipped with Predictive Failure Analysis (PFA), an IBM-developed technology that periodically measures selected drive attributes and sends a warning message when a predefined threshold is exceeded. IBM turned this technology over to the ANSI organization and it subsequently became the ANSI-standard S.M.A.R.T. protocol for SCSI drives as defined in the ANSI-SCSI Informational Exception Control (IEC) document X3T10/94-190.

Interest in extending this technology to IDE/ATA drives led to the creation of the S.M.A.R.T. Working Group in 1995. Besides IBM, other companies represented in the original group were Seagate Technology, Conner Peripherals (now a part of Seagate), Fujitsu, Hewlett-Packard, Maxtor, Quantum, and Western Digital. The S.M.A.R.T. specification produced by this group and placed in the public domain covers both IDE/ATA and SCSI hard disk drives, and can be found in most of the more recently produced drives on the market.

The S.M.A.R.T. design of attributes and thresholds is similar in IDE/ATA and SCSI environments, but the reporting of information differs.

In an IDE/ATA environment, driver software on the system interprets the alarm signal from the drive generated by the S.M.A.R.T. "report status" command. The driver polls the drive on

a regular basis to check the status of this command and, if it signals imminent failure, sends an alarm to the operating system where it will be passed on via an error message to the end user. This structure also allows for future enhancements, which might allow reporting of information other than drive failure conditions. The system can read and evaluate the attributes and alarms reported in addition to the basic “report status” command.

SCSI drives with S.M.A.R.T. only communicate a reliability condition as either good or failing. In a SCSI environment, the failure decision occurs at the disk drive, and the host notifies the user for action. The SCSI specification provides for a sense bit to be flagged if the drive determines that a reliability issue exists. The system then alerts the end user via a message.

The basic requirements for S.M.A.R.T. to function in a system are simple. All you need are a S.M.A.R.T. capable hard disk drive and a S.M.A.R.T. aware BIOS or hard disk driver for your particular operating system. If your BIOS does not support S.M.A.R.T., there are utility programs that can support S.M.A.R.T. on a given system. These include Norton Smart Doctor from Symantec, EZ Drive from Microhouse International, or Data Advisor from Ontrack Data International.

Note that traditional disk diagnostics such as Scandisk and Norton Disk Doctor work only on the data sectors of the disk surface and do not monitor all the drive functions that are monitored by S.M.A.R.T. Most modern disk drives keep spare sectors available to use as substitutes for sectors which have errors. When one of these spares is reallocated, the drive reports the activity to the S.M.A.R.T. counter but still looks completely defect-free to a surface analysis utility such as Scandisk.

Drives with S.M.A.R.T. monitor a variety of attributes that vary from one manufacturer to another. Attributes are selected by the device manufacturer based on their capability to contribute to the prediction of degrading or fault conditions for that particular drive. Most drive manufacturers consider the specific set of attributes being used and the identity of those attributes as vendor specific and proprietary.

Some drives monitor the floating height of the head above the magnetic media. If this height changes from a nominal figure, the drive could fail. Other drives can monitor different attributes such as ECC (error correcting code) circuitry that indicates whether soft errors are occurring when reading or writing data. Some of the attributes monitored on different drives include the following:

- Head floating height
- Data throughput performance
- Spin-up time
- Reallocated (spared) sector count
- Seek error rate
- Seek time performance
- Drive spin-up retry count
- Drive calibration retry count

Each attribute has a threshold limit that is used to determine the existence of a degrading or fault condition. These thresholds are set by the drive manufacturer and cannot be changed.

When there are sufficient changes in the monitored attributes to trigger a S.M.A.R.T. alert, the drive will send an alert message via an IDE/ATA or SCSI command (depending on the type of hard disk drive you have) to the hard disk driver in the system BIOS, which then forwards the message to the operating system. The operating system will then display a warning message as follows:

Caution

Immediately back up your data and replace your hard disk drive. A failure may be imminent.

The message might contain additional information, such as which physical device initiated the alert, a list of the logical drives (partitions) that correspond to the physical device, and even the type, manufacturer, and serial number of the device.

The first thing to do when you receive such an alert would be to heed the warning and back up all the data on the drive. It would be wise to back up to new media and not overwrite any previous good backups you might have, just in case the drive fails before the backup is complete.

After backing up your data, what should you do? S.M.A.R.T. warnings can be caused by an external source and may not actually indicate the drive itself is going to fail. For example, environmental changes such as high or low ambient temperatures can trigger a S.M.A.R.T. alert, as can excessive vibration in the drive caused by an external source. Additionally, electrical interference from motors or other devices on the same circuit as your PC can also induce these alerts.

If the alert was not caused by an external source, a drive replacement may be indicated. If the drive is under warranty, contact the vendor and ask them whether they will replace it. If no further alerts occur, the problem may have been an anomaly and you might not need to replace the drive. If you receive further alerts, replacing the drive is recommended. If you can connect both the new and existing (failing) drive to the same system, you might be able to copy the entire contents of the existing drive to the new one, saving you from having to install or reload all the applications and data from your backup.

Performance

When you select a hard disk drive, one of the important features you should consider is the performance (speed) of the drive. Hard drives can have a wide range of performance capabilities. As is true of many things, one of the best indicators of a drive's relative performance is its price. An old saying from the automobile-racing industry is appropriate here: "Speed costs money. How fast do you want to go?"

You can measure the speed of a disk drive in two ways:

- Average seek time
- Transfer rate

Average seek time, normally measured in milliseconds (ms), is the average amount of time it takes to move the heads from one cylinder to another a random distance away. One way to measure this specification is to run many random track-seek operations, and then divide the timed results by the number of seeks performed. This method provides an average time for a single seek.

The standard method used by many drive manufacturers to measure the average seek time involves measuring the time it takes the heads to move across one-third of the total cylinders. Average seek time depends only on the drive itself; the type of interface or controller has little effect on this specification. The rating is a gauge of the capabilities of the head actuator.

Note

Be wary of benchmarks that claim to measure drive seek performance. Most IDE and SCSI drives use a scheme called sector translation, so any commands that the drive receives to move the heads to a specific cylinder may not actually result in the intended physical movement. This situation renders some benchmarks meaningless for those types of drives. SCSI drives also require an additional step, because the commands first must be sent to the drive over the SCSI bus. These drives may seem to have the fastest access times because the command overhead is not factored in by most benchmarks. However, when this overhead is factored in by benchmark programs, these drives receive poor performance figures.

A slightly different measurement, called average access time, involves another element called *latency*. Latency is the average time (in milliseconds) that it takes for a sector to be available after the heads have reached a track. On average, this figure is half the time that it takes for the disk to rotate once, which is 8.33ms at 3,600rpm. A drive that spins twice as fast would have half the latency. A measurement of a drive's average access time is the sum of its average seek time and its latency. This number provides the average amount of time required before the drive can access a randomly requested sector.

Latency is a factor in disk read and write performance. Decreasing the latency increases the speed of access to data or files and is accomplished only by spinning the drive platters faster. I have a drive that spins at 4,318rpm, for a latency of 6.95ms. Some drives spin at 7,200rpm, resulting in an even shorter latency time of only 4.17ms, while others spin at 10,000rpm, resulting in an incredible 3.00ms latency. In addition to increasing performance where real-world access to data is concerned, spinning the platters faster also increases the data-transfer rate after the heads arrive at the desired sectors.

The transfer rate is probably more important to overall system performance than any other statistic. Transfer rate is the rate at which the drive and controller can send data to the system. The transfer rate depends primarily on the drive's HDA and secondarily on the controller. Transfer rates used to be bound more to the limits of the controller, meaning that drives that were connected to newer controllers often outperformed those connected to older controllers. This situation is where the concept of interleaving sectors came from. Interleaving refers to the ordering of the sectors so they are not sequential, enabling a slow controller to keep up without missing the next sector.

Modern drives with integrated controllers are fully capable of keeping up with the raw drive transfer rate. In other words, they no longer have to interleave the sectors to slow the data for the controller. Interleaving was done when slower controllers were used that were not ready for the next sector immediately after the previous one had been read, causing it to go by before the controller was ready, and the drive to spin another complete revolution just to read it. By numbering the sectors out of order, skipping one or more at a time, the controller would only have to read every second or third sector, which actually made things faster because additional revolutions would not be required. Modern controllers are very fast, and interleaving is no longer necessary since the controller can read the sectors one after the other in consecutive order. Interleaving is covered in more detail later in this chapter.

Another performance issue is the raw interface performance which, in IDE or SCSI drives, is usually far higher than any of the drives themselves are capable of sustaining. Be wary of transfer specifications that are quoted for the interface and not the drive, because they may have little effect on what the drive can actually produce. The drive interface limits the maximum theoretical transfer rate; the actual drive and controller generate the real limits on performance.

To calculate the true transfer rate of a drive, you have to know several important specifications. The two most important specifications are the true rotational speed of the drive (in rpm) and the average number of physical sectors on each track (SPT). I say “average” because most drives today use a zoned bit recording technique that creates different numbers of sectors on the cylinders. The transfer rate on zoned bit recording drives always is fastest in the outermost zone, where the sector per track count is highest. Also, be aware that many drives (especially zoned bit recording drives) are configured with sector translation, so the number of sectors per track reported by the BIOS has little to do with the actual physical characteristics of the drive. You must know the drive’s true physical parameters, rather than the values that the BIOS uses.

When you know these figures, you can use the following formula to determine the maximum data transfer rate in millions of bits per second (Mbps):

$$\text{Maximum Transfer Rate (Mbps)} = \text{SPT} \times 512 \text{ bytes} \times \text{rpm} / 60 \text{ seconds} / 1,000,000 \text{ bits}$$

For example, the Seagate ST-12551N 2G 3 1/2-inch drive spins at 7,200rpm and has an average of 81 sectors per track. The maximum transfer rate for this drive is figured as follows:

$$81 \times 512 \times 7,200 / 60 / 1,000,000 = 4.98 \text{ Mbps}$$

Using this formula, you can calculate the true maximum sustained transfer rate of any drive.

Cache Programs and Caching Controllers

At the software level, disk cache programs such as SMARTDRV (in DOS) or VCACHE (in Windows 9x, Windows NT, and Windows 2000) can have a major effect on disk drive performance. These cache programs hook into the BIOS hard drive interrupt and intercept the read and write calls to the disk BIOS from application programs and device drivers.

When an application program wants to read data from a hard drive, the cache program intercepts the read request, passes the read request to the hard drive controller in the usual way, saves the data read from the disk in its cache memory buffer, and then passes the data back to the application program. Depending on the size of the cache buffer, data from numerous sectors can be read into and saved in the buffer.

When the application wants to read more data, the cache program again intercepts the request and examines its buffers to see whether the requested data is still in the cache. If so, the program passes the data back from the cache to the application immediately, without another hard drive operation. Because the cached data is stored in memory, this method speeds access tremendously and can greatly affect disk drive performance measurements.

Most controllers now have some form of built-in hardware buffer or cache that doesn't intercept or use any BIOS interrupts. Instead, the drive caches data at the hardware level, which is invisible to normal performance-measurement software. Manufacturers originally included track read-ahead buffers in controllers to permit 1:1 interleave performance. Some manufacturers now increase the size of these read-ahead buffers in the controller, while others add intelligence by using a cache instead of a simple buffer.

Many IDE and SCSI drives have cache memory built directly into the drive's on-board controller. For example, the Seagate Hawk 4GB drive on which I am saving this chapter has 512KB of built-in cache memory. Other drives have even larger built-in caches, such as the Seagate Barracuda 4GB with 1MB of integrated cache memory. I remember when 640KB was a lot of memory for an entire system. Now, tiny 3 1/2-inch hard disk drives have more than that built right in! These integrated caches are part of the reason many IDE and SCSI drives perform so well.

Although software and hardware caches can make a drive faster for routine transfer operations, a cache will not affect the true maximum transfer rate that the drive can sustain.

Interleave Selection

In a discussion of disk performance, the issue of interleave often comes up. Although traditionally this was more a controller performance issue than a drive issue, modern IDE and SCSI hard disk drives with built-in controllers are fully capable of processing the data as fast as the drive can send it. In other words, all modern IDE and SCSI drives are formatted with no interleave (sometimes expressed as a 1:1 interleave ratio). On older hard drive types, such as MFM and ESDI, you could modify the interleave during a low-level format to optimize the drive's performance. Today, drives are low-level formatted at the factory and interleave adjustments are a moot topic. Since altering the interleave or sector ordering in any way requires a low-level format to be performed, all data is normally lost in this process.

When a disk is low-level formatted, numbers are assigned to the sectors. These numbers are written in the Sector ID fields in the Sector header and can be written or updated only by a low-level format. With older drive interfaces that used discrete controllers such as ST-506/412 or ESDI, you often had to calculate the best interleave value for the particular controller and system that you were using. This allowed you to low-level format the drive and number the sectors to offer optimum performance.

Notice that nearly all IDE and SCSI drives have interleave ratios fixed at 1:1 and built-in controllers that can handle these ratios with no problem. In these drives, there no longer is a need to calculate or specify an interleave ratio, but knowing about interleaving can give you some further insight into the way these drives function.

Many older ST-506/412 controllers could not handle the sectors as quickly as the drive could send them. Suppose that you have a standard ST-5096/412 drive with 17 sectors on each track and you low-level formatted the drive and specified a 1:1 interleave—numbered the sectors on each track consecutively.

Now suppose that you want to read some data from the drive. The controller commands the drive to position the heads at a specific track and to read all 17 sectors from that track. The heads move and arrive at the desired track. The time it takes for the heads to move is called the seek time. When the heads arrive at the desired track, you have to wait for an average half-revolution of the disk for the first sector to arrive. This wait is called *latency*. After an average latency of half of a disk revolution, the sector numbered 1 arrives below the heads. While the disk continues to spin at 3,600rpm (60 revolutions per second), the data is read from Sector 1, and as the data is being transferred from the controller to the system board, the disk continues to spin. Finally, the data is completely moved to the motherboard, and the controller is ready for Sector 2. Figure 10.17 shows what is happening.

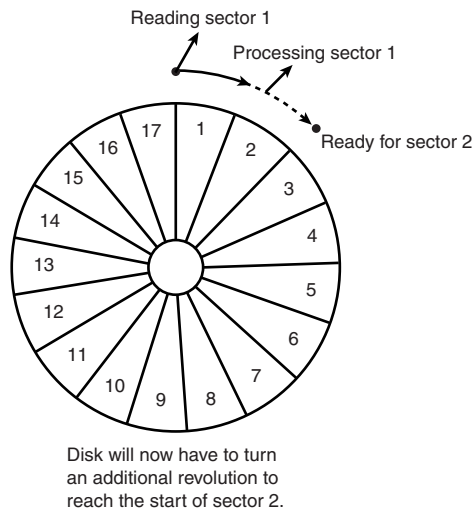

Figure 10.17 A hard disk interleave ratio (1:1) too low for the controller.

But wait, there's a problem here. Because the disk continues to spin at such a high rate of speed, the Sector 2 passed below the head while the controller was working, and by the time the controller is ready again, the heads will be coming to the start of Sector 3. Because the controller needs to read sector 2 next, however, the controller must wait for the disk to spin a full revolution, or until the start of Sector 2 comes below the heads. After this additional disk revolution, Sector 2 arrives below the heads and is read. While the controller is transferring the data from

Sector 2 to the motherboard, Sector 3 passes below the heads. When the controller finally is ready to read Sector 3, the heads are coming to the start of Sector 4, so another complete revolution is required, and the controller will have to get Sector 4 on the next go-around. This scenario continues, with each new revolution allowing only one sector to be read and missing the next sector because that sector passes below the heads before the controller is ready.

As you can see, the timing of this procedure is not working out very well. At this pace, 17 full revolutions of the disk will be required to read all 17 sectors. Because each revolution takes $1/60$ of one second, it will take $17/60$ of one second to read this track, or almost one-third of a second—a very long time, by computer standards.

Can this performance be improved? You notice that after reading a specific sector from the disk, the controller takes some time to transfer the sector data to the motherboard. The next sector that the controller can catch in this example is the second sector away from the first one. In other words, the controller seems to be capable of catching every second sector.

I hope that you now can imagine the perfect solution to this problem: Number the sectors out of order. The new numbering scheme takes into account how fast the controller works; the sectors are numbered so that each time the controller is ready for the next sector, the sector coming below the heads is numbered as the next sector that the controller will want to read. Figure 10.18 shows this new interleaved sector-numbering scheme.

Figure 10.18 A hard disk interleave ratio (2:1) matching the controller's capabilities.

The new numbering system eliminates the extra disk revolution that previously was required to pick up each sector. Under the new scheme, the controller will read all 17 sectors on the disk in only two complete revolutions. Renumbering the sectors on the disk in this manner is called *interleaving*, which normally is expressed as a ratio. The interleave ratio in this example is 2:1, which means that the next numbered sector is 2 sectors away from the preceding one. If the controller is capable of handling this, only two complete revolutions are needed to read an entire track. Thus, reading the track takes only $2/60$ of one second at the 2:1 interleave, rather than the

17/60 of one second required to read the disk at the 1:1 interleave—an improvement of 800 percent in the data transfer rate.

This example depicts a system in which the ideal interleave is 2:1. I used this example because most controllers that came in older 286 and 386 class systems worked in exactly this manner. If you set such a controller for a 1:1 interleave, you likely would make the drive eight times slower than it should be. This situation, however, has changed with newer controller technology.

The correct interleave for an older system depends primarily on the controller and secondarily on the speed of the system into which the controller is plugged. A controller and system that can handle a *consecutive sector interleave* (a 1:1 interleave) must transfer data as fast as the disk drive can present it; this used to be quite a feat but now is standard. Any 286 or faster system easily can handle the 1:1 interleave data transfer rate. The only types of systems that truly were too slow to handle a 1:1 interleave effectively are the original 4.77MHz PC- and XT-type systems. Those systems have a maximum throughput to the slots of just under 400KB per second—not fast enough to support a 1:1 interleave controller.

Head and Cylinder Skewing

Another performance adjustment that you could make at one time during a low-level format of a drive was to adjust the skew of the drive's heads and cylinders. Head skew is the offset in logical sector numbering between the same physical sectors on two tracks below adjacent heads of the same cylinder. The number of sectors skewed when switching from head to head within a single cylinder compensates for head switching and controller overhead time. *Cylinder skew* is the offset in logical sector numbering between the same physical sectors on two adjacent tracks on two adjacent cylinders.

Note that just as with interleaving, neither of these parameters is adjustable on modern IDE or SCSI drives. This information is relevant only for older drive technology. The discussion is included here to help understand what happens inside the drive. IDE and SCSI drives do use skewing, but it is factory preset and impossible to change.

With a 1:1 interleave controller, the maximum data transfer rate can be maintained when reading and writing sectors to the disk. Although it would seem that there is no other way to further improve efficiency and the transfer rate, there are two other factors that are similar to interleave: head and cylinder skewing.

When a drive is reading (or writing) data sequentially, all the sectors on a given track are read, and then the drive must electronically switch to the next head in the cylinder to continue the operation. If the sectors are not skewed from head to head within the cylinder, no delay occurs after the last sector on one track and before the arrival of the first sector on the next track. Because all drives require some time (although a small amount) to switch from one head to another, and because the controller also adds some overhead to the operation, it is likely that by the time the drive is ready to read the sectors on the newly selected track, the first sector will already have passed by. By skewing the sectors from one head to another—that is, rotating their arrangement on the track so that the arrival of the first sector is delayed relative to the preceding

track—you can ensure that no extra disk revolutions will be required when switching heads. This method provides the highest possible transfer rate when head switching is involved.

In a similar fashion, it takes considerable time for the heads to move from one cylinder to another. If the sectors on one cylinder were not skewed from those on the preceding adjacent cylinder, it is likely that by the time the heads arrive, the first sector will already have passed below them, requiring an additional revolution of the disk before reading of the new cylinder can begin. By skewing the sectors from one cylinder to the next, you can account for the cylinder-to-cylinder head-movement time and prevent any additional revolutions of the drive.

Head skew is the offset in logical sector numbering between the same physical sectors on two tracks below adjacent heads of the same cylinder. The number of sectors skewed when switching from head to head within a single cylinder is to compensate for head switching and controller overhead time. Think of it as the surface of each platter being rotated as you traverse from head to head. This method permits continuous read or write operations across head boundaries without missing any disk revolutions, thus maximizing system performance.

To understand head skew, you first need to know the order in which tracks and sectors are read from a disk. If you imagine a single-platter (two-head) drive with 10 cylinders and 17 sectors per track, the first sector that will be read on the entire drive is Cylinder 0, Head 0, Sector 1. Following that, all the remaining sectors on that first track (Cylinder 0, Head 0) will be read until Sector 17 is reached. After that, two things could take place: The heads could be moved so that the drive could continue reading the next track on the same side of the platter, or the second head could be selected, and therefore another entire track could be read with no head movement. Because head movement takes much longer than electronically selecting another head, all disk drives will select the subsequent heads on a cylinder before physically moving the heads to the next cylinder. Thus, the next sector to be read would be Cylinder 0, Head 1, Sector 1. Next, all the remaining sectors on that track are read (2–17), and then in our single platter example it is time to switch heads. This sequence continues until the last sector on the last track is read—in this example, Cylinder 9, Head 1, Sector 17.

If you could take the tracks off a cylinder in this example and lay them on top of one another, the tracks might look like this:

Cyl. 0, Head 0: 1- 2- 3- 4- 5- 6- 7- 8- 9- 10- 11- 12- 13- 14- 15- 16- 17-

Cyl. 0, Head 1: 1- 2- 3- 4- 5- 6- 7- 8- 9- 10- 11- 12- 13- 14- 15- 16- 17-

After reading all the sectors on Head 0, the controller switches heads to Head 1 and continues the read (looping around to the beginning of the track). In this example, the sectors were not skewed at all between the heads, which means that the sectors are directly above and below one another in a given cylinder.

Now the platters in this example are spinning at 3,600rpm, so one sector is passing below a head once every 980 millionths of a second! This obviously is a very small timing window. It takes some time for the head switch to occur (usually, 15 millionths of a second), plus some overhead time for the controller to pass the head-switch command. By the time the head switch is complete and you are ready to read the new track, Sector 1 has already gone by! This problem is

similar to interleaving when the interleave is too low. The drive is forced to wait while the platter spins around another revolution so that it can begin to pick up the track, starting with Sector 1.

This problem is easy to solve: Offset the sector numbering on subsequent tracks from those that precede them sufficiently to account for the head-switching and controller overhead time. That way, when Head 0, Sector 17 finishes and the head switches, Head 1, Sector 1 arrives right on time. The result looks something like this:

```
Cyl. 0, Head 0: 1- 2- 3- 4- 5- 6- 7- 8- 9- 10- 11- 12- 13- 14- 15- 16- 17-
```

```
Cyl. 0, Head 1: 16- 17- 1- 2- 3- 4- 5- 6- 7- 8- 9- 10- 11- 12- 13- 14- 15-
```

Shifting the second track by two sectors provides time to allow for the head-switching overhead and is the equivalent to a head-skew factor of 2. In normal use, a drive switches heads much more often than it switches physical cylinders, which makes head skew more important than cylinder skew. Throughput can rise dramatically when a proper head skew is in place. Different head skews can account for different transfer rates among drives that have the same number of sectors per track and the same interleave.

A nonskewed MFM drive, for example, might have a transfer rate of 380KB per second, whereas the transfer rate of a drive with a head skew of 2 could rise to 425KB per second. Notice that different controllers and drives have different amounts of overhead, so real-world results will be different in each case. In most cases, the head-switch time is very small compared with the controller overhead. As with interleaving, it is better to be on the conservative side to avoid additional disk revolutions.

Cylinder skew is the offset in logical sector numbering between the same physical sectors on two adjacent tracks on two adjacent cylinders.

The number of sectors skewed when switching tracks from one cylinder to the next is to compensate for track-to-track seek time. In essence, all the sectors on adjacent tracks are rotated with respect to each other; this method permits continuous read or write operations across cylinder boundaries without missing any disk revolutions, thus maximizing system performance.

Cylinder skew is a larger numerical factor than head skew because more overhead exists. It takes much longer to move the heads from one cylinder to another than to switch heads. Also, the controller overhead in changing cylinders is higher as well.

Following is a depiction of our sample drive with a head-skew factor of 2 but no cylinder skew.

```
Cyl. 0, Head 0: 1- 2- 3- 4- 5- 6- 7- 8- 9- 10- 11- 12- 13- 14- 15- 16- 17-
```

```
Cyl. 0, Head 1: 16- 17- 1- 2- 3- 4- 5- 6- 7- 8- 9- 10- 11- 12- 13- 14- 15-
```

```
Cyl. 1, Head 0: 8- 9- 10- 11- 12- 13- 14- 15- 16- 17- 1- 2- 3- 4- 5- 6- 7-
```

In this example, the cylinder-skew factor is 8. Shifting the sectors on the subsequent cylinder by eight sectors gives the drive and controller time to be ready for Sector 1 on the next cylinder and eliminates an extra revolution of the disk.

Today's IDE and SCSI drives have their interleave and skew factors set to their optimum values by the manufacturer. In virtually all cases, you cannot change these values. In the cases where you

can, the most likely result is decreased performance. For this reason, most IDE drive manufacturers recommend against low-level formatting their drives. With some IDE drives, unless you use the right software, you might alter the optimum skew settings and slow down the drive's transfer rate. Drives that use zoned bit recording (which would be virtually all drives made in the last several years) cannot ever have the interleave or skew factors changed, and as such, they are fully protected. No matter how you try to format these drives, the interleave and skew factors cannot be altered. The drive will ignore any specific sector ordering requests during the format.

Shock Mounting

Most hard disks manufactured today have a *shock-mounted* HDA, which means that there is a rubber cushion placed between the disk drive body and the mounting chassis. Some drives use more rubber than others, but for the most part, a shock mount is a shock mount. Some drives do not have a shock-isolated HDA because of physical or cost constraints. Be sure that the drive you are using has adequate shock-isolation mounts for the HDA, especially if you are using the drive in a portable PC system or in a system used in a non-office environment where conditions might be less favorable. I usually never recommend a drive that lacks at least some form of shock mounting.

Cost

The cost of hard disk storage is continually falling and can now be as little as 4 cents per megabyte or less. You can now purchase a 10GB IDE drive for under \$150.

That places the value of the 10MB drive I bought in 1983 at about 15 cents. (Too bad that I paid \$1,800 for it at the time!)

Of course, the cost of drives continues to fall, and eventually, even 1.5 cents per megabyte will seem expensive. Because of the low costs of disk storage today, not many drives with capacities of less than 10GB are even being manufactured.

Capacity

There are four figures commonly used in advertising drive capacity:

- Unformatted capacity, in millions of bytes
- Formatted capacity, in millions of bytes
- Unformatted capacity, in megabytes
- Formatted capacity, in megabytes

The term *formatted*, in these figures, refers to the low-level (or physical) formatting of the drive. Most manufacturers of IDE and SCSI drives now report only the formatted capacities because these drives are delivered preformatted. Usually, advertisements and specifications refer to the unformatted or formatted capacity in millions of bytes, because these figures are larger than the same capacity expressed in megabytes. This situation generates a great deal of confusion when the user runs FDISK (which reports total drive capacity in megabytes) and wonders where the missing space is. This question can seem troubling. Fortunately, the answer is easy; it only involves a little math to figure it out.

Perhaps the most common questions I get are concerning “missing” drive capacity. Consider the following example: I just installed a new Western Digital AC2200 drive, billed as 212MB. When I entered the drive parameters (989 cylinders, 12 heads, 35 sectors per track), both the BIOS Setup routine and FDISK report the drive as only 203MB! “What happened to the other 9MB?”

The answer is only a few calculations away. By multiplying the drive specification parameters, you get this result:

Cylinders:	989
Heads:	12
Sectors per track:	35
Bytes per sector:	512
Total bytes (in millions):	212.67
Total megabytes:	202.82

The result figures to a capacity of 212.67 million bytes or 202.82MB. Drive manufacturers usually report drive capacity in millions of bytes because they result in larger, more impressive sounding numbers, although your BIOS and the FDISK program usually report the capacity in megabytes. One megabyte equals 1,048,576 bytes (or 1,024KB in which each kilobyte is 1,024 bytes). So the bottom line is that, because the same abbreviations are often used for both millions of bytes and megabytes, this 212.67MB drive also is a 202.82MB drive!

One additional item to note about this particular drive is that it is a zoned bit recording drive and the actual physical parameters are different. Physically, this drive has 1,971 cylinders and 4 heads; however, the total number of sectors on the drive (and, therefore, the capacity) is the same no matter how you translate the parameters.

Although Western Digital does not report the unformatted capacity of this particular drive, unformatted capacity usually works out to be about 19 percent larger than a drive’s formatted capacity. The Seagate ST-12550N Barracuda 2GB drive, for example, is advertised as having the following capacities:

Unformatted capacity:	2,572.00 million bytes
Unformatted capacity:	2,452.85 megabytes
Formatted capacity:	2,139.00 million bytes
Formatted capacity:	2,039.91 megabytes

Each of these four figures is a correct answer to the question, “What is the storage capacity of the drive?” As you can see, however, the numbers are different. In fact, there is yet another number you can use. Divide the 2,039.91 megabytes by 1,024, and the drive’s capacity is 1.99GB! So when you are comparing or discussing drive capacities, make sure that you are working with a consistent unit of measure, or your comparisons will be meaningless.

Specific Recommendations

If you are going to add a hard disk to a system today, I can give you a few recommendations. For the drive interface, there really are only two types to consider:

- IDE (Integrated Drive Electronics)
- SCSI (Small Computer System Interface)

SCSI offers great expandability, cross-platform compatibility, high capacity, performance, and flexibility. IDE is less expensive than SCSI and also offers a very high-performance solution, but expansion, compatibility, capacity, and flexibility are more limited when compared with SCSI. I usually recommend IDE for most people for two reasons. First, the interface is already integrated into virtually every motherboard and BIOS sold today. Second, most users will not need more capacity than the four devices supported by the standard primary and secondary IDE interfaces found in most systems. SCSI offers additional performance potential with a multithreaded operating system such as Windows NT, as well as support for more devices, but it also requires the purchase of a separate host adapter card, which is in addition to the higher cost for the drive itself.

Note

Note that the current IDE standard is ATA-4 (AT Attachment), otherwise loosely called Fast ATA or Enhanced IDE. SCSI-3 is the most current SCSI standard, which although not fully approved, is nearing completion.

Floppy Disk Storage

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Floppy Disk Drives

Drive Components

Disk Physical Specifications and Operation

Types of Floppy Disk Drives

Analyzing Floppy Disk Construction

Drive-Installation Procedures

Troubleshooting Floppy Drives

Repairing Floppy Disk Drives

Floppy Disk Drives

This chapter examines floppy disk drives and disks. It explores the different types of drives and disks that have been and are now available, how they function, and how to properly install and service these drives and disks.

Alan Shugart is generally credited with inventing the floppy disk drive in 1967 while working for IBM. One of Shugart's senior engineers, David Noble, actually proposed the flexible medium (then 8 inches in diameter) and the protective jacket with the fabric lining. Shugart left IBM in 1969, and in 1976 his company, Shugart Associates, introduced the minifloppy (5 1/4-inch) disk drive. It, of course, became the standard eventually used by personal computers, rapidly replacing the 8-inch drives. He also helped create the Shugart Associates System Interface (SASI), which was later renamed SCSI (Small Computer System Interface) when approved as an ANSI standard.

Sony introduced the first 3 1/2-inch microfloppy drives and diskettes in 1983. The first significant company to adopt the 3 1/2-inch floppy for general use was Hewlett-Packard in 1984 with their partially PC-compatible HP-150 system. The industry adoption of the 3 1/2-inch drive was furthered by Apple using it in the first Macintosh systems in 1984, and IBM putting it into their entire PC product line starting in 1986.

Note that all PC floppy disk drives are still based on (and mostly compatible with) the original Shugart designs, including the electrical and command interfaces. Compared to other parts of the PC, the floppy disk drive has undergone relatively few changes over the years.

Drive Components

All floppy disk drives, regardless of type, consist of several basic common components. To properly install and service a disk drive, you must be able to identify these components and understand their functions (see Figure 11.1).

Read/Write Heads

A floppy disk drive normally has two read/write heads, one for each side of the disk, with both heads being used for reading and writing on their respective disk sides (see Figure 11.2). At one time, single-sided drives were available for PC systems (the original PC had such drives), but today single-sided drives are a fading memory.

Note

Many people do not realize that the first head on a floppy disk drive is the bottom one. Single-sided drives, in fact, used only the bottom head; the top head was replaced by a felt pressure pad. Another bit of disk trivia is that the top head (Head 1) is not directly over the bottom head (Head 0). The top head is offset either four or eight tracks inward from the bottom head, depending on the drive type.

Figure 11.1 A typical floppy disk drive.

Figure 11.2 A double-sided drive head assembly.

The head mechanism is moved by a motor called a *head actuator*. The heads can move in and out over the surface of the disk in a straight line to position themselves over various tracks. On a floppy drive, the heads move in and out tangentially to the tracks that they record on the disk. This is different from hard disks where the heads move on a rotating arm similar to the tone-arm of a record player. Because the top and bottom heads are mounted on the same rack, or mechanism, they move in unison and cannot move independently of each other. Both the upper and lower heads each define tracks on their respective side of the disk medium, while at any given head position, the tracks under the top and bottom head simultaneously are called a *cylinder*. Most floppy disks are recorded with 80 tracks on each side (160 tracks total), which would be 80 cylinders.

The heads themselves are made of soft ferrous (iron) compounds with electromagnetic coils. Each head is a composite design, with a read/write head centered within two tunnel-erase heads in the same physical assembly (see Figure 11.3).

Figure 11.3 Composite construction of a typical floppy disk drive head.

Floppy disk drives use a recording method called *tunnel erasure*. As the drive writes to a track, the trailing tunnel-erase heads erase the outer bands of the track, trimming it cleanly on the disk. The heads force the data into a specified narrow “tunnel” on each track. This process prevents the signal from one track from being confused with the signals from adjacent tracks, which would happen if the signal were allowed to naturally “taper off” to each side. *Alignment* is the placement of the heads with respect to the tracks they must read and write. Head alignment can be checked only against some sort of reference-standard disk recorded by a perfectly aligned machine. These types of disks are available, and you can use one to check your drive’s alignment. However, this is usually not practical for the end user, because one calibrated analog alignment disk can cost more than a new drive.

The floppy disk drive's two heads are spring-loaded and physically grip the disk with a small amount of pressure, which means that they are in direct contact with the disk surface while reading and writing to the disk. Because floppy disk drives spin at only 300 or 360rpm, this pressure does not present an excessive friction problem. Some newer disks are specially coated with Teflon or other compounds to further reduce friction and enable the disk to slide more easily under the heads. Because of the contact between the heads and disk, a buildup of the magnetic material from the disk eventually forms on the heads. The buildup should periodically be cleaned off the heads as part of a preventive-maintenance or normal service program. Most manufacturers recommend cleaning the heads after every 40 hours of drive operation, which, considering how many people use these drives today, could be a lifetime.

To read and write to the disk properly, the heads must be in direct contact with the magnetic medium. Very small particles of loose oxide, dust, dirt, smoke, fingerprints, or hair can cause problems with reading and writing the disk. Disk and drive manufacturers' tests have found that a spacing as little as .000032 inch (32 millionths of an inch) between the heads and medium can cause read/write errors. You now can understand why it is important to handle disks carefully and avoid touching or contaminating the surface of the disk medium in any way. The rigid jacket and protective shutter for the head access aperture on 3 1/2-inch disks is excellent for preventing problems caused by contamination. Disks that are 5 1/4-inch do not have the same protective elements, which is perhaps one reason why they have fallen into disuse. If you still use 5 1/4-inch floppy disks, you should exercise extra care in their handling.

The Head Actuator

The head actuator for a floppy disk drive uses a special kind of motor, called a *stepper motor*, that rotates in discrete increments or steps (see Figure 11.4). This type of motor does not spin around continuously; rather, the motor turns a precise specified distance and stops. Stepper motors are not infinitely variable in their positioning; they move in fixed increments, or *detents*, and must stop at a particular detent position. This is ideal for disk drives, as the location of each track on the disk can then be defined by moving one or more increments of the motor's motion. The disk controller can instruct the motor to position itself any number of steps within the range of its travel. To position the heads at cylinder 25, for example, the controller instructs the motor to go to the 25th detent position or step from Cylinder 0.

The stepper motor can be linked to the head rack in one of two ways. In the first, the link is a coiled, split-steel band. The band winds and unwinds around the spindle of the stepper motor, translating the rotary motion into linear motion. Some drives, however, use a worm-gear arrangement rather than a band. In this type of drive, the head assembly rests on a worm gear driven directly off the stepper motor shaft. Because this arrangement is more compact, you normally find worm-gear actuators on the smaller 3 1/2-inch drives.

Most stepper motors used in floppy disk drives can step in specific increments that relate to the track spacing on the disk. Older 48 Track Per Inch (TPI) drives have a motor that steps in increments of 3.6 degrees. This means that each 3.6 degrees of stepper motor rotation moves the heads from one track to the next. Most 96 or 135 TPI drives have a stepper motor that moves in 1.8 degree increments, which is exactly half of what the 48 TPI drives use. Sometimes you see

this information actually printed or stamped right on the stepper motor itself, which is useful if you are trying to figure out what type of drive you have. 5 1/4-inch 360K drives were the only 48 TPI drives that used the 3.6 degree increment stepper motor. All other drive types normally use the 1.8 degree stepper motor. On most drives, the stepper motor is a small cylindrical object near one corner of the drive.

Figure 11.4 An expanded view of a stepper motor and head actuator.

A stepper motor usually has a full travel time of about 1/5 of a second—about 200ms. On average, a half-stroke is 100ms, and a one-third stroke is 66ms. The timing of a one-half or one-third stroke of the head-actuator mechanism is often used to determine the reported average-access time for a disk drive. Average-access time is the normal amount of time the heads spend moving at random from one track to another.

The Spindle Motor

The spindle motor is what spins the disk. The normal speed of rotation is either 300 or 360rpm, depending on the type of drive. The 5 1/4-inch high-density (HD) drive is the only drive that spins at 360rpm; all others, including the 5 1/4-inch double-density (DD), 3 1/2-inch DD, 3 1/2-inch HD, and 3 1/2-inch extra-high density (ED) drives, spin at 300rpm. This is a slow speed when compared to a hard disk drive, which helps to explain why floppy disk drives have much lower data transfer rates. However, this slow speed also makes it possible for the drive heads to be in physical contact with the disk while it is spinning, without causing friction damage.

Most earlier drives used a mechanism by which the spindle motor physically turned the disk spindle with a belt, but all modern drives use a direct-drive system with no belts. The direct-drive systems are more reliable and less expensive to manufacture, as well as smaller in size. The earlier

belt-driven systems did have more rotational torque available to turn a sticky disk because of the torque multiplication factor of the belt system. Most newer direct-drive systems use an automatic torque-compensation capability that sets the disk-rotation speed to a fixed 300 or 360rpm, and compensates with additional torque for high-friction disks or less torque for more slippery ones. Besides compensating for different amounts of friction, this arrangement eliminates the need to adjust the rotational speed of the drive, something that was frequently required on older drives.

Circuit Boards

A disk drive always incorporates one or more *logic boards*, which are circuit boards that contain the circuitry used to control the head actuator, read/write heads, spindle motor, disk sensors, and other components on the drive. The logic board implements the drive's interface to the controller board in the system unit.

The standard interface used by all PC floppy disk drives is termed the Shugart Associates SA-400 interface, which was invented in the 1970s and is based on the NEC 765 controller chip. All modern floppy controllers contain circuits that are compatible with the original NEC 765 chip. This industry-standard interface is why you can purchase “off-the-shelf” drives (raw, or bare, drives) that can plug directly into your controller.

Tip

Logic boards for a drive can fail and usually are difficult to obtain as a spare part. One board often costs more than replacing the entire drive. I recommend keeping failed or misaligned drives that might otherwise be discarded so they can be used for their remaining good parts, such as logic boards. You can use the parts to restore a failing drive very cost-effectively.

The Controller

At one time, the controller for a computer's floppy disk drives took the form of a dedicated expansion card installed in an ISA bus slot. Later implementations used a multifunction card that provided the IDE/ATA, parallel, and serial port interfaces in addition to the floppy disk drive controller. Today's PCs have the floppy controller integrated into the motherboard, usually in the form of a Super I/O chip that also includes the parallel and serial interfaces, among other things. Even though the floppy controller can be found in the Super I/O chip on the motherboard, it is still interfaced to the system via the ISA (Industry Standard Architecture) bus, and functions exactly as if it were a card installed in an ISA slot. These built-in controllers are normally configured via the system BIOS Setup routines, and can be disabled if an actual floppy controller card is going to be installed.

Whether it is built-in or not, all primary floppy controllers use a standard set of system resources as follows:

- IRQ 6 (Interrupt Request)
- DMA 2 (Direct Memory Address)
- I/O ports 3F0-3F5, 3F7 (Input/Output)

These system resources are standardized and generally not changeable. This normally does not present a problem because no other devices will try to use these resources (which would result in a conflict).

◀◀ See “System Resources,” p. 311.

Unlike the IDE interface, the floppy disk controller has not changed much in recent years. Virtually the only thing that has changed is the controller's maximum speed. As the data density of floppy disks (and their capacity) has increased over the years, the controller speed has had to increase, as well. Nearly all floppy disk controllers in computers today support speeds of up to 1Mbit/sec, which supports all the standard floppy disk drives. 500Kbit/sec controllers can support all floppy disk drives except for the 2.88MB extra high-density models. Older computers used 250Kbit/sec controllers that could support only 360KB 5 1/4-inch and 720KB 3 1/2-inch drives. To install a standard 1.44MB 3 1/2-inch drive in an older machine, you might have to replace the floppy controller with a faster model.

Tip

The best way to determine the speed of the floppy disk drive controller in your computer is to examine the floppy disk drive options provided by the system BIOS.

◀◀ See “Motherboard BIOS,” p. 349.

Even if you do not intend to use a 2.88MB floppy disk drive, you still might want to make sure that your computer has the fastest possible controller. Some of the tape drives on the market use the floppy disk interface to connect to the system, and in this case the controller has a profound effect on the overall throughput of the tape drive.

The Faceplate

The *faceplate*, or *bezel*, is the plastic piece that comprises the front of the drive. These pieces, usually removable, come in different colors and configurations.

Most drives use a bezel that is slightly wider than the drive. You have to install these types of drives from the front of a system because the faceplate is slightly wider than the hole in the computer case. Other drive faceplates are the same width as the drive's chassis; you can install these drives from the rear—an advantage in some cases.

Most floppy drive manufacturers offer drives with matching faceplates in gray, beige, or black, and with a choice of red, green, or yellow activity LEDs as well. This allows a system builder to better match the drive to the aesthetics of the case for a seamless, integrated and more professional look.

Connectors

Nearly all floppy disk drives have two connectors—one for power to run the drive and the other to carry the control and data signals to and from the drive. These connectors are fairly standardized

in the computer industry. A four-pin in-line connector (called Mate-N-Lock, by AMP), in both a large and small style, is used for power (see Figure 11.5); and a 34-pin connector in both edge and pin header designs is used for the data and control signals. Normally, 5 1/4-inch drives use the large style power connector and the 34-pin edge type connector, while most 3 1/2-inch drives use the smaller version of the power connector and the 34-pin header type logic connector. The drive controller and logic connectors and pinouts are detailed later in this chapter as well as on the CD-ROM Vendor List.

Figure 11.5 A disk drive female power supply cable connector.

Both the large and small power connectors from the power supply are female plugs. They plug into the male portion, which is attached to the drive itself. One common problem with upgrading an older system with 3 1/2-inch drives is that your power supply only has the large style connectors, while the drive has the small style. An adapter cable is available, from Radio Shack (Cat. No. 278-765) and other sources, which converts the large-style power connector to the proper small style used on most 3 1/2-inch drives.

Most standard PCs use 3 1/2-inch drives with a 34-pin signal connector and a separate small-style power connector. For older systems, many drive manufacturers also sell 3 1/2-inch drives installed in a 5 1/4-inch frame assembly with a special adapter built in that enables you to use the larger power connector and standard edge-type signal connectors. Because no cable adapters are required and they install in a 5 1/4-inch half-height bay, these types of drives are ideal for upgrading earlier systems. Most 3 1/2-inch drive-upgrade kits sold today are similar and include the drive, appropriate adapters for the power and control and data cables, a 5 1/4-inch frame adapter and faceplate, and mounting rails. The frame adapter and faceplate enable you to install the drive where a 5 1/4-inch half-height drive would normally go.

The Floppy Disk Drive Cable

The 34-pin connector on a floppy disk drive takes the form of either an edge connector (on 5 1/4-inch drives) or a pin connector (on 3 1/2-inch drives). The pinouts for the connector are shown in Table 11.1.

Table 11.1 Pinouts for the Standard Floppy Disk Drive Connector

Pin	Signal	Pin	Signal	Pin	Signal
1	Ground	13	Ground	24	Write Enable
2	Unused	14	Drive Select A	25	Ground
3	Ground	15	Ground	26	Track 0
4	Unused	16	Motor Enable B	27	Ground
5	Ground	17	Ground	28	Write Protect
6	Unused	18	Direction (Stepper motor)	29	Ground
7	Ground	19	Ground	30	Read Data
8	Index	20	Step Pulse	31	Ground
9	Ground	21	Ground	32	Select Head 1
10	Motor Enable A	22	Write Data	33	Ground
11	Ground	23	Ground	34	Ground
12	Drive Select B				

The cable used to connect the floppy disk drive(s) to the controller on the motherboard is quite strange. To support various drive configurations, the cable typically has five connectors on it, two edge connectors and two pin connectors to attach to the drives, and one pin connector to connect to the controller. The cable has redundant connectors for each of the two drives (A and B) supported by the standard floppy disk drive controller, so you can install any combination of 5 1/4-inch and 3 1/2-inch drives (see Figure 11.6).

**Figure 11.6** Standard five-connector floppy interface cable.

In addition to the connectors, the cable on most systems has a special twist that inverts the signals of wires 10–16. These are the wires carrying the Drive Select and Motor Enable signals for each of the two drives. Floppy disk drives have DS (Drive Select) jumpers that were designed to enable you to select whether a given drive should be recognized as A or B.

You may not even know that these jumpers exist, because the twist in the cable prevents you from having to adjust them. When installing two floppy disk drives in one system (admittedly a rarity nowadays), the cable electrically changes the DS configuration of the drive that is plugged in after the twist. Thus, the twist causes a drive physically set to the second DS position (B) to appear to the controller to be set to the first DS position (A) and vice versa. The adoption of this cable has made it possible to use a standard jumper configuration for all floppy disk drives, regardless of whether you install one or two drives in a computer.

If you install only a single floppy disk drive, you use the connector after the twist, which will cause the drive to be recognized as drive A.

Disk Physical Specifications and Operation

Most of the PCs sold today are equipped with a 3 1/2-inch 1.44MB floppy disk drive. You might run into an older system that has a 5 1/4-inch 1.2MB drive instead of, or in addition to, the 3 1/2-inch drive. There are also PC systems which have a 2.88MB 3 1/2-inch drive that can also read and write 1.44MB disks. The older drive types—5 1/4-inch 360KB and 3 1/2-inch 720KB—are obsolete and rarely found anymore.

The physical operation of a disk drive is fairly simple to describe. The disk rotates in the drive at either 300 or 360rpm. Most drives spin at 300rpm; only the 5 1/4-inch 1.2MB drives spin at 360rpm. With the disk spinning, the heads can move in and out approximately one inch and write 80 tracks. The tracks are written on both sides of the disk and are therefore sometimes called cylinders. A single cylinder comprises the tracks on the top and bottom of the disk. The heads record by using a tunnel-erase procedure that writes a track to a specified width, and then erases the edges of the track to prevent interference with any adjacent tracks.

Different drives record tracks at different widths. Table 11.2 shows the track widths in both millimeters and inches for the different types of floppy disk drives found in modern PC systems.

Table 11.2 Floppy Disk Drive Track-Width Specifications

Drive Type	No. of Tracks	Track Width	
5 1/4-in. 360KB	40 per side	0.300mm	0.0118 in.
5 1/4-in. 1.2MB	80 per side	0.155mm	0.0061 in.
3 1/2-in. 720KB	80 per side	0.115mm	0.0045 in.
3 1/2-in. 1.44MB	80 per side	0.115mm	0.0045 in.
3 1/2-in. 2.88MB	80 per side	0.115mm	0.0045 in.

How the Operating System Uses a Disk

To the operating system, data on your PC disks is organized in tracks and sectors, just as on a hard disk drive. Tracks are narrow, concentric circles on a disk. Sectors are pie-shaped slices of the individual tracks.

Table 11.3 summarizes the standard disk formats for PC floppy disk drives.

Table 11.3 3 1/2-Inch and 5 1/4-Inch Floppy Disk Drive Formats

5 1/4-inch Floppy Disks	Double-Density 360KB (DD)	High-Density 1.2MB (HD)	
Bytes per Sector	512	512	
Sectors per Track	9	15	
Tracks per Side	40	80	
Sides	2	2	
Capacity (Kilobytes)	360	1,200	
Capacity (Megabytes)	0.352	1.172	
Capacity (Million Bytes)	0.369	1.229	

3 1/2-inch Floppy Disks	Double-Density 720KB (DD)	High-Density 1.44MB (HD)	Extra High-Density 2.88MB (ED)
Bytes per Sector	512	512	512
Sectors per Track	9	18	36
Tracks per Side	80	80	80
Sides	2	2	2
Capacity (kilobytes)	720	1,440	2,880
Capacity (megabytes)	0.703	1.406	2.813
Capacity (million bytes)	0.737	1.475	2.949

You can calculate the capacity differences between different formats by multiplying the sectors per track by the number of tracks per side together with the constants of two sides and 512 bytes per sector.

Note that the floppy disk's capacity can actually be expressed in different ways. The traditional method is to refer to the capacity of a floppy by the number of kilobytes (1,024 bytes equals 1KB). This works fine for the old-style 360KB and 720KB disks but is strange when applied to the 1.44MB and 2.88MB disks. As you can see, a 1.44MB disk is really 1,440KB and not actually 1.44 megabytes. Because a megabyte is 1,024KB, what we call a 1.44MB disk actually has a capacity of 1.406MB.

Another way of expressing disk capacity is in millions of bytes. In that case, the 1.44MB disk has 1.475 million bytes of capacity.

Note

Again, as with hard disk drives, both megabyte and millions of bytes are abbreviated as MB or M, often resulting in a great deal of confusion.

Like blank sheets of paper, new disks contain no information. Formatting a disk is similar to adding lines to the paper so you can write straight across. Formatting the disk writes the information that the operating system needs to maintain a directory and file table of contents. On a floppy disk, there is no distinction between a high-level and low-level format, nor do you have to create any partitions. When you format a floppy disk with Windows 9x Explorer or the DOS FORMAT.COM program, both the high- and low-level formats are performed at the same time.

When you format a floppy disk, the operating system reserves the track nearest to the outside edge of a disk (track 0) almost entirely for its purposes. Track 0, Side 0, Sector 1 contains the DOS Boot Record (DBR), or Boot Sector, that the system needs to begin operation. The next few sectors contain the FATs, which keep records of which clusters or allocation units on the disk contain file information and which are empty. Finally, the next few sectors contain the root directory, in which the operating system stores information about the names and starting locations of the files on the disk.

Cylinders

The cylinder number is usually used in place of track number, because all floppy drives today are double-sided. A cylinder on a floppy disk includes two tracks: the one on the bottom of the disk above head 0, and the one on the top of the disk below head 1. Because a disk cannot have more than two sides and the drive has two heads, there are always two tracks per cylinder for floppy disks. Hard disk drives on the other hand can have multiple disk platters, each with two heads, resulting in many tracks per single cylinder. The simple rule is that there are as many tracks per cylinder as there are heads on the drive.

Cylinders are discussed in more detail in Chapter 10, “Hard Disk Storage,” and Chapter 27, “File Systems and Data Recovery.”

Clusters or Allocation Units

A *cluster* also is called an *allocation unit* in DOS version 4.0 and higher. The term is appropriate because a single cluster is the smallest unit of the disk that DOS can allocate when it writes a file. A cluster or allocation unit consists of one or more sectors—usually a power of two (1, 2, 4, 8, and so on). Having more than one sector per cluster reduces the file allocation table (FAT) size and enables DOS to run faster because it has fewer individual clusters to manage. The tradeoff is in some wasted disk space. Because DOS can manage space only in the cluster size unit, every file consumes space on the disk in increments of one cluster.

For more information on allocation units, see Chapter 27.

Table 11.4 lists the default cluster sizes used by DOS and Windows for different floppy disk formats.

Table 11.4 Default Cluster and Allocation Unit Sizes

Floppy Disk Capacity	Cluster/Allocation Unit Size	FAT Type
5 1/4-in., 360KB	2 sectors	1,024 bytes 12-bit
5 1/4-in., 1.2MB	1 sector	512 bytes 12-bit
3 1/2-in., 720KB	2 sectors	1,024 bytes 12-bit
3 1/2-in., 1.44MB	1 sector	512 bytes 12-bit
3 1/2-in., 2.88MB	2 sectors	1,024 bytes 12-bit

KB = 1,024 bytes

MB = 1,048,576 bytes

Diskette Changeline

The standard PC floppy controller and drive use a special signal on pin 34 called *Diskette Changeline* to determine whether the disk has been changed. Or more accurately, to determine whether the same disk loaded during the previous disk access is still in the drive. Disk Change is a pulsed signal that changes a status register in the controller to let the system know that a disk has been either inserted or ejected. This register is set to indicate that a disk has been inserted or removed (changed) by default.

The register is cleared when the controller sends a step pulse to the drive and the drive responds, acknowledging that the heads have moved. At this point, the system knows that a specific disk is in the drive. If the disk change signal is not received before the next access, the system can assume that the same disk is still in the drive. Any information read into memory during the previous access can therefore be reused without rereading the disk.

Because of this process, systems can buffer or cache the contents of the FAT or directory structure of a disk in the system's memory. By eliminating unnecessary rereads of these areas of the disk, the apparent speed of the drive is increased. If you move the door lever or eject button on a drive that supports the disk change signal, the DC pulse is sent to the controller, thus resetting the register and indicating that the disk has been changed. This procedure causes the system to purge buffered or cached data that had been read from the disk because the system then cannot be sure that the same disk is still in the drive.

One interesting problem can occur when certain drives are installed in a 16-bit or greater system. As mentioned, some drives use pin 34 for a "Ready" (RDY) signal. The RDY signal is sent whenever a disk is installed and rotating in the drive. If you install a drive that has pin 34 set to send RDY, the system "thinks" that it is continuously receiving a disk change signal, which causes problems. Usually the drive fails with a Drive Not Ready error and is inoperable. The only reason that the RDY signal exists on some drives is that it happens to be a part of the standard Shugart SA-400 disk interface; however, it has never been used in PC systems.

The biggest problem occurs if the drive is not sending the DC signal on pin 34, and it should. If a system is told (through CMOS setup) that the drive is any other type than a 360KB (which cannot ever send the DC signal), the system expects the drive to send DC whenever a disk has been

ejected. If the drive is not configured properly to send the signal, the system never recognizes that a disk has been changed. Therefore, even if you do change the disk, the system still acts as though the first disk is in the drive and holds the first disk's directory and FAT information in RAM. This can be dangerous because the FAT and directory information from the first disk can be partially written to any subsequent disks written to in the drive.

Caution

If you ever have seen a system with a floppy disk drive that shows "phantom directories" of the previously installed disk, even after you have changed or removed it, you have experienced this problem firsthand. The negative side effect is that all disks after the first one you place in this system are in extreme danger. You likely will overwrite the directories and FATs of many disks with information from the first disk.

If even possible at all, data recovery from such a catastrophe can require quite a bit of work with utility programs such as Norton Utilities. These problems with Disk Change most often are traced to an incorrectly configured drive.

If the drive you are installing is a 5 1/4-inch 1.2MB or 3 1/2-inch 720KB, 1.44MB, or 2.88MB drive, be sure to set pin 34 to send the Disk Change (DC) signal.

Types of Floppy Disk Drives

The characteristics of the floppy disk drives you might encounter in PC-compatible systems are summarized in Table 11.5. As you can see, the different disk capacities are determined by several parameters, some of which seem to remain constant on all drives, although others change from drive to drive. For example, all drives use 512-byte physical sectors, which is true for hard disks as well.

Table 11.5 Floppy Disk Logical Formatted Parameters

Disk Size (inches)	Current Formats					Obsolete Formats		
	3 1/2	3 1/2	3 1/2	5 1/4	5 1/4	5 1/4	5 1/4	5 1/4
Disk Capacity (KB)	2,880	1,440	720	1,200	360	320	180	160
Media Descriptor Byte	FOh	FOh	F9h	F9h	FDh	FFh	FCh	FEh
Sides (Heads)	2	2	2	2	2	2	1	1
Tracks per Side	80	80	80	80	40	40	40	40
Sectors per Track	36	18	9	15	9	8	9	8
Bytes per Sector	512	512	512	512	512	512	512	512
Sectors per Cluster	2	1	2	1	2	2	1	1
FAT Length (Sectors)	9	9	3	7	2	1	2	1
Number of FATs	2	2	2	2	2	2	2	2
Root Dir. Length (Sectors)	15	14	7	14	7	7	4	4
Maximum Root Entries	240	224	112	224	112	112	64	64
Total Sectors per Disk	5,760	2,880	1,440	2,400	720	640	360	320
Total Available Sectors	5,726	2,847	1,426	2,371	708	630	351	313
Total Available Clusters	2,863	2,847	713	2,371	354	315	351	313

The 1.44MB 3 1/2-Inch Drive

The 3 1/2-inch, 1.44MB, high-density (HD) drives first appeared from IBM in the PS/2 product line introduced in 1987. Most other computer vendors started offering the drives as an option in their systems immediately afterward. This type of drive is still the most popular in systems today.

The drive records 80 cylinders consisting of two tracks each with 18 sectors per track, resulting in a formatted capacity of 1.44MB. Some disk manufacturers label these disks as 2.0MB, and the difference between this unformatted capacity and the formatted usable result is lost during the format. Note that the 1,440KB of total formatted capacity does not account for the areas that the FAT file system reserves for file management, leaving only 1,423.5KB of actual file-storage area.

The drive spins at 300rpm, and in fact must spin at that speed to operate properly with existing high- and low-density controllers. To use the 500KHz data rate (the maximum from most standard high- and low-density floppy controllers), these drives must spin at a maximum of 300rpm. If the drives were to spin at the faster 360rpm rate of the 5 1/4-inch drives, they would have to reduce the total number of sectors per track to 15, or else the controller could not keep up. In short, the 1.44MB 3 1/2-inch drives store 1.2 times the data of the 5 1/4-inch 1.2MB drives, and the 1.2MB drives spin exactly 1.2 times faster than the 1.44MB drives. The data rates used by both of these HD drives are identical and compatible with the same controllers. In fact, because these 3 1/2-inch HD drives can run at the 500KHz data rate, a controller that can support a 1.2MB 5 1/4-inch drive can also support the 1.44MB drives.

The 2.88MB 3 1/2-Inch Drive

The 3 1/2-inch, 2.88MB drive was developed by Toshiba Corporation in the 1980s and was officially announced in 1987. Toshiba began production manufacturing of the drives and disks in 1989, and several vendors began selling the drives as upgrades for their systems. IBM officially adopted these drives in their PS/2 systems in 1991, and a number of manufacturers began making them, including Toshiba, Mitsubishi, Sony, and Panasonic. Because a 2.88MB drive can fully read and write 1.44MB disks, the change is an easy one. Unfortunately, due to high media costs and a relatively low increase in data capacity, these drives never caught on widely, although virtually all systems today have built-in support for them. DOS version 5.0 or later is required to support the 2.88MB drives.

The 2.88MB extra high-density (ED) drive uses a technique called *vertical recording* to achieve its great linear density of 36 sectors per track. This technique increases density by magnetizing the domains perpendicular to the recording surface. By essentially placing the magnetic domains on their ends and stacking them side by side, the disk density increases enormously.

The technology for producing heads that can perform a vertical or perpendicular recording has been around for some time. But, it is not the heads or even the drive that represent the major breakthrough in technology; rather, it is the medium that is special. Standard disks have magnetic particles shaped like tiny needles that lie on the surface of the disk. Orienting these acicular particles in a perpendicular manner to enable vertical recording is very difficult. The particles on a barium-ferrite floppy disk are shaped like tiny, flat, hexagonal platelets that can more easily be arranged to have their axes of magnetization perpendicular to the plane of recording.

Toshiba perfected a glass-crystallization process for manufacturing the ultra-fine platelets used in coating the barium-ferrite disks. This technology, patented by Toshiba, is being licensed to a number of disk manufacturers, all whom are producing barium-ferrite disks by using Toshiba's process. Toshiba also made certain modifications to the design of standard disk drive heads to enable them to read and write the new barium-ferrite disks, as well as standard cobalt or ferrite disks. This technology is being used not only in floppy disk drives but also is appearing in a variety of tape drive formats.

The disks are called 4MB disks in reference to their unformatted capacity. The actual formatted capacity is 2,880KB, or 2.88MB. Because of space lost in the formatting process, as well as space occupied by the volume boot sector, FATs, and root directory, the total usable storage space is 2,863KB.

To support the 2.88MB drive, modifications to the disk controller circuitry were required, because these drives spin at the same 300rpm but have an astonishing 36 sectors per track. Since all floppy disks are formatted with consecutively numbered sectors (1:1 interleave), the drive has to read and write 36 sectors in the same time it takes a 1.44MB drive to read and write 18 sectors. This requires that the controller support a much higher data transmission rate of 1MHz (1 million bps). Most older floppy controllers support only the maximum of 500KHz data rate used by the 1.44MB drives. To upgrade to a 2.88MB drive requires that the controller be changed to one that supports the higher 1MHz data rate.

An additional support issue is the ROM BIOS. The BIOS must have support for the controller and the capability to specify and accept the 2.88MB drive as a CMOS setting. Some newer motherboard BIOS sets from companies such as Phoenix, AMI, and Award have support for ED controllers.

Virtually all modern PCs have built-in floppy controllers and ROM BIOS software that fully support the 2.88MB drives. Adding or upgrading to a 2.88MB drive in these systems is as easy as plugging in the drive and running the CMOS Setup program. For systems that do not have this built-in support, the upgrade process is much more difficult. Several companies offer new controllers and BIOS upgrades as well as the 2.88MB drives specifically for upgrading older systems.

Although the 2.88MB drives themselves are not much more expensive than the 1.44MB drives they replace, the disk media can be expensive and hard to find, as this format never really caught on in the mainstream, although all modern PCs support it.

The 720KB 3 1/2-Inch Drive

The 720KB, 3 1/2-inch, DD drives first appeared in an IBM system with the IBM Convertible laptop system introduced in 1986. In fact, all IBM systems introduced since that time have 3 1/2-inch drives as the standard supplied drives. This type of drive also is offered by IBM as an internal or external drive for the AT or XT systems.

Note

Outside the PC-compatible world, other computer-system vendors (Apple, Hewlett-Packard, and so on) offered 3 1/2-inch drives for their systems two years before the PC-compatible world "caught on."

The 720KB, 3 1/2-inch, DD drive normally records 80 cylinders of two tracks each, with nine sectors per track, resulting in the formatted capacity of 720KB.

It is interesting to note that many disk manufacturers label these disks as 1.0MB disks, which is true. The difference between the actual 1.0MB of capacity and the usable 720KB after formatting is that some space on each track is occupied by the header and trailer of each sector, the inter-sector gaps, and the index gap at the start of each track before the first sector. These spaces are not usable for data storage and account for the differences between the unformatted and formatted capacities. Most manufacturers report the unformatted capacities because they do not know on which type of system you will format the disk. Apple Macintosh systems, for example, can store 800KB of data on the same disk because of a different formatting technique.

Note also that the 720KB of usable space does not account for the disk areas DOS reserves for managing the disk (boot sectors, FATs, directories, and so on). Because of these areas, only 713KB remains for file data storage.

PC-compatible systems have used 720KB, 3 1/2-inch DD drives primarily in XT-class systems because the drives operate from any low-density controller. The drives spin at 300rpm, and therefore require only a 250KHz data rate from the controller to operate properly. This data rate is the same as the 360KB disk drives, which means that any controller that supports a 360KB drive also supports the 720KB drives.

An IBM system with a ROM BIOS date of 06/10/85 or later has built-in support for 720KB drives and requires no driver to use them. If your system has an earlier ROM BIOS date, the DRIVER.SYS program from DOS V3.2 or later—as well as the DRIVPARM CONFIG.SYS command in some OEM DOS versions—is all you need to provide the necessary software support to operate these drives.

The 1.2MB 5 1/4-Inch Drive

The 1.2MB high-density floppy disk drive first appeared in the IBM AT system introduced in August 1984. The drive required the use of a new type of disk to achieve the 1.2MB format capacity, but it still could read and write (although not always reliably) the lower density 360KB disks.

The 1.2MB 5 1/4-inch drive normally recorded 80 cylinders of two tracks each, starting with cylinder 0 at the outside of the disk. This situation differs from the low-density 5 1/4-inch drive in its capability to record twice as many cylinders in approximately the same space on the disk. This capability alone suggests that the recording capacity for a disk would double, but that is not all. Each track normally is recorded with 15 sectors of 512 bytes each, increasing the storage capacity even more. In fact, these drives store nearly four times the data of the 360KB disks. The density increase for each track required the use of special disks with a modified medium designed to handle this type of recording. Because these disks initially were expensive and difficult to obtain, many users attempted incorrectly to use the low-density disks in the 1.2MB 5 1/4-inch drives and format them to the higher 1.2MB-density format, which resulted in data loss and unnecessary data-recovery operations.

A compatibility problem with the 360KB drives stems from the 1.2MB drive's capability to write twice as many cylinders in the same space as the 360KB drives. The 1.2MB drives position their

heads over the same 40 cylinder positions used by the 360KB drives through *double stepping*, a procedure in which the heads are moved every two cylinders to arrive at the correct positions for reading and writing the 40 cylinders on the 360KB disks. The problem is that because the 1.2MB drive normally has to write 80 cylinders in the same space in which the 360KB drive writes 40, the heads of the 1.2MB units had to be made dimensionally smaller. These narrow heads can have problems overwriting tracks produced by a 360KB drive that has a wider head because the narrower heads on the 1.2MB drive cannot “cover” the entire track area written by the 360KB drive.

The 1.2MB 5 1/4-inch drives spin at 360rpm, or six revolutions per second, or 166.67ms per revolution. The drives spin at this rate no matter what type of disk is inserted—either low- or high-density. To send or receive 15 sectors (plus required overhead) six times per second, a controller must use a data-transmission rate of 500,000bps (500KHz). All standard high- and low-density controllers support this data rate and, therefore, these drives.

This support depends also on proper ROM BIOS support of the controller in this mode of operation. When a standard 360KB disk is running in an HD drive, it also is spinning at 360rpm. A data rate of 300,000bps (300KHz), therefore, is required to work properly. All standard AT-style low- and high-density controllers support the 250KHz, 300KHz, and 500KHz data rates. The 300KHz rate is used only for HD 5 1/4-inch drives reading or writing to low-density 5 1/4-inch disks.

Virtually all standard AT-style systems have a ROM BIOS that supports the controller’s operation of the 1.2MB drive, including the 300KHz data rate.

The 360KB 5 1/4-Inch Drive

The 5 1/4-inch double-density drive is designed to create a standard-format disk with 360KB capacity. The term double-density arose from the use of the term single density to indicate a type of drive that used frequency modulation (FM) encoding to store approximately 90KB on a disk. This type of obsolete drive never was used in any PC-compatible systems, but was used in some older systems such as the original Osborne-1 portable computer. When drive manufacturers changed the drives to use Modified Frequency Modulation (MFM) encoding, they began using the term double-density to indicate it, as well as the (approximately doubled) increase in recording capacity realized from this encoding method.

The 360KB 5 1/4-inch drives spin at 300rpm, which equals exactly five revolutions per second, or 200ms per revolution. All standard floppy controllers support a 1:1 interleave, in which each sector on a specific track is numbered (and read) consecutively. To read and write to a disk at full speed, a controller sends data at a rate of 250,000bps.

All standard PC-compatible systems include ROM BIOS support for these drives; therefore, you usually do not need special software or driver programs to use them.

Analyzing Floppy Disk Construction

The 5 1/4-inch and 3 1/2-inch disks each have unique construction and physical properties.

The flexible (or floppy) disk is contained within a plastic jacket. The 3 1/2-inch disks are covered by a more rigid jacket than the 5 1/4-inch disks. The disks within the jackets, however, are virtually identical except, of course, for size.

When you look at a typical 5 1/4-inch floppy disk, you see several things (see Figure 11.7). Most prominent is the large round hole in the center. When you close the disk drive's "door," a cone-shaped clamp grabs and centers the disk through the center hole. Many disks come with *hub-ring reinforcements*—thin, plastic rings that help the disk withstand the mechanical forces of the clamping mechanism. The HD disks usually lack these reinforcements because the difficulty in accurately placing them on the disk means they can cause alignment problems.

On the right side, just below the center of the hub hole, is a smaller round hole called the *index hole*. If you carefully turn the disk within its protective jacket, you can see a small hole in the disk itself. The drive uses the index hole as the starting point for all the sectors on the disk—sort of the "prime meridian" for the disk sectors. A disk with a single index hole is a soft-sectored disk; the software (operating system) decides the actual number of sectors on the disk. Some older equipment, such as Wang word processors, use hard-sectored disks, which have an index hole to demarcate individual sectors. Do not use hard-sectored disks in a PC.

Courtesy of IBM Corporation

Figure 11.7 Construction of a 5 1/4-inch floppy disk.

Below the hub hole is a slot shaped somewhat like a long racetrack through which you can see the disk surface. The disk drive heads read and write data to the disk surface through this media-access hole.

On the right side, about one inch from the top, is a rectangular punch from the side of the disk cover. If this write-enable notch is present, writing to the disk has been enabled. Disks without this notch (or with the notch taped over) are write-protected disks. The notch might not be present on all disks, particularly those purchased with programs on them.

On the rear of the disk jacket at the bottom, two very small oval notches flank the head slot. These notches relieve stress on the disk and help prevent it from warping. The drive might also use these notches to assist in keeping the disk in the proper position in the drive.

Because the 3 1/2-inch disks use a much more rigid plastic case, which helps stabilize the magnetic medium inside, these disks can record at track and data densities greater than the 5 1/4-inch disks (see Figure 11.8). A metal shutter protects the media-access hole. The drive manipulates the shutter, leaving it closed whenever the disk is not in a drive. The medium is then completely insulated from the environment and from your fingers. The shutter also obviates the need for a disk jacket.

Because the shutter is not necessary for the disk to work, you can remove it from the plastic case if it becomes bent or damaged. Pry it off of the disk case; it will pop off with a snap. You should also remove the spring that pushes it closed. After removing the damaged shutter, it would be a good idea to copy the data from the damaged disk to a new one.

Rather than an index hole in the disk, the 3 1/2-inch disks use a metal center hub with an alignment hole. The drive “grasps” the metal hub, and the hole in the hub enables the drive to position the disk properly.

Figure 11.8 Construction of a 3 1/2-inch floppy disk.

On the lower-left part of the disk is a hole with a plastic slider—the write-protect/enable hole. When the slider is positioned so the hole is visible, the disk is *write-protected*—the drive is prevented from recording on the disk. When the slider is positioned to cover the hole, writing is enabled, and you can save data to the disk. For more permanent write-protection, some commercial software programs are supplied on disks with the slider removed so you cannot easily enable recording on the disk. This is exactly opposite of a 5 1/4-inch floppy in which covered means write-protected, not write-enabled.

On the other (right) side of the disk from the write-protect hole, there is usually another hole called the media-density-selector hole. If this hole is present, the disk is constructed of a special medium and is therefore an HD or ED disk. If the media-sensor hole is exactly opposite the write-protect hole, it indicates a 1.44MB HD disk. If the media-sensor hole is located more toward the top of the disk (the metal shutter is at the top of the disk), it indicates an ED disk. No hole on the right side means that the disk is a low-density disk. Most 3 1/2-inch drives have a media sensor that controls recording capability based on the absence or presence of these holes.

The actual magnetic medium in both the 3 1/2-inch and 5 1/4-inch disks is constructed of the same basic materials. They use a plastic base (usually Mylar) coated with a magnetic compound. High-density disks use a cobalt-ferric compound; extended-density disks use a barium-ferric media compound. The rigid jacket material on the 3 1/2-inch disks often causes people to believe incorrectly that these disks are some sort of “hard disk” and not really a floppy disk. The disk “cookie” inside the 3 1/2-inch case is just as floppy as the 5 1/4-inch variety.

Floppy Disk Media Types and Specifications

This section examines the types of disks that have been available to PC owners over the years. Especially interesting are the technical specifications that can separate one type of disk from another, as Table 11.6 shows. The following sections define all the specifications used to describe a typical disk.

Table 11.6 Floppy Disk Media Specifications

Media Parameters	5 1/4-inch			3 1/2-inch		
	Double-Density (DD)	Quad Density (QD)	High Density (HD)	Double Density (DD)	High Density (HD)	Extra High Density (ED)
Tracks Per Inch (TPI)	48	96	96	135	135	135
Bits Per Inch (BPI)	5,876	5,876	9,646	8,717	17,434	34,868
Media Formulation	Ferrite	Ferrite	Cobalt	Cobalt	Cobalt	Barium
Coercivity (Oersteds)	300	300	600	600	720	750
Thickness (Micro-in.)	100	100	50	70	40	100
Recording Polarity	Horiz.	Horiz.	Horiz.	Horiz.	Horiz.	Vert.

Density

Density, in simplest terms, is a measure of the amount of information that can be reliably packed into a specific area of a recording surface. The keyword here is reliably.

Disks have two types of densities: longitudinal density and linear density. *Longitudinal density* is indicated by how many tracks can be recorded on the disk, and is often expressed as a number of tracks per inch (TPI). *Linear density* is the capability of an individual track to store data, and is often indicated as a number of bits per inch (BPI). Unfortunately, these types of densities are often confused when discussing different disks and drives.

Media Coercivity and Thickness

The *coercivity* specification of a disk refers to the magnetic-field strength required to make a proper recording. Coercivity, measured in oersteds, is a value indicating magnetic strength. A disk with a higher coercivity rating requires a stronger magnetic field to make a recording on that disk. With lower ratings, the disk can be recorded with a weaker magnetic field. In other words, the lower the coercivity rating, the more sensitive the disk.

HD media demands higher coercivity ratings so the adjacent magnetic domains don't interfere with each other. For this reason, HD media is actually less sensitive and requires a stronger recording signal strength.

Another factor is the thickness of the disk. The thinner the disk, the less influence a region of the disk has on another adjacent region. The thinner disks, therefore, can accept many more bits per inch without eventually degrading the recording.

Caring for and Handling Floppy Disks and Drives

Most computer users know the basics of disk care. Disks can be damaged or destroyed easily by the following:

- Touching the recording surface with your fingers or anything else
- Writing on a disk label (which has been affixed to a disk) with a ball-point pen or pencil
- Bending the disk
- Spilling coffee or other substances on the disk
- Overheating a disk (leaving it in the hot sun or near a radiator, for example)
- Exposing a disk to stray magnetic fields

Despite all these cautions, disks are rather hardy storage devices; I can't say that I have ever destroyed one by just writing on it with a pen, because I do so all the time. I am careful, however, not to press too hard, so I don't put a crease in the disk. Also, touching a disk does not necessarily ruin a disk, but rather makes the disk and your drive head dirty with oil and dust. The real danger to your disks comes from magnetic fields that, because they are unseen, can sometimes be found in places you never imagined.

For example, all color monitors (and color TV sets) have a degaussing coil around the face of the tube that demagnetizes the shadow mask when you turn the monitor on. If you keep your disks anywhere near (within one foot) of the front of the color monitor, you expose them to a strong magnetic field every time you turn on the monitor. Keeping disks in this area is not a good idea because the field is designed to demagnetize objects, and indeed works well for demagnetizing disks. The effect is cumulative and irreversible.

Another source of powerful magnetic fields is an electric motor found in vacuum cleaners, heaters, air conditioners, fans, electric pencil sharpeners, and so on. Do not place these devices near areas where you store disks. Audio speakers also contain magnets, but most of the speakers sold for use with PCs are shielded to minimize disk corruption.

Three and a half-inch disks should be stored between 40–127° Fahrenheit. Five and a 1/4-inch disks should be stored between 40–140° Fahrenheit. In both cases, humidity should not exceed 90 percent.

Airport X-ray Machines and Metal Detectors

People associate myths with things they cannot see, and we certainly cannot see data as it is stored on a disk or the magnetic fields that can alter the data.

One of my favorite myths to dispel is that the airport X-ray machine somehow damages disks. I have a great deal of experience in this area from having traveled around the country for the past 10 years or so with disks and portable computers in hand. I fly about 150,000 miles per year, and my portable computer equipment and disks have been through X-ray machines more than 100 times each year.

The biggest problem people have when they approach the airport X-ray machines with disks or computers is that they don't pass the stuff through! Seriously, X-rays are essentially just a form of light, and disks and computers are not affected by X-rays at anywhere near the levels found in these machines.

What can damage your magnetic media is the metal detector. Time and time again, someone with magnetic media or a portable computer approaches the security check. They freeze and say, "Oh no, I have disks and a computer—they have to be hand-inspected." The person then refuses to place the disk and computer on the X-ray belt, and either walks through the metal detector with disks and computer in hand or passes the items over to the security guard, in very close proximity to the metal detector.

Metal detectors work by monitoring disruptions in a weak magnetic field. A metal object inserted in the field area causes the field's shape to change, which the detector observes. This principle, which is the reason that the detectors are sensitive to metal objects, can be dangerous to your disks; the X-ray machine, however, is the safest area through which to pass either your disk or your computer.

The X-ray machine is not dangerous to magnetic media because it merely exposes the media to electromagnetic radiation at a particular (very high) frequency. Blue light is an example of electromagnetic radiation of a different frequency. The only difference between X-rays and blue light is in the frequency, or wavelength, of the emission.

Some people worry about the effect of X-ray radiation on their system's EPROM (Erasable Programmable Read-Only Memory) chips. This concern might actually be more valid than worrying about disk damage because EPROMs are erased by certain forms of electromagnetic radiation. In reality, however, you do not need to worry about this effect either. EPROMs are erased by direct exposure to very intense ultraviolet light. Specifically, to be erased an EPROM must be exposed to a 12,000 uw/cm² UV light source with a wavelength of 2,537 angstroms for 15 to 20 minutes, and at a distance of 1 inch. Increasing the power of the light source or decreasing the distance from the source can shorten the erasure time to a few minutes.

The airport X-ray machine is different by a factor of 10,000 in wavelength. The field strength, duration, and distance from the emitter source are nowhere near what is necessary for EPROM erasure. Many circuit-board manufacturers even use X-ray inspection on circuit boards (with components including EPROMs installed) to test and check quality control during manufacture.

In my own experiences, I have passed one disk through different airport X-ray machines for two years, averaging two or three passes a week. The same disk still remains intact with all the original files and data and has never been reformatted. I also have a portable computer that has gone through X-ray machines safely every week for more than four years. I prefer to pass computers and disks through the X-ray machine because it offers the best shielding from the magnetic fields produced by the metal detector standing next to it. Doing so may also lessen the “hassle factor” with the security personnel because if I have the computer X-rayed, they often do not require that I unpack it and turn it on. Unfortunately, with the greater emphasis on airport security these days, even when the computer is X-rayed, some airlines require that the system be demonstrated (turned on) anyway.

Now you may not want to take my word for it, but there has been scientific research published that corroborates what I have stated. A few years ago, a study was published by two scientists, one of whom actually designs X-ray tubes for a major manufacturer. Their study was titled “Airport X-rays and Floppy Disks: No Cause for Concern,” and was published in 1993 in the journal *Computer Methods and Programs in Biomedicine*. According to the abstract,

A controlled study was done to test the possible effects of X-rays on the integrity of data stored on common sizes of floppy disks. Disks were exposed to doses of X-rays up to seven times that to be expected during airport examination of baggage. The readability of nearly 14 megabytes of data was unaltered by X-irradiation, indicating that floppy disks need not be given special handling during X-ray inspection of baggage.

In fact, the disks were retested after two years of storage, and there has still been no measurable degradation since the exposure.

Drive-Installation Procedures

In most cases, installing a floppy disk drive is a matter of physically attaching the drive to the computer chassis or case, and then plugging the power and signal cables into the drive. Some type of bracket and screws are normally required to attach the drive to the chassis. These are normally included with the chassis or case itself. Several companies listed in Appendix A specialize in cases, cables, brackets, screw hardware, and other items useful in assembling systems or installing drives.

Note

Because floppy disk drives are generally installed into the same half-height bays as hard disk drives, the physical mounting of the drive in the computer case is the same for both units. See “Hard Disk Installation Procedures,” in Chapter 14, “Physical Drive Installation and Configuration,” for more information on the process.

When you connect a drive, make sure the power cable is installed properly. The cable is normally keyed so you cannot plug it in backward. Also, install the data and control cable. If there is no key in this cable, use the colored wire in the cable as a guide to the position of pin 1. This cable is oriented correctly when you plug it in so the colored wire is plugged into the disk drive connector toward the cut-out notch in the drive edge connector.

Older drives used to require various jumpers to be set to allow the drive to work properly. The two most common jumpers were the Drive Select (DS) jumper and the Disk Change (DC) jumper. If you encounter an older drive with these jumpers, there are a few simple rules to follow. The DS (Drive Select) jumper will normally have two positions, labeled 0 and 1 or in some cases 1 and 2. In all PC installations, the DS jumper should be set on the second position, no matter what it is numbered. This will allow the drive on the cable before the twist to function as drive B; and the drive at the end of the cable after the twist to function as drive A. The DC jumper setting is normally an on or off setting. For PC usage, if the drive has a DC jumper, it must be set on or enabled.

Troubleshooting Floppy Drives

Because of their very low cost, floppy drives have become a fairly disposable item these days. Also their connection to the system has become simpler over the years as drives today come preconfigured with no jumpers or switches to set. The cables are fairly standardized as well. What all this means is that if the drive or cable are suspected as being defective, they should be replaced rather than repaired. This section discusses some of the most common problems floppy drives can have and how to troubleshoot them.

Problem

Dead drive—the drive does not spin and the LED never comes on.

Cause/Solution

Drive or controller not properly configured in BIOS setup. Check BIOS setup for proper drive type and make sure the controller is enabled if built-in to the motherboard.

Other causes for a dead drive include:

- Bad power supply or power cable—Measure the power at the cable with a voltmeter, ensure that 12v and 5v are available to the drive.
- Bad data cable—Replace the cable and retest.
- Defective drive—Replace the drive and retest.
- Defective controller—Replace the controller and retest. If the controller is built-in to the motherboard, disable it via the BIOS setup, install a card-based controller and retest, or replace the entire motherboard and retest.

Problem

Drive LED remains on continuously.

Cause/Solution

Data cable is on backward at either the drive or controller connection. Reinstall the cable properly and retest.

Also, the data cable could be offset on the connector by one or more pins. Reinstall the cable properly and retest. If this does not solve the problem, it could be a defective cable. Replace the cable and retest.

Problem

Phantom directories—you have exchanged disks in the drive, but the system still believes the previous disk is inserted, and even shows directories of the previous disk.

Cause/Solution

There are several possible causes and solutions:

- *Defective cable (pin 34).* Replace the cable and retest.
- *Improper drive configuration.* If the drive is an older model and has a DC jumper, it must be set enabled.
- *Defective drive.* Replace the drive and retest.

Common Floppy Drive Error Messages—Causes and Solutions

Error Message

Invalid Media or Track Zero Bad, Disk Unusable

Cause/Solution

You are formatting the disk and the disk media type does not match the format parameters. Make sure you are using the right type of disk for your drive and formatting the disk to its correct capacity. Other causes and solutions are:

- *Defective or damaged disk.* Replace the disk and retest.
- *Dirty heads.* Clean the drive heads and retest.

Error Message

CRC Error or Disk Error 23

Cause/Solution

The data read from the diskette does not match the data that was originally written. (CRC stands for Cyclic Redundancy Check.) Replace the disk and retest. Possibly clean the drive heads. Use the Norton Utilities for possible data recovery from the disk.

Error Message

General Failure Reading Drive A, Abort, Retry, Fail; or Disk Error 31

Cause/Solution

The disk is not formatted or has been formatted for a different operating system (Macintosh, for example). Reformat the disk and retest. Another cause could be that there are damaged areas on the disk medium. Replace the disk and retest. Use the Norton Utilities for possible data recovery from the disk.

Error Message

Access Denied

Cause/Solution

You are trying to write to a write-protected disk or file. Move the write-protect switch to allow writing on the disk, or remove the read-only file attribute from the file(s). File attributes can be changed by the ATTRIB command.

Error Message

Insufficient Disk Space or Disk Full

Cause/Solution

The disk is filled, or the root directory is filled. Check to see if sufficient free space is available on the disk for your intended operation.

Error Message

Bytes in Bad Sectors

Cause/Solution

This is displayed after formatting or running the CHKDSK command, and shows that the disk has several allocation units that are marked bad. This is not a problem in itself because when they are marked in this fashion, the operating system will not use them for file storage. Even so, I normally don't recommend using disks with bad sectors.

Error Message

Disk Type or Drive Type Incompatible or Bad

Cause/Solution

You are attempting to DISKCOPY between two incompatible drive or disk types. Disks can only be copied between drives using the same disk density and size.

Repairing Floppy Disk Drives

Attitudes about repairing floppy disk drives have changed over the years, primarily because of the decreasing cost of drives. When drives were more expensive, people often considered repairing

the drive rather than replacing it. With the cost of drives decreasing every year, however, certain labor- or parts-intensive repair procedures have become almost as expensive as replacing the drive with a new one. Because of cost considerations, repairing floppy disk drives usually is limited to cleaning the drive and heads and lubricating the mechanical mechanisms.

Cleaning Floppy Disk Drives

Sometimes read and write problems are caused by dirty drive heads. Cleaning a drive is easy; you can proceed in two ways:

- *Use one of the simple head-cleaning kits available from computer- or office-supply stores.* These devices are easy to operate and don't require you to open the computer case to access the drive.
- *The manual method: Use a cleaning swab with a liquid such as pure alcohol or trichloroethane.* With this method, you must open the system unit to expose the drive and, in many cases (especially in earlier full-height drives), also remove and partially disassemble the drive.

The manual method can result in a better overall job, but usually the work required is not worth the difference.

The cleaning kits come in two styles: The wet type uses a liquid squirted on a cleaning disk to wash off the heads; the dry kit relies on abrasive material on the cleaning disk to remove head deposits. I recommend that you never use the dry drive-cleaning kits. Always use a wet system in which a liquid solution is applied to the cleaning disk. The dry disks can prematurely wear the heads if used improperly or too often; wet systems are very safe to use.

The manual drive-cleaning method requires that you have physical access to the heads to swab them manually with a lint-free foam swab soaked in a cleaning solution. This method requires some level of expertise: Simply jabbing at the heads incorrectly with a cleaning swab might knock the drive heads out of alignment. You must use a careful in-and-out motion, and lightly swab the heads. No side-to-side motion (relative to the way the heads travel) should be used; this motion can snag a head and knock it out of alignment. Because of the difficulty and danger of this manual cleaning, for most applications I recommend a simple wet-disk cleaning kit because it is the easiest and safest method.

One question that comes up repeatedly in my seminars is "How often should you clean a disk drive?" Most drive and disk manufacturers recommend cleaning after every 40 hours of drive operation. Since the floppy drives are rarely used except for file backups or system configuration and setup or diagnostics, it is hard to gauge when this much time will have elapsed. Depending on the number and size of fans in the system, there might be a large amount of air flowing through the floppy drive, which means it can be subject to contamination even though it is not being used. In some cases this means cleaning is often required more frequently than the recommendations suggest.

What type of environment is the system in? Do you smoke cigarettes near the system? If so, more frequent cleaning would be required. Usually, a safe rule of thumb is to clean drives about once a year if the system is in a clean office environment in which no smoke or other particulate matter is in the air. In a heavy-smoking environment, you might have to clean every six months or

perhaps even more often. In dirty industrial environments, you might have to clean every month or so. Your own experience is your guide in this matter. If the operating system reports drive errors such as the familiar DOS Abort, Retry, Ignore prompt, you should clean your drive to try to solve the problem. If cleaning does solve the problem, you probably should step up the interval between preventive-maintenance cleanings.

In some cases, you might want to place a very small amount of lubricant on the door mechanism or other mechanical contact point inside the drive. Do not use oil; use a pure silicone lubricant. Oil collects dust rapidly after you apply it and usually causes the oiled mechanism to gum up later. Silicone does not attract dust in the same manner and can be used safely. Use very small amounts of silicone; do not drip or spray silicone inside the drive. You must make sure that the lubricant is applied only to the part that needs it. If the lubricant gets all over the inside of the drive, it can cause unnecessary problems.

Aligning Floppy Disk Drives

If your disk drives are misaligned, you will notice that other drives cannot read disks created in your drive, and you might not be able to read disks created in other drives. This situation can be dangerous if you allow it to progress unchecked. If the misalignment is bad enough, you will probably notice it first in the drive's inability to read original application-program disks, while still being able to read the disks you have created yourself.

To solve this problem, you can have the drive realigned. I usually don't recommend realigning drives because of the low cost of replacing the drive compared to aligning one. Also, an unforeseen circumstance catches many people off-guard: You may find that your newly aligned drive might not be capable of reading all the disks you created while the drive was out of alignment. If you replace the misaligned drive with a new one, and keep the misaligned drive, you can use it for DISKCOPY purposes to transfer the data to newly formatted disks in the new drive.

Aligning disk drives is usually no longer performed because of the high relative cost. In the past, aligning a drive properly required access to an oscilloscope (for about \$500), a special analog-alignment disk (\$75), the OEM service manual for the drive, and a half hour to an hour of time.

Some programs on the market evaluate the condition of floppy disk drives by using a disk created or formatted on the same drive. A program that uses this technique cannot make a proper evaluation of a disk drive's alignment. To do this, you must use a specially created disk produced by a tested and calibrated machine. You can use this type of disk as a reference standard by which to judge a drive's performance. Accurite, the primary manufacturer of reference standard floppy disks, helps specify floppy disk industry standards. Accurite produces the following three main types of reference standard disks used for testing drive function and alignment:

- Digital Diagnostic Diskette (DDD)
- Analog Alignment Diskette (AAD)
- High-Resolution Diagnostic Diskette (HRD)

The HRD disk, introduced in 1989, represented a breakthrough in floppy disk drive testing and alignment. The disk is accurate to within 50 μ -inches (millionths of an inch)—accurate enough to use not only for precise testing of floppy disk drives, but also for aligning drives. With software that uses this HRD disk, you can align a floppy disk drive without having to use special tools or an oscilloscope. Other than the program and the HRD disk, you need only a PC to which to connect the drive. This product has significantly lowered the cost of aligning a floppy disk drive and has eliminated the need for special test equipment.

The Accurite program Drive Probe is designed to work with the HRD disks. Drive Probe is the most accurate and capable floppy disk testing program on the market, thanks to the use of HRD disks. Until other programs utilize the HRD disks for testing, Drive Probe is my software of choice for floppy disk drive testing and alignment. Because the Drive Probe software also acts as a disk exerciser for use with AAD disks and an oscilloscope, you can move the heads to specific tracks for controlled testing.

With the price of most types of floppy disk drives hovering at or below the \$25 mark, aligning drives usually is not a cost-justified alternative to replacement. The Drive Probe and HRD system can make alignment more cost-effective than before, but it is still a labor- and cost-intensive operation. Weigh this cost against the replacement cost and age of the drive. I have purchased brand-new 1.44MB floppy disk drives for as low as \$15. At these prices, alignment is no longer a viable option.

High-Capacity Removable Storage

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Why Use Removable Drives?
Types of Removable Media Drives
Removable Drive Letter Assignments
Comparing Removable Drives
Tape Drives

Why Use Removable Drives?

The reason for the shortage of storage space on today's PCs is easy enough to understand. With fancier user interfaces and more and more features being added, both operating systems and applications continue to grow in size. Take a look at the sheer number and size of the files stored in the two main directories used by Windows 9x (usually C:\WINDOWS and C:\WINDOWS\SYSTEM). The amount of disk space used by the files in those two directories alone can quickly balloon to 200MB or more after you also install a few Windows applications. The reason is simple: Nearly all Windows applications place files in one of the Windows directories that the application will use later. These files include those with extensions such as DLL, 386, VBX, DRV, TTF, and many others. Similarly other operating systems—such as Windows NT, OS/2, Linux, and UNIX—as well as the software applications that run in these operating systems can require enormous amounts of storage space.

Applications also use more graphics and sound. Digital cameras and video recorders allow you to capture and store images that can easily consume hundreds of megabytes of space.

This section focuses on some of the more advanced data storage options on the market: high capacity removable media storage, including both disk and tape drives. This chapter focuses on magnetic or magneto-optical storage. Pure optical storage—such as CD-R, CD-RW, DVD-R, DVD-RAM, and others—is covered in Chapter 13, “Optical Storage.”

Some removable media drives use media as small as a 3 1/2-inch floppy disk, whereas others use larger media up to 5 1/4-inches. Most popular removable storage drives today have capacities that range from 100MB to 70GB or more. These drives offer fairly speedy performance and the capability to store anything from a few data files or less frequently used programs to complete hard disk images on a removable disk or tape. Besides backup this allows the capability to easily transport huge data files—Computer Aided Drawing (CAD) files and graphics files, for example—from one computer to another. Or, you can use a removable cartridge to take sensitive data away from your office so you can lock it safely away from prying eyes.

There are two basic categories of removable media: disk and tape. Disk media is much more expensive, usually has a lower capacity, and is more easily used on a file-by-file basis as compared to tape. Disk media is faster for copying a few files, but normally slower for copying large numbers of files or entire drives. Tape media is much less expensive overall, has a higher total capacity, and is more easily used on an image or multiple file basis. Such tape drives are more suited for complete backups of entire hard disks including all applications and data. Because it is suited for mass backup, tape can be painstaking to use for copying single files. This chapter covers both removable disk and tape storage.

Note

Removable media disk drives can be used as system backup devices similar to tape. However, the higher price of the medium itself (disks or cartridges) and the generally slower speed at which they perform can make this use somewhat prohibitive on a large scale. For file-by-file backups, disk media is ideal; if, however, you're completely backing up entire drives or systems, tape is faster and more economical.

Tip

There are literally dozens of removable storage devices currently on the market. Be sure to compare your chosen solution against the competition before making a final purchase. Be especially wary of missing statistics in press releases and product packaging—manufacturers are apt to omit a specification if their drive doesn't measure up to the competition.

Types of Removable Media Drives

There are two commonly used types of removable media disk drives: magnetic media and optical media, also called magneto-optical media. Magnetic media drives use technology very much like that of a floppy or hard disk drive to encode data for storage. Magneto-optical media drives encode information on disk by using newer technology—a combination of traditional magnetic and laser technologies.

There are also several connection options for the leading removable drives. Although SCSI has been, and continues to be, a popular solution, most of the removable drives today connect to an IDE port, a parallel port, or a USB (Universal Serial Bus) port. The parallel and USB connections are external, which allows you to share one drive between several different computers. Unfortunately, the parallel port drives generally provide relatively poor performance levels, and although USB is better, it still cannot match the performance of IDE or SCSI. For a high-performance connection, SCSI is still the ultimate for external high-capacity drives. Although SCSI can work internally as well, most internal drives use IDE because it is less expensive.

Note

Connecting or installing removable media drives is similar to connecting and installing other internal and external peripherals.

The external USB or parallel port drives are the simplest of the available interfaces, requiring only a special cable that comes with the drive and installation of special software drivers. See the instructions that come with each drive for the specifics of its installation.

A small group of companies dominates the market for magnetic and magneto-optical removable media drives. 3M's spin-off company Imation and Iomega are the leading names in removable magnetic media drives.

Removable magnetic media drives are usually floppy or hard disk based. For example, the popular Zip drive is a 3 1/2-inch version of the original Bernoulli floppy disk drive made by Iomega. The new 3M LS-120 drive is a floppy-based drive that stores 120MB on a disk that looks exactly like a 1.44MB floppy! The former SyQuest drive and current Iomega Jaz drive are both hard disk-based designs.

Both the Iomega and SyQuest designs are proprietary standards, while the LS-120 is a true industry standard supported by many companies. However, the Iomega Zip drive has become a de facto standard in the industry. Many new PCs sold today include a Zip drive as standard equipment. Even so, because the LS-120 SuperDisk is supported as a bootable direct floppy replacement by virtually all new systems today, and many vendors supply them as standard equipment, I expect the market to shift to the LS-120 and derivatives as the de facto standard for the future.

The following sections provide information about both magnetic media and magneto-optical drive types.

High-Capacity Floptical Drives

There is a special type of high-capacity floppy disk drive being marketed by several companies that is sometimes called a floptical drive. These drives are unique in that they can both read and write standard floppy disks as well as higher-capacity floptical disks. A 21MB version was originally available but more recently a 120MB version has become popular; with 250MB and 500MB versions coming, the 21MB version has become obsolete. The older 21MB version was created by Insite Peripherals, and packed 21MB of data on the same size disk as a 3 1/2-inch floppy. The 21MB floptical drive is an ancestor of the newer SuperDisk (LS-120) drives, which can store 120MB on a 3 1/2-inch floppy disk.

In addition, all floptical drives can read and write 1.44MB and 720KB floppy disks (although they cannot handle 2.88MB disks). Because of their greatly increased storage capacity and capability to use common floppy disks, the newer 120MB flopticals are considered by many as the perfect replacement floppy disk drive.

The name floptical might suggest the use of laser beams to burn or etch data onto the disk or to excite the media in preparation for magnetic recording—as is the case with the CD-R and Write Once, Read Many (WORM) drives—but this suggestion is erroneous. The read/write heads of a floptical drive use magnetic recording technology, much like that of floppy disk drives.

The floptical disk itself is composed of the same ferrite materials common to floppy and hard disks. Floptical drives are capable of such increased capacity because many more tracks are packed on each disk, compared with a standard 1.44MB floppy. Obviously, to fit so many tracks on the floptical disk, the tracks must be much more narrow than those on a floppy disk.

That's where optical technology comes into play. Flopticals use a special optical mechanism to properly position the drive read/write heads over the data tracks on the disk. Servo information, which specifically defines the location of each track, is embedded in the disk during the manufacturing process. Each track of servo information is actually etched or stamped on the disk and is never disturbed during the recording process. Each time the floptical drive writes to the disk, the recording mechanism (including the read/write heads) is guided by a laser beam precisely into place by this servo information. When the floptical drive reads the encoded data, the laser uses this servo information again to guide the read/write heads precisely into place.

21MB Floptical Drives

The original Insite 21MB floptical disks used tracks formatted to 27 sectors of 512 bytes. The disks revolved at 720rpm. Flopticals are capable of nearly 10MB per minute data throughput, using a SCSI interface.

Unfortunately, the 21MB drives by Insite never really caught on due to several reasons. One is that no leading manufacturer has included these drives in a standard configuration with built-in BIOS drivers and support. Also, Microsoft, IBM, and Apple have not built support for these drives directly into their operating systems.

LS-120 (120MB) SuperDisk Drives

The LS-120 drive (also called a SuperDisk drive) was designed to become the new standard floppy disk drive in the PC industry. LS-120 technology was developed by Imation (3M) Corporation; Matsushita-Kotobuki Industries, Ltd. (MKE); and O.R. Technology and stores 120MB of data, or about 83 times more data than current 1.44MB floppy disks. In addition to storing more, these drives read and write at up to five times the speed of standard floppy disk drives.

The LS-120 floppy disk drive can act as the PC's bootable A: drive (in newer systems with BIOS support) and is fully compatible with Windows NT, Windows 2000, Windows 95/98. Macintoshes can also use SuperDisk drives, so data can be exchanged between PCs and Macs.

In addition to the new 120MB floppy disks, the LS-120 drive accepts standard 720KB and 1.44MB floppy disks, and actually reads and writes those disks up to three times faster than standard floppy disk drives. Iomega Zip drives are not backward compatible and cannot use existing floppy disks; the proprietary Zip media stores less and is more expensive than the 3M LS-120 media. Many people in the computer industry believe that LS-120 technology will replace the 1.44MB floppy disk in new computers.

The LS-120 normally uses the standard IDE interface, which is already built into most existing systems, and it is perfect for portable systems. There are also USB and parallel versions for an easy external connection. The LS-120 provides a solution that not only replaces the existing floppy, but can even replace the floppy disk drive internally. Having one of these high-capacity drives in a portable allows the use of relatively inexpensive 120MB removable disks while on the road. They are perfect for storing entire applications or datasets and can be removed and secured when the portable system is not in use.

LS-120 specifications are compared to standard 1.44MB floppy disks in Table 12.1.

Table 12.1 LS-120 Specifications

Drive Type	LS-120 Floppy	Standard 1.44MB Floppy Disk
Formatted Capacity	120MB	1.44MB
Transfer Rate: parallel port	290KB/sec	45KB/sec
Transfer Rate: internal IDE	484KB/sec	n/a
Average seek time	70ms	84ms
Disk rotational speed	720rpm	300rpm
Track density	2,490tpi	135tpi
Number of tracks	1,736 × 2 sides	80 × 2 sides

The 3MB LS-120 disk has the same shape and size as a standard 1.44MB 3 1/2-inch floppy disk; however, it uses a combination of magnetic and optical technology to enable greater capacity and performance. Named after the Laser Servo (LS) mechanism it employs, LS-120 technology places optical reference tracks on the disk that are both written and read by a laser system. The optical sensor in the drive enables the read/write head to be precisely positioned over the magnetic data tracks, enabling track densities of 2,490tpi versus 135tpi for a 1.44MB floppy disk.

Virtually all new PCs now come with LS-120 support directly in the BIOS, which means that these drives are easy to install, they can directly replace the A: floppy disk drive, and they're bootable, as well. Many newer laptop systems come with LS-120 drives that replace and yet are fully compatible with the standard floppy disk drive. Unlike Zip, you can install the LS-120 in your laptop and leave the standard floppy disk drive at home.

Many PC manufacturers are incorporating LS-120 drives in their products as standard equipment. Besides coming in new systems, these drives are also available separately at a cost of about \$75 or less in internal or external versions for upgrading older systems. The 120MB floppy disks are available for about \$10 per disk or less, almost half the cost of the proprietary Zip media.

Bernoulli Drives

In the early 1980s, Iomega introduced the Bernoulli drive. The disk used in the original Bernoulli drive was a thick cartridge roughly the same size as a 5 1/4-inch floppy disk, although a large shutter, similar to the shutter on a 3 1/2-inch floppy disk, easily distinguished Bernoulli disks from standard floppy disks. Bernoulli cartridges were originally available in 10MB capacities, but those were replaced by 35MB, 65MB, 105MB, and 150MB capacities.

Bernoulli disks were originally known as the most durable of the removable media drive types. For example it is probably safer to mail a Bernoulli cartridge than another type of removable disk because the media is well protected inside the cartridge. Bernoulli encases a magnetic-media-covered flexible disk (in effect, a floppy disk) in a rigid cartridge in the same way the thin disk of a 1.44MB floppy is encased in a rigid plastic shell.

When it rotates in the drive, the disk is pulled by air pressure toward the drive heads. Many people think that there is no head-to-disk contact in a Bernoulli drive, but indeed there is. As the disk spins, the airflow generated by the disk movement encounters what is called a Bernoulli plate, which is a stationary plate designed to control the air flow so the disk is pulled toward the read/write head. At full speed, the head touches the disk, which causes wear. Bernoulli drives have built-in random seek functions that prevent any single track on the disk from wearing excessively during periods of inactivity. Bernoulli disk cartridges should be replaced periodically because they can wear out. The disk itself spins at speeds approaching the 3,600rpm of relatively slow hard drives. The drive has an average seek time of 18ms, not a great deal slower than today's medium-priced hard drives.

Zip Drives

Another form of Bernoulli drive from Iomega is the popular Zip drive. This device is available as an internal SCSI or IDE unit, or as an external SCSI or parallel port device. There is also a low-power version designed for use in notebook computers and a "plus" version that features both SCSI and parallel interfaces. The drive is capable of storing up to 100MB of data on a small removable magnetic cartridge that resembles a 3 1/2-inch floppy disk. The drive has approximately a 29ms access time and a 1MB/sec transfer rate when used with a SCSI connection. When using the parallel connection, the drive's speed is often limited by the speed of the parallel port.

Zip drives use a proprietary 3 1/2-inch disk made by Iomega. It is about twice as thick as a standard 3 1/2-inch floppy disk.

The Zip drives do not accept standard 1.44MB or 720KB floppy disks, making this an unlikely candidate for a floppy disk drive replacement. Internal Zip drives have become popular options in new PCs, and the external models are an effective solution for exchanging data between systems, but the major PC manufacturers have not recognized the proprietary format directly in the system BIOS, meaning you cannot boot from a Zip drive, nor can it replace the A: floppy disk drive.

Zip drives have also suffered from reliability problems, such as the so called "click death," which occurs when the drive begins a rhythmic ticking sound. At this point, the data on the disk can be corrupted and both the drive and the media must be replaced.

►► See "Zip Drive 'Click of Death,'" p. 678.

Finally, the media costs of Zip are almost double that of the higher-capacity LS-120 drives, which are an industry standard fully supported by the system BIOS in modern PCs. Table 12.2 lists the Zip specifications.

Table 12.2 Zip Specifications (100 and 250MB Capacity)

Model (Interface)	SCSI and/or Parallel	EIDE
Formatted capacity	100MB or 250MB	100MB or 250MB
Sustained transfer rate	1.40MB/sec	1.40 maximum MB/sec
Sustained transfer rate	0.79MB/sec	0.79 minimum MB/sec
Maximum throughput	60MB/min (SCSI); 20MB/min (parallel)	84MB/min
Average seek time	29ms	29ms
Disk rotational speed	2,941 rpm	2,941 rpm
Buffer size	32KB	16KB

Figure 12.1 shows the interior of a Zip drive, listing the various components within.

The interior assembly forms a tray that is mounted on a sliding track. This allows the entire tray to move with the disk.

Iomega also introduced a smaller and lower capacity version of Zip called the Klik! drive, primarily for notebook computers. Unfortunately, these drives never became popular because of their low capacity and proprietary nature, compared to the industry standard SuperDisk (LS-120) drives. Most newer desktop and laptop systems support the SuperDisk drives internally as a direct and compatible replacement for the standard floppy drive. SuperDisk drives can be connected externally to all systems via USB or parallel interfaces.

Figure 12.1 Iomega Zip drive internal view.

Zip Drive “Click of Death”

Iomega has acknowledged that as many as 100,000 users of Zip drives have suffered what is called the “Click of Death.” The name refers to a sharp clicking sound which is heard from the drive as the heads are continually loaded and unloaded as they try to read a disk. This unfortunately means at a minimum that the disk, and possibly the drive, is likely trashed.

In fact many have found that the disk cartridge can be damaged in such a way that if you attempt to read it on another Zip drive, that drive will be damaged as well. The only solution is to get a new disk and drive, and do not try to read damaged disks in new drives.

If you believe your drive or disk has been damaged, call Iomega technical support (see the Vendor List on the CD) and they should replace the defective disk and possibly the drive as well.

Iomega lists these precautions to help prevent damaged disks and drives.

- Eject disks prior to transporting any Iomega drive. This allows the drive heads (which read and write to the disks) to park in a natural position.
- Avoid dropping your drive; it can damage internal structures.
- Be especially careful to transport and store Jaz disks only in the Jaz disk cases.

Note

Iomega offers utility diagnostics software that tests the integrity of the Zip heads and Zip media. You can download this from their Web site.

Another company, Gibson Research, has developed a unique program for diagnosing problems with Zip and Jaz drives. It is called Trouble In Paradise (TIP), and can also be downloaded free from the Gibson Research site. They are well known as the manufacturers of the Spinrite program for hard disks. See the Vendor List in the CD for their URL and address.

Because of the high frequency of this problem, many data recovery companies have had a large business in recovering data from damaged Zip cartridges. In fact the problem has even prompted a class action suit. The law firm of Dodge, Fazio, Anderson, and Jones, P.C. has announced that a nationwide class action was commenced on September 10, 1998 in the Superior Court of New Castle County in Delaware on behalf of all owners of the Iomega Zip drive. The complaint contains claims for breach of warranty, negligence in manufacturing and design, consumer fraud, and failure to warn.

Investigation has shown that the Click of Death has three main causes.

1. Magnetic particles corrupt the read/write mechanism of the drive, as well as any disk it is attempting to read.
2. Lubricant on the disk decomposes, forming a solid material, which accumulates on the heads of the drive. This prevents the heads from reading the disk, and subsequently corrupts it.
3. The drive heads come in contact with the edge of the spinning disk, which can dislodge the drive heads and/or tear the storage media and render the disk useless.

This latter point is especially troublesome, because if damaged media is inserted into a new drive, it can damage the new drive as well, in some cases tearing the heads off their mount.

Data recovery from a damaged Zip disk can run \$400 or more, so I suggest you keep backups of any important data you store on these disks.

Zip 250 (SCSI and Parallel)

The Zip 250 drive is an extension of Iomega's popular Zip product line, offering enhanced features such as increased capacity and performance, as well as compatibility with existing Zip 100 disks.

The SCSI version of the Zip 250 runs about 1.6 times faster than the Zip 100; however, the parallel port version has about the same performance due to limitations of the parallel interface.

Jaz Drives

Another type of removable hard disk drive is the Jaz drive from Iomega. This is physically and functionally identical to the SyQuest drives in that it is a true removable cartridge hard disk, except that the capacity of the cartridge has been increased; 1GB and 2GB models are available. Unfortunately, the cartridges themselves cost \$100 to \$125, which is about seven times the cost of a digital audio tape (DAT) cartridge that stores up to four times more data! The high cost of the media makes the Jaz drive unsuitable for backup when compared to traditional tape media, but possibly useful as an add-on external SCSI hard disk drive. Jaz drives are available in SCSI interface versions only. Table 12.3 lists the specifications for Jaz drives.

Table 12.3 Jaz Specifications

Model	1GB	2GB
Formatted Capacity	1070 million bytes	2000 million bytes
Transfer rate:		
Maximum	6.62MB/sec	8.7MB/sec
Average	5.4MB/sec	7.35MB/sec
Minimum	3.41MB/sec	3.41MB/sec
Burst	10MB/sec	20MB/sec
Average seek time read	10 ms	10 ms
Average seek time write	12 ms	12 ms
Access Time	15.5–17.5ms	15.5–17.5ms
Disk Rotational speed	5400rpm	5394rpm
Buffer size	256KB	512KB
Interface	Fast SCSI II	Ultra SCSI

SyQuest Drives

SyQuest has filed for bankruptcy, but they do continue to support their existing products. All their technology was purchased by Iomega. SyQuest manufactured some drives that use 5 1/4-inch cartridges and others that use 3 1/2-inch cartridges. But the SyQuest disks, like the Bernoulli cartridges, are easily distinguished from floppy disks. The 5 1/4-inch 44MB and 88MB cartridges used in some SyDOS drives are encased in clear plastic, as are the SyDOS 3 1/2-inch 105MB and SyQuest 270MB cartridges. The disk spins inside the cartridge at several thousand rpm. SyQuest claims a 14ms average access time for the drives it manufactures.

The disks for the SyQuest and SyDOS drives are composed of a rigid platter inside a plastic cartridge but are not as well-protected as the disk in a Bernoulli cartridge. Some people consider these disks fragile. If the SyQuest and SyDOS cartridges are not severely jostled or dropped, however, they can be transported safely. These cartridges must be carefully protected when you mail or ship them.

The SyQuest/SyDOS drives are available in internal and external models. The internal models require a connection to the existing IDE hard drive interface card. The external models require a SCSI interface card with an external connector and are powered by a transformer that connects to a grounded AC wall plug.

SyQuest filed a Chapter 11 petition with the United States Bankruptcy Court in Oakland, California on November 17, 1998. On January 13, 1999 SyQuest announced that it had entered into an agreement with Iomega Corporation to sell certain assets including all its intellectual property, its U.S. inventory, and its U.S. fixed assets.

SyQuest has commenced limited sales and support operations. This includes online technical support via the World Wide Web, warranty returns, and product service operations. This means that you should still be able to purchase blank cartridges and get repairs, but it is doubtful they will be making any new products in the future. Note that Iomega did not take on support of their older products, they only purchased their technology.

SparQ Drives

The SparQ drive is a removable hard disk drive by SyQuest that was designed to be a low-cost alternative to other technologies with similar capacities, such as the Jaz and the SyJet. The medium is a proprietary cartridge containing a single disk platter with a 1GB capacity. At \$99 for a three pack of cartridges, the cost per megabyte of the SparQ is substantially less than that of comparable removable hard disk media, although it still does not approach that of tape or CD-R.

The drive was available in internal IDE and external parallel port versions. The parallel port version, like all drives using this interface, is limited by the throughput of the port itself, but the IDE version of the SparQ provides data transfer rates that are faster than most competing drives. EIDE burst transfer rates can be as high as 16.6MB/sec by using PIO mode 4, with sustained rates ranging from 3.7 to 6.8MB/sec. Table 12.4 lists the specifications for the SparQ drive.

Table 12.4 SparQ Specifications

Formatted Capacity	1008 million bytes
Transfer rate: EIDE version	
Maximum	6.9MB/sec
Minimum	3.7MB/sec
Burst (PIO mode 4)	16.6MB/sec
Sustained transfer rate: parallel version	1.25MB/sec
Average seek time	12ms
Disk rotational speed	5,400rpm

Because SyQuest has declared bankruptcy, there will likely not be any further developments in the SparQ line, although they do intend to continue to support the existing products sold.

Removable Drive Letter Assignments

One problem people have when installing new drives is confusion with drive letter assignments. This becomes especially true when adding a new drive moves the assignments of previous drives, something that most people don't expect. Some simple rules govern drive letter assignments in Windows and DOS, which I will discuss here. These basic rules apply to all versions of Windows through Win98 and NT (Windows 2000) and DOS as well, although in some operating systems and with some drivers you can have specific control over certain drives.

The basic rule is that devices supported by ROM BIOS-based drivers come first, and those assigned by disk-loaded drivers come second. Because floppy drives and hard drives are normally ROM BIOS supported, these would come first, before any other removable drives.

The system therefore assigns the drive letter A to the first physical floppy drive. If a second physical floppy drive is present, it is assigned drive letter B. If there is no second floppy drive, the system automatically reserves B: as a logical drive representation of the same physical drive A:. This allows files to be copied from one disk to another by specifying `COPY file.ext A: B:.`

The system then checks for installed hard drives and begins by assigning C: to the master partition on the first drive. If you have only one hard disk, any extended partitions on that drive are read, and any volumes in them are assigned consecutive letters after C:. For example, if you have a hard disk with a primary partition as C: and an extended partition divided into two logical volumes, they will be assigned D: and E:.

After the hard drive partitions and logical volumes are assigned, the system begins assigning letters to devices that are driver controlled such as CD-ROM drives, PCMCIA attached devices, parallel port devices, SCSI devices, and so on.

Here is how it works with only one hard drive split into three volumes, and a CD-ROM drive:

One Drive Primary Partition	C:
One Drive Extended Partition 1st Volume	D:
One Drive Extended Partition 2nd Volume	E:
CD-ROM Drive	F:

When a removable drive is added to this mix, it is assigned either F: or G: depending on the driver and when it is loaded. If the CD-ROM driver is loaded first, the removable drive is G:. If the removable drive driver is loaded first, it becomes F: and the CD-ROM drive is bumped to G:.

In DOS, you control the driver load order by rearranging the `DEVICE=` statements in the `CONFIG.SYS` file. This doesn't work in Windows because Win 9x and NT use 32-bit drivers, which aren't loaded via `CONFIG.SYS`. You can exert control over the drive letters in Windows by manually assigning drive letters to the CD-ROM or removable drives. You do this as follows:

1. Right-click My Computer, and choose Properties.
2. Choose the Device Manager tab.
3. Click the + next to the CD-ROM drive icon. Right-click the CD-ROM drive, choose Properties, and select the Settings tab.
4. Select and change the Start Drive Letter.
5. Select the same letter for End Drive Letter.
6. Click OK and allow your system to reboot for changes to take effect.
7. Repeat the previous steps by clicking the + next to Disk Drives and assign a different drive letter to your removable drive.

Using these steps you can interchange the removable drive with the CD-ROM drive, but you cannot set either type to a drive letter below any of your existing floppy or hard drives.

So far this seems just as everybody would expect, but from here forward is where it can get strange. The rule is that the system always assigns a drive letter to all primary partitions first, and all logical volumes in extended partitions second. This means that if you have a second hard disk, it also has primary and extended partitions, and the extended partition has two logical volumes, the primary partition on the second drive becomes D:, with the extended partition logical volumes becoming G: and H:.

Here is how it works with two hard drives, each split into three volumes, and a CD-ROM drive:

First Drive Primary Partition	C:
Second Drive Primary Partition	D:
First Drive Extended Partition 1st Volume	E:
First Drive Extended Partition 2nd Volume	F:
Second Drive Extended Partition 1st Volume	G:
Second Drive Extended Partition 2nd Volume	H:
CD-ROM Drive	I:

In this example if a removable drive were added it would become either I: or J:. Using the same procedure outlined previously, you could swap I: or J: or assign them higher (but not lower) letters as well.

Drive Remapping Utilities

While some utilities are available for remapping drive letters under Windows, I normally don't recommend them. This is because if you boot under DOS or via a floppy, these remappings will no longer be in place and the standard BIOS mapping will prevail. Since one often boots to DOS to do setup, diagnostics, configuration or formatting/partitioning, confusion about which drive letters are what can lead to mistakes and lost data!

Comparing Removable Drives

Deciding on a removable drive is getting tougher, because many removable drives are currently on the market. Iomega and SyQuest lead the pack, but new entries from Exabyte and Avatar Peripherals provide their own proprietary drives, as well. Unfortunately, all these drives use their own proprietary media that are universally incompatible. If you want to exchange files with another user, that user must have a drive made by the same manufacturer. The ease of portability is one reason why the parallel port models of many of these drives are popular.

Table 12.5 shows a direct comparison between the most popular removable drives on the market.

Table 12.5 Removable Drive Specifications

Drive Type	Disk/Cartridge Capacity	Average Seek Time	Data Transfer Rate
Iomega Zip Parallel	100MB	29ms	1.4MB/sec
Iomega Zip IDE	100MB	29ms	1.4MB/sec
Iomega Zip SCSI	100MB	29ms	1.4MB/sec
Imation LS-120 Internal	120MB	70ms	4.0MB/sec
SyQuest 235 Parallel	235MB	13.5ms	1.25MB/sec
Avatar Shark 250 Parallel	250MB	12ms	1.2MB/sec
Avatar Shark PCMCIA	250MB	12ms	2.0MB/sec
SyQuest 235 SCSI/IDE	235MB	13.5ms	2.4MB/sec
Iomega Jaz (SCSI)	2GB	12ms	5.4MB/sec
Avatar Shark IDE	250MB	12ms	2.5MB/sec
SyQuest SyJet SCSI	1.5GB	12ms	5.3MB/sec
SyQuest SyJet IDE	1.5GB	12ms	5.3MB/sec
SyQuest SparQ IDE	1GB	12ms	6.9MB/sec
SyQuest SparQ Parallel	1GB	12ms	1.25MB/sec
CD-R Drives	650MB	<150ms	1.50KB/sec–2.4MB/sec

When shopping for a removable drive, keep the following in mind:

- *Price per megabyte of storage.* Take the cost of the drive's cartridge or disk and divide it by the storage capacity to see how much you are paying per megabyte of storage. This difference in price will become quite apparent as you buy more cartridges or disks for the drive. (Don't forget to factor in the cost of the drive itself!)
- *Access time versus need of access.* The access and data transfer speeds are important only if you need to access the data frequently or quickly. If your primary use is archiving data, a slower drive might be fine. However, if you plan to run programs off the drive, choose a faster drive instead.
- *Compatibility and portability.* Opt for an external SCSI or parallel port solution if you need to move the drive between various computers. Also verify that there are drivers available for each type of machine and operating system you want to use with the drive. Also consider whether you have to exchange disks with other users. The Iomega Zip disk is rapidly becoming the standard for removable cartridge media, but the graphic design industry has long used SyQuest drives. For some users, this might be the most important factor in choosing a drive.
- *Internal versus external.* Most users find external parallel port or USB drives the easiest to install; additionally they give you the option of using the drive on several systems. Internal drives are usually faster because their IDE or SCSI interfaces and are more cleanly integrated into the system from a physical perspective.
- *Bootable or not.* The LS-120 SuperDisk drives are BIOS supported in almost all new systems, and they are fully compatible with existing floppy drives. This means they can completely replace the floppy, a decided advantage over Zip and the others.

Tape Drives

The data backup and archive needs of a personal computer can be overwhelming. People with large hard drives and numerous applications installed and those who generate a large amount of data might find it necessary to back up their computers on a weekly or even a daily basis.

In addition, a critical need on today's PCs is data storage space. Sometimes it seems as though the storage requirements of a PC can never be satisfied. On nearly any PC used for business, study, or even fun, the amount of software installed can quickly overwhelm even a large hard drive. To save space on the primary storage devices, you can archive infrequently used data to another storage medium.

This section focuses on tape backup drives, which can solve the problems of the growing need for data storage space and the need for a fast and efficient way to back up many megabytes of data.

Any computer book worth reading warns repeatedly that you should back up your system regularly. Backups are necessary because at any time a major problem, or even some minor ones, can corrupt the important information and the programs stored on your computer's hard disk drive, rendering this information useless. A wide range of problems can damage the data on your hard drive. Here is a list of some of these data-damaging problems:

- Sudden fluctuations in the electricity that powers your computer (power spikes) resulting in data damage or corruption.
- Overwriting a file by mistake.
- Mistakenly formatting your hard disk when you meant to format a floppy.
- Hard drive failure resulting in loss of data that has not been backed up. Not only do you have to install a new drive but, because you have no backup, you also must reinstall all your software.
- Catastrophic damage to your computer (storm, flood, lightning strike, fire, theft). A single lightning strike near your office or home can destroy the circuitry of your computer, including your hard drive. Theft of your computer, of course, is equally devastating. A recent, complete backup greatly simplifies the process of setting up a replacement computer.
- Loss of valuable data due to a computer-related virus. One single download or floppy disk can contain a virus that can damage valuable files and even your entire hard disk. With several hundred new viruses appearing each month, no antivirus software program can keep you entirely safe. A recent backup of uninfected, critical files can help repair even the worst damage.

Backups are also the cure for such common headaches as a full hard drive and the need to transfer data between computers. By backing up data you rarely use and deleting the original data from your hard drive, you free up space once occupied by that data. If you later need a particular data file, you can retrieve that file from your backup. You can also more easily share large amounts of data between computers—as when you send data from one city to another, for example—by backing up the data to a tape and sending the tape.

Regardless of how important regular backups are, many people avoid making them. A major reason for this lapse is that for many people, backing up their system is tedious work when they have to use floppy disks or other low-capacity media. When you use these media, you might have to insert and remove many disks to back up all the important programs and data.

Tape backup drives are the most simple and efficient device for backing up your system. With a tape backup drive installed in your computer, you insert a tape into the drive, start your backup software, and select the drive and files you want to back up. The backup software copies your selected files onto the tape while you attend to other business. Later, when you need to retrieve some or all the files on the backup tape, you insert the tape in the drive, start your backup program, and select the files you want to restore. The tape backup drive takes care of the rest of the job.

This section examines the various types of tape backup drives on the market, describing the capacities of different drives as well as the system requirements for installation and use of a tape drive. The following topics are covered in this section:

- Common standards for tape backup drives
- Common backup tape capacities
- Newer higher capacity tape drives
- Common tape drive interfaces
- The QIC standards for tape backup drives
- Portable tape drives
- Tape backup software

The Origins of Tape Backup Standards

The evolution of tape backup standards is similar to that of standards for many computer components. Using tape to back up computer data became a common practice long before accepted tape backup standards existed. At first, computers used reel-to-reel tape systems (somewhat similar to old reel-to-reel audio tape recorders) to store data. The most commonly used tape—quarter-inch—eventually developed into a de facto standard. But each tape system manufacturer used its own data-encoding specifications for backup tapes. Variations included not only the number of tracks and data density on the tape, but also the interface used to connect the drive to the computer.

In 1972, more than a decade before the introduction of the first IBM PC, 3M introduced the first quarter-inch tape cartridge designed for data storage. The cartridge measured $6 \times 4 \times 5/8$ inches. Inside this cartridge, the tape was threaded onto two reels. The tape was moved from one reel to

another during the recording or read-back process by a drive belt. Because of the reliability of this tape cartridge, the demand for tape backup systems began to grow, despite the lack of established standards for storing data on these cartridges.

The result of this lack of standardization was that quarter-inch tapes written on one manufacturer's tape backup drive generally could not be read by another manufacturer's quarter-inch tape drive. One problem created by this situation was that the way particular manufacturers encoded data on a tape continued to change. If a particular model of tape drive became disabled and the manufacturer had discontinued that particular drive and no longer used its encoding format, the data stored on tapes written on the disabled drive would be unavailable until the drive was repaired. In the event the manufacturer could not repair the drive, the data was lost forever.

As with other computer components, such as hard drive interface cards, consumers were the force behind standardization. Consumers clamored for standardized tape drives that could read tapes created on different tape drives manufactured by different companies.

The QIC Standards

In response to this demand for standardization, the tape drive industry formed the Quarter-Inch Cartridge Drive Standards Inc., sometimes referred to as the Quarter-Inch Committee (QIC). In 1983–84, the first tape drive based on a QIC standard was shipped: the QIC-02, which stored 60MB of data encoded in nine data tracks on roughly 300 feet of tape.

As the technology improved, and because the $4 \times 6 \times 5/8$ -inch size of the first tape cartridges was difficult to adapt to the $5 \frac{1}{2}$ -inch drive bays in most PCs, QIC adopted a second standard for tape cartridges roughly the size of an audio cassette. These minicartridges measure $3 \frac{1}{4} \times 2 \frac{1}{2} \times 3/5$ inches.

These two cartridge sizes are currently used in various QIC-standard tape drives. A two-letter code at the end of the QIC standard number designates whether the tape standard is based on the full-sized cartridge or the minicartridge. These two-letter codes are as follows:

- DC in a QIC standard number stands for data cartridge, the $4 \times 6 \times 5/8$ -inch cassette.
- MC in a QIC standard number stands for minicartridge, the $3 \frac{1}{4} \times 2 \frac{1}{2} \times 3/5$ -inch cassette.

The new QIC-5B-DC, for example, is a 5GB-capacity tape based on the QIC standard for the full-sized cartridge. The new QIC-5010-MC, which has 13GB capacity, is based on the minicartridge standard.

Table 12.6 shows the common QIC-standard tape formats and their technical specifications.

Table 12.6 Specifications of QIC-Standard Quarter-Inch Tape Cassettes and Minicartridges QIC Minicartridge Tape Standards DC-2000 QIC Tape Standards (Approximate Dimensions 3 1/4 by 2 1/2 by 3/5)

QIC Standard Number	Capacity (w/o Compression) (1)	Tracks	Data Transfer Rate (Approximate)
QIC-40	40MB/60MB	20	2MB-to-8MB/minute
QIC-80	80MB/120MB	28	3MB-to-9MB/minute
QIC-100 (obsolete)	20MB/40MB	12 or 24	—
QIC-128	86MB/128MB	32	—
QIC-3010	255MB	40	9MB/minute
QIC-3020	500MB	40	9MB/minute
QIC-3030	555MB	40	—
QIC-3040	840MB (3)	42 or 52	—
QIC-3050	750MB	40	—
QIC-3060 (inactive)	875MB	38	—
QIC-3070	4GB	144	—
QIC-3080	1.6GB	50	—
QIC-3095	2–5GB	72	30–60MB*
QIC-3110	2GB	48	—
QIC-3210	2.3/5.7GB	72	30MB*
QIC-5010	13GB	144	—

Data Density	Tape Length (1)	Encoding Method	Interface Type
—	450 ft.	MFM	QIC-02
8,000	450 ft. or 600 ft.	MFM	SCSI or QIC-02
10,000	600 ft.	MFM	SCSI or QIC-02
10,000bpi	600 ft. or 1,000 ft.	MFM	SCSI or QIC-02
16,000bpi	1,000 ft.	MFM	SCSI or SCSI-2
36,000bpi	760 ft.	MFM	SCSI or SCSI-2
51,000bpi	760 ft.	RLL	SCSI-2
68,000bpi	875 ft.	RLL	SCSI-2
40,640bpi	900 ft.	MFM	SCSI-2
96,000bpi	1,200 ft.	RLL	SCSI-2
68,000bpi	—	RLL	SCSI-2
101,600bpi	1,200–1,500 ft	RLL	SCSI or SCSI-2

Unlike software with version numbers (1.0, 1.1, 2.0, 2.1) that tell you which version of the software is the most recent, the QIC number designation does not serve as an accurate guide to understanding which QIC-standard tape drives are the latest technology. The designations QIC-100 and QIC-128, for example, were used for tape drives marketed long before today's QIC-40 and QIC-80 drives. Furthermore, the QIC-standard version numbers frequently have no correlation with the capacity of the tape cassettes or minicartridges used by the drive. For example, the QIC-40 tapes have a capacity of 60MB; the QIC-80 tapes, a capacity of 120MB.

QIC-standard backup tapes are magnetic media, primarily ferric oxide, and are recorded in a manner similar to the way data is encoded on your hard drive, using either Modified Frequency Modulation (MFM) or Run-Length Limited (RLL) technology.

Early QIC Tape Backup Types

The original QIC-standard drives, QIC-40 and QIC-80, are based on minicartridges. There are several reasons for the success of QIC-40 and QIC-80, not the least of which is that these two standards resulted in the first generation of economically attractive tape drives that store data in a manner that is compatible with products made by different manufacturers. In other words, QIC-40 and QIC-80 tape drives and tapes are quite affordable, and backups made on one QIC-40 or QIC-80 tape drive can be read in a tape drive built by another manufacturer.

In addition, the compact size of the minicartridge used for QIC-40 and QIC-80 tapes has resulted in drives made by numerous manufacturers that fit easily into both 5 1/2-inch half-height drive bays and 3 1/2×1-inch drive bays.

Backup tapes, such as floppy disks and hard drives, must be formatted before use, and one aspect of using a QIC-80 tape drive that was never improved was the time it takes to format a tape. Formatting a 125MB-capacity QIC-80 tape can take more than three hours. It's almost impossible to find a preformatted tape because of these long format times. The industry has been preformatting tapes since 1994. Other tape formats have the capability to format on-the-fly, which means they don't require preformatted tapes.

Data is stored on QIC-40 and QIC-80 tapes in MFM format, the format used on floppy disks (and older hard drives). Another similarity between formatting a backup tape, floppy disks, and a hard drive is that the formatting process creates a record-keeping system. The record-keeping system used on QIC-40 and QIC-80 tapes is similar to that on a hard drive or floppy disk.

The QIC standard calls for a file allocation table (FAT) that keeps track of where data is stored on the tape and keeps bad sectors from being used for data storage. A QIC-40 tape is divided into 20 tracks, with each track divided into 68 segments of 29 sectors each. Each sector stores 1KB (1,024 bytes). This record-keeping system and the error-correcting system that ensures reliably stored backup data use a total of 30% or more of each QIC-40 tape.

Despite the slow backup speeds of tape backup drives on some computers and the time it takes to format tapes, the ease of using a backup tape drive makes it easy to understand why the QIC-40 and QIC-80 tape drives were very popular.

High-Capacity QIC-Standard Drives

Using a QIC-80 tape drive to back up a network server's 4GB drive or other large hard drive packed with data can be nearly as frustrating as swapping floppy disks during a backup, because you have to switch media many times to protect the whole drive.

The solution to this tape-swapping problem is to use a larger capacity tape drive system. QIC has established a number of standards for higher-capacity tape drive systems ranging from 86MB to 13GB. Generally, these larger capacity systems pack data more densely on the tape, using as many as 144 tracks to pack 60,000 bits per inch (bpi) or more onto the tape (compared to the QIC-40's 20 tracks and 10,000bpi). To achieve these higher capacities, QIC-standards call for tape media with a higher coercivity level of 1,300 oersteds or more (compared to QIC-40 and QIC-80 tape media, which has a coercivity level of 550 oersteds). High-capacity tapes are also longer. QIC-5010 tapes, for example, are 1,200 feet long (compared to QIC-40 and QIC-80 tapes, both of which are roughly 300 feet long).

Note

Just as the higher coercivity level of 1.44MB floppy disks enables an HD drive to write more densely packed tracks than is possible with 720KB floppy disks, higher coercivity tape media enables higher densities, as well.

Although tape systems based on the minicartridge dominate the market for lower capacity tape drives, high-capacity tape backup systems are based on both minicartridge-sized tapes and full-sized data cartridge tapes. For example, the QIC-525 standard, which has a capacity of 525MB (without data compression), is based on the full-sized (4×6×5/8) cartridge. The QIC-5010 standard is based on a minicartridge (3 1/4×2 1/2×3/5).

QIC-Tape Compatibility

Although QIC-standard drives are based on the standard minicartridge and the full-sized data cartridge, it would be a mistake to assume that tapes based on the same cartridge standard are always compatible. For example, QIC-5010-standard tapes are incompatible with QIC-40 and QIC-80 tape backup systems, although both standards are based on the minicartridge. Similarly, QIC-525-standard tapes are incompatible with earlier standards based on the full-sized data cartridge. The lack of compatibility between tapes based on the same sized cartridge is due to differences in tape drive mechanisms, as well as the coercivity differences between tape standards. Table 12.8 shows the compatibility of common QIC-standard backup tapes.

Table 12.8 QIC-Tape-Standard Compatibility

QIC Minicartridge Standard	Compatibility
QIC-40	n/a
QIC-80	QIC-40 (read-only)
QIC-3010	QIC-40 and QIC-80 (read-only)
QIC-3020	QIC-40, QIC-80, and QIC-3010 (read only)
QIC-3030	QIC-3010 (read-only)

(continues)

Table 12.8 Continued

QIC Minicartridge Standard	Compatibility
QIC-3040	n/a
QIC-3050	n/a
QIC-3070	QIC-3030 (read-only)
QIC-3080	n/a

QIC-1000	QIC-120, QIC-150, and QIC-525 (read-only)
QIC-1350	QIC-525 and QIC-1000 (read-only)
QIC-2G	QIC-120, QIC-150, QIC-525, and QIC-1000 (read-only)
QIC-2100	QIC-525 and QIC-1000 (read-only)
QIC-5G	QIC-24, QIC-120, QIC-150, QIC-525, and QIC-1000 (read-only)
QIC-5010	QIC-150, QIC-525, and QIC-1000 (read-only)

Tape compatibility is an important issue to consider when you choose a tape backup system. For example, as you can see from Table 12.8, the 4GB QIC-3070-standard drive can read only its own tapes and those that conform to the QIC-3030 standard. If you have many QIC-80 tapes containing data that you must continue to access, a better choice might be a drive based on the 2GB QIC-3010 standard. The QIC-3010 can read QIC-40 and QIC-80 tapes.

Other High-Capacity Tape Drive Standards

Ferric oxide QIC-standard tapes have declined in popularity in recent years, whereas two other types of tape backup systems are becoming increasingly popular for backing up networks and other systems with large amounts of data: 4mm digital audio tape (DAT) and 8mm videotape.

Sony introduced DAT, and licenses DAT technologies to other manufacturers, in effect setting the standard for drives and tapes manufactured by those companies. There is only one company, Exabyte, that manufactures 8mm tape drive assemblies. As a result, you're assured compatibility. Table 12.9 shows the basic specifications of the DAT and 8mm technology tapes.

Table 12.9 DAT and 8mm Tape Specifications

Tape Standard	Capacity (w/o Compression)	Data Density	Tracks (Approximate)	Tape Length	Recording Technology	Encoding Format	Interface
DAT (4mm metal particle)	2GB/4GB	114MB/in	1,869	195 ft./ 300 ft.	Helical Scan DataDAT	DDS*	SCSI
8mm video tape	14GB	n/a	n/a	120m	Helical Scan		

*DDS: Digital data storage

Helical scan recording is similar in many ways to the way video images are recorded to videotape. As with QIC-standard tape drives, DAT and 8mm tapes move past the recording heads, which are mounted on a drum. These read/write heads rotate at a slight angle to the tape, writing a section of a helix, or spiral. The tape drive mechanism wraps the tape about halfway around the read/write heads, causing the heads to touch the tape at an angle. With helical scan technology, the entire surface of the tape is used to record data, unlike other technologies in which data tracks are separated by areas of unrecorded tape. This use of the entire tape surface enables helical scan backup drives to pack a much greater amount of data on a particular length of tape.

The DAT Tape Drive Standard

Digital audio tape (DAT) is a tape standard that has primarily been developed and marketed by Hewlett-Packard. HP chairs the DDS (digital data storage) Manufacturers Group, and has led the development of the DDS standards.

The technology behind digital audio tape is similar in many ways to the techniques used to record music and encode it on audio compact discs (CDs). DAT drives do not record data on the tape in the MFM or RLL formats used by QIC-standard drives; rather, bits of data received by the tape drive are assigned numerical values, or digits. Then the drive translates these digits into a stream of electronic pulses that are written to the tape. Later, when you restore information to a computer from the tape, the DAT tape drive translates these digits back into the original binary bits.

DAT tapes can store up to 12GB of uncompressed data, or about 24GB compressed. Two types of data formats—digital data storage (DDS) and DataDAT—are used for DAT tapes; however, DDS-type drives are by far the most common. DDS drives are available in three types:

- DDS-1 drives store 2GB of uncompressed data (4GB compressed).
- DDS-2 drives can store 4GB of uncompressed data (up to 8GB with compression).
- DDS-3 drives have a native 12GB capacity, or 24GB compressed.

DDS-3 drives offer full read and write compatibility with all DDS-2 and DDS-1 drives, as well as three times the capacity and double the data-transfer rate of current DDS-2 drives. DDS-3 drives are designed to provide reliable high-performance backup for medium to large networks at a substantially lower price than 8mm or DLT (digital linear tape) products with similar capacities.

The new HP DDS-3 drive (Model C1537A) has a native capacity of 12GB with a transfer rate of 1MB/sec. The DDS-3 drive typically can store 24GB on a single 125m tape at a rate of 2MB/sec by using built-in hardware data compression. The new HP DDS-3 drive incorporates several innovations, including the use of a partial response maximum likelihood (PRML) data-channel detection scheme that enables the tape's read head to differentiate between bits of data picked up simultaneously.

A typical DDS-2 drive costs about \$800, whereas DDS-3 drives are approximately \$1,300. DDS technology has an excellent track record and a reputation for reliability that has made it the technology of choice for workstation, end user, and network backups.

The 8mm Tape Drive

A single manufacturer, Exabyte, offers tape backup drives that use 8mm tape cartridges like those used for videotape. However, although the cartridge design is the same as a videotape, the actual magnetic medium is not. It is strongly recommended that you do not use videotapes for backing up your data. You should use only tapes that are intended for use as a data storage medium. Exabyte offers drives in several capacities—1.5GB (3GB with hardware data compression), 5GB (10GB with hardware compression), 7GB (14GB with hardware compression), and 20GB (40GB with hardware compression).

Although these drives use 8mm videotapes, they do not use video technology for the process of writing computer data to the tape. Rather, Exabyte developed its own technology for encoding information on the tapes, using the helical scan method to record the data.

The 6MB/sec data throughput rate of the Exabyte 8mm tape backup drive, compared with the 10MB per minute throughput of the DAT drive, makes the 8mm tape drive a more attractive choice. The extraordinary speed and huge capacity of these 8mm tape drives makes them extremely attractive for backing up network servers and for backing up workstations from the server.

DLT (Digital Linear Tape)

Digital linear tape (DLT) is now considered one of the hottest products in the high-end tape-backup market, because of its capability to provide high-capacity, high-speed, and highly reliable backups. DLT started as a proprietary technology belonging to Digital Equipment Corporation. The technology has been on the market since 1991, but in December 1994, Quantum purchased Digital's DLT and magneto-resistive drive technology.

DLT has a capacity of up to 35–70GB compressed, and a data-transfer rate of 5–10MB/sec or more. This is approximately the same speed as a high-speed 8mm drive; however, 8mm has a slight performance advantage in real-world tests.

DLT segments the tape into parallel horizontal tracks and records data by streaming the tape across a single stationary head at 100–150 inches/sec during read/write operations. This is a dramatic contrast to traditional helical-scan technology, in which the data is recorded in diagonal stripes with a rotating drumhead while a much slower tape motor draws the media past the recording head.

The result is a very durable drive and a robust medium. DLT drive heads have a minimum life expectancy of 15,000 hours under worst-case temperature and humidity conditions, and the tapes have a life expectancy of 500,000 passes. DLT drives are designed primarily for network server backup, and cost \$6,000 to \$8,000 or more depending on capacity. With automatic tape changers, DLT drives can be left unattended for many network backup tasks.

Travan Cartridge Tape

3M has created an entirely new tape cartridge standard based on the QIC format called Travan. Tape drives based on Travan technology have had a significant impact on the tape market for PCs and workstations, and drives based on this technology should have a prominent place in this market over the next several years.

The Travan platform features a unique drive/minicartridge interface that is patented by 3M. The Travan platform fits in a 3 1/2-inch form factor, making it easy to install in a variety of systems and enclosures. Travan drives can accept current QIC and Travan minicartridges—a critical need for users, given the installed base of more than 200 million QIC-compatible minicartridges worldwide.

Travan cartridges contain 750 feet of .315-inch wide tape. There are currently several different levels of Travan cartridges and drives available called TR-1 through TR-4, each based on a particular QIC standard:

- The TR-1 minicartridge provides users with 400MB of uncompressed storage, more than doubling the capacity of the QIC-80 minicartridge (125MB).
- The TR-2 minicartridge, a new modified QIC-3010 drive/cartridge, stores 800MB of uncompressed data, which is significantly more than the 340MB capacity of QIC-3010 tapes.
- The capacity of the TR-3 minicartridge, a new modified 3020 drive/cartridge, is 1.6GB of uncompressed data (up from 670MB in the QIC-3020).
- The newest Travan cartridge, TR-4, stores 4GB of uncompressed data and is compatible with the QIC-3095 standard.

Notice that virtually all Travan drives offer 2:1 data compression, which doubles the uncompressed native capacity. This means that a Travan TR-4 drive can store up to 8GB on a single cartridge! A typical TR-4 based drive, such as those from Hewlett-Packard's Colorado Memory Systems Division, sell for about \$300. Because Travan tapes sell in the \$35 price range and are available through many distributors and resellers, the low cost and high availability of these drives and cartridges make Travan one of the best backup solutions possible for most individuals.

The TR-1 through TR-3 drives usually interface to the system via the floppy controller or parallel port. I recommend using an EPP or ECP parallel port for ease of use and performance. The higher-end TR-4 drives often use a SCSI-2 interface, which offers greater performance than either the floppy or parallel port interface. A typical TR-4 system such as the HP T4000 drive operates at 514KB/sec, which is approximately four times faster than floppy-interface systems, providing backup speeds up to 31MB per minute native and up to 62MB per minute with 2:1 data compression. Using a typical Pentium system, users can back up a 1GB hard drive in about 30 minutes. If you use the floppy controller or parallel port, you can expect backup times about four times longer or about two hours for a 1GB drive.

Storage industry leaders such as 3M, HP/Colorado, Iomega, Exabyte, Tandberg Data, and Sony offer Travan drives and support future development of Travan drive and recording formats.

Choosing a Tape Backup Drive

Choosing a tape backup drive can be a simple job if you need to back up a single standalone system with a relatively small hard drive. The decision becomes more complex if the system has a larger hard drive, or if you must back up not only a desktop system but also a laptop. Choosing a tape backup drive type can be an even more complex program if you must back up a network server's hard drives and perhaps even back up the workstations from the server. As you ponder which backup tape drive type you should choose, consider the following factors:

- The amount of data you must back up
- The data throughput you need
- The tape standard that is best for your needs
- The cost of the drive and tapes
- The capabilities and compatibility of the included driver and backup software

By balancing the considerations of price, capacity, throughput, compatibility, and tape standard, you can find a tape drive that best meets your needs.

Note

When purchasing a tape backup drive, take the time to look through magazines where dealers or distributors advertise. Several publications specialize in PCs and carry advertising from many hardware and software distributors. I recommend publications such as the *Computer Reseller News* and *Computer Shopper*.

These publications cater to people or companies willing to go around the middlemen and buy direct. By reading such publications, you can get an excellent idea of the drives available and the price you can expect to pay.

While reading about drive capabilities and prices, don't neglect to read reviews of the software included with each drive. Verify that the software capabilities match your expectations and needs. This is especially important if you intend to use the drive on a non-Windows 9x system, because most backup software today is tailored for Windows 9x.

Capacity

The first rule for choosing a tape backup drive is to buy a drive whose capacity is large enough for your needs, now and for the foreseeable future. The ideal is to buy a drive with enough capacity so you can start your backup software, insert a blank tape in the drive, walk away from the system, and find the backup completed when you return.

No matter the capacity needs for a workstation, I generally recommend either DAT drives or the newer Travan drives. These are the most cost-effective and highest-performing drives on the market today. The tapes are preformatted, which saves a lot of time, and can store up to 8GB on a single Travan TR-4 tape or 24GB on a single DDS-3 DAT tape.

You should always make sure that your tape backup medium supports a capacity larger than your largest single drive or partition. This makes automated backups possible because you won't have

to change a tape in the middle of a backup. Because the DAT drives normally interface via SCSI, you can use a parallel port SCSI adapter to connect the drive to a system's parallel port or a standard internal SCSI adapter. Of course, the internal adapter performs better, but a portable DAT drive connected via the parallel port can be used to back up many different systems. The DAT medium is also cheaper than any other tape medium on the market when you consider its cost per megabyte.

Tape Standards

The next most important consideration, after adequate capacity, is choosing a drive whose tapes meet a standard that is useful to you. For example, if you must be able to restore backup data by using any of a number of different tape backup drives, you should make sure that all these drives can at least read the tapes. For this reason, if you have several systems to work with, you should choose a tape standard that will work in them all.

There is no quick, simple answer as to which standard is the best. Many people stick with QIC-standard drives because QIC created the first standards and continues to develop new standards for large-capacity tape backups. But if you need a large-capacity backup tape system, DAT or 8mm might be the correct choice.

If you need backward compatibility with tapes or tape drives you already have, you will need to buy drives that are the same standard or a higher compatible standard. For example, if you need a large-capacity tape drive that is backward compatible with your QIC-80 tapes, you should consider the 2GB-capacity QIC-3010, which reads QIC-40 and QIC-80 tapes. If, on the other hand, you don't have to worry about data already stored on old tapes, the important considerations might be capacity and performance. Therefore, DAT or 8mm drives might be the best choice.

Tip

It is important that you make a choice you can live with. If you manage a large installation of computers, mixing QIC, Travan, DAT, and 8mm drives among systems is seldom a good idea.

Software Compatibility

Equally important to your consideration is the software required to operate each drive. Currently, most drives come with software that runs under the Windows 9x operating system. However, finding software that runs equally well under Windows NT or UNIX might be difficult.

Most operating systems have their own software for backing up data to a tape drive. If you intend to use this software, you should verify that the drive you purchase is supported by each piece of software on each system that you intend to use with the drive.

Data Throughput

You should consider the 8mm or DLT drives if performance is more important to you than price or compatibility. These drives offer huge capacity and tremendous data throughput—as high as 6MB/sec. Large-capacity drives based on newer QIC-standards are capable of 18MB per minute throughput. DAT tape drives offer throughput of 10MB per minute.

The low end of the tape backup drive performance spectrum is the older QIC-80 standard drives. When linked to a floppy controller, these drives achieve 3MB to 4MB per minute throughput. Even with a dedicated interface card purchased at added cost, QIC-80 drives are lucky to achieve their advertised throughput of 9MB per minute. Portable QIC-80 drives are advertised at 3MB to 8MB per minute, but 2MB or 3MB a minute is a more realistic figure.

The Cost of the Drive and Tapes

The price of tape drives varies considerably based on where you buy, so it pays to shop enthusiastically for a good price after you have settled on the type of drive you want to buy.

The cost of backup tapes also varies widely, depending on where you buy. Because many computer retailers and direct channel vendors offer lower prices when you buy three or more tapes at a time, it pays to shop for price and buy the largest quantity of tapes you expect to need.

Tip

One point worth remembering when you evaluate whether to buy a tape drive is that the cost of the tapes and drive, taken as a whole, is nowhere near as high as the costs (in terms of frustration and lost productivity) of a single data-damaging hard drive problem. Considering that most people are more likely to back up their system if they have a tape drive installed than if they must use another medium for the backup, the cost of a drive and tapes is quite small, even on a standalone PC used mostly for fun.

Portable Tape Drives

The portable tape drive is one of the most popular tape drive configurations because portables can be moved easily from system to system—desktops, laptops, a single system, or multisystem installations. Portable tape drives are particularly useful to people who use laptops (in which an internal tape backup drive will not fit) and those who want to back up a number of systems on a single tape backup drive. Portable tape drives are good also for people who want to use a tape backup drive for their desktop system but whose system has no available drive bay, as is often the case with small profile, or Slimline, desktop systems.

Portable tape drives can meet so many needs because these drives are self-contained. The unit connects to the computer's parallel port and is powered by a transformer that plugs into a standard AC socket.

To set up a portable tape drive, you plug the transformer cord into the system unit and an AC socket, connect the data cable to the computer's parallel port, and run the backup software. One limitation of portable units is availability of compatible backup software. Although portable tape drive manufacturers include software that operates the drive, some popular third-party backup software cannot be used with portable drives.

Tape Drive Installation Issues

Each of the tape drive standards covered in this chapter provides a range of options for installation, usually including both internal and external models. Whether to choose an internal or external drive, and which external drive to choose if that appears to be the best choice for you, is

not always a cut-and-dried issue. If you must back up a single computer with a relatively small hard drive, an internal drive might be your best choice. If you have to back up several computers, or if you must be able to share data between several computers, a portable would be preferable. If your backup needs are not that simple, however, here are some additional considerations:

- If your computer has a large hard drive and you back up often, or if you administer a large number of systems, you should consider installing large-capacity QIC, DAT, or 8mm tape drives. Using these tape formats minimizes the amount of work you must do and the number of tapes you have to store for each computer.
- If your best choice is a large capacity QIC, DAT, or 8mm tape drive and almost all the computers you administer have an available drive bay, you might choose a portable DAT or 8mm tape system, which you can move from system to system.

The following sections cover some important installation issues for internal and external mounted drives.

Internal Installation

Virtually all internal tape backup drives available today are designed to be installed in a half-height drive bay. Many are designed to be installed in either half-height drive bays or the smaller drive bays generally used for 3 1/2-inch floppy disk drives. Drives that can be installed in 3 1/2-inch floppy disk drive bays generally are shipped in a cage, or frame, that also enables them to be installed in a 5 1/4-inch bay. To install the drive in a 3 1/2-inch bay, you remove the cage and the 5 1/4-inch bay faceplate. Most tape drives are between 5 and 9 inches deep and require that much clearance inside the system case. To mount tape drives inside the system, use the same rails or cage apparatus used for floppy disk drives, hard drives, and other devices such as CD-ROM drives.

Internal tape drives require a spare power connector, usually the larger connector used for hard drives, although some might require the smaller power connector used by 3 1/2-inch floppy disk drives. If a power connector is not available inside your system, you can buy a power splitter from a computer store or cable supply vendor.

Internal tape drives also require an interface to the system. QIC-40 and QIC-80 drives most often connect to the system through the floppy controller. On a system with only one floppy disk drive, you connect the tape drive to an unused connector on the floppy disk data cable. On systems with two floppy disk drives, you use a special cable linked to the floppy disk data cable, in effect a splitter cable.

Internal drives other than QIC-40s and QIC-80s usually connect to either a SCSI adapter or the IDE interface integrated into the system's motherboard.

External Installation

If you want to move an external tape drive from computer to computer, you must have the appropriate interface installed in each system on which you want to use the drive. Portable tape backup drives such as the DAT portables use either a standard SCSI connection or have a SCSI-to-parallel port converter that uses the computer's parallel port connector. There are no external IDE devices.

Power is supplied to external units by a transformer that plugs into an ordinary 120v AC wall socket. Generally, the transformer connects to the external tape drive with a small connector. When you choose an external tape drive, be sure you have enough AC power sockets available for your computer, its peripherals, and the tape drive.

Tape Drive Backup Software

The most important decision you can make after you choose the tape standard and capacity of your backup tape drive is the backup software you will use with it. Most tape drives are shipped with backup software that generally is adequate for your basic backup needs.

Often, however, third-party software compatible with the drive you have chosen gives you greater flexibility and functionality. For example, some tape drives might not ship with software for the operating system that you want to use. If you want to use one of these drives with another operating system, you might need to purchase third-party backup software. And if you will be backing up network workstations from a server, you must make sure that the drive is shipped with software capable of performing this function; otherwise, you will need to acquire third-party software. The most important issue when selecting a third-party backup software package is compatibility with your drive. Be sure to check the software company's list of certified tape drives for the exact manufacturer and model number for your unit before you make a purchase. Some software manufacturers even certify specific firmware revisions in a tape drive.

One important issue with backup software is data compression, special programming that stores data on the backup tape in less space than is needed on the original source disk. Some companies produce backup software that is well-known for especially efficient data compression. In other words, backup software produced by these companies does a better job of compressing large data files into a small amount of space. However, if your tape drive provides compression at the hardware level, this point is moot, as far as the software is concerned. You can compress data only once, and hardware compression is always preferable to software compression.

You might want to take the time to read reviews on backup software in one of the many monthly computer magazines, such as *PC Magazine*, *Windows Magazine*, or *BYTE*. The reviews can help you determine which backup software does the best job of compressing data; they also provide information on how quickly backup software programs perform a typical backup. The speed of the backup software and its data-compression capabilities are important considerations. Also of great importance is whether the software is easy to use. If your backup software makes backing up more difficult than it has to be, chances are you won't back up as often as you should.

Tip

Some of the more recent software for tape drives include a "Disaster Recovery" feature. This feature creates a boot disk (floppy) that can quickly reformat a drive and perform a basic operating system installation. Look for this feature when considering your purchase decision.

Bundled Software

Before you buy a backup tape drive, you should always check whether the drive includes software that will meet your needs and, if it doesn't, be sure to buy third-party software that does the job. Generally, the software bundled with most tape backup drives will do the job for you—provided that you don't plan to place great demands on the tape drive.

Third-Party Software

A large number of companies manufacture backup software designed for different types of tape drives and different uses. For example, many manufacturers design their backup software to be compatible with most networks. Others specialize in DOS and Windows backup software. Some specialize in OS/2 software. Others are well-known among those whose computers run in UNIX. You might need to call the software company to determine whether a particular type of software is compatible not only with the tape drive you have chosen, but also with your network and operating environment.

Often, third-party software is easier to use than the software designed by a tape manufacturer. The tape manufacturer's software might have an unfamiliar interface or its commands might seem cryptic to you, even if you have used backup software for years. It is not uncommon for tape manufacturers to include inadequate or even incomplete documentation for the backup software included with the drive, although this is generally the case only with lower-cost models. In such a case, you might be able to solve the problem by purchasing third-party software.

Third-party software often does a better job of data compression than the software designed by a tape manufacturer. In addition, third-party software often includes capabilities not included with the software bundled with many drives. Some of the capabilities you might want to look for include the following:

- *Unattended backup scheduling.* Enables you to schedule a backup for a time when you won't need to use your computer.
- *Macro capability.* Use when selecting options and the files to back up.
- *A quick tape-erase capability.* Use when erasing the entire contents of a tape.
- *Partial tape-erase capability.* Use when erasing only part of a tape.
- *Tape unerase capability.* Use when recovering erased data.
- *Password-protect capability.* Enables you to protect backup data from access by unauthorized persons.

You can find backup software manufacturers by reading some of the many monthly computer magazines, paying particular attention to their usability reviews. Generally, if a backup software product gets good reviews, works on a system configuration such as yours, and has the features you need, it is worth the price you pay.

Tape Drive Troubleshooting

Tape drives can be troublesome to install and operate. Any type of removable media is more susceptible to problems or damage, and tape is no exception. This section lists some common problems and resolutions. After each problem or symptom there is a list of troubleshooting steps.

Backup or Restore Operation Failure

If your tape drive suffers a backup or restore operation failure, follow these steps:

1. Make sure you are using the correct type of tape cartridge.
2. Remove and replace the cartridge.
3. Restart the system.
4. Retension the tape.
5. Try a new tape.
6. Clean the tape heads.
7. Make sure all cables are securely connected.

Bad Block or Other Tape Media Errors

To troubleshoot bad block or other types of media errors, follow these steps:

1. Retension the tape.
2. Clean the heads.
3. Try a new tape.
4. Restart the system.
5. Try initializing the tape.
6. Perform a Secure Erase on the tape (previous data will no longer be retrievable from the tape).

Note that most minicartridge tapes are preformatted, and cannot be reformatted by your drive. Do not attempt to bulk erase preformatted tapes, as this will render the tapes unusable.

System Lockup or System Freezing when Running a Tape Backup

If your system locks up or freezes while running a tape backup, follow these steps:

1. Ensure that your system meets at least the minimum requirements for both the tape drive and the backup software.
2. Check for driver or resource (IRQ, DMA, or I/O port address) conflicts with your tape drive controller card or interface.
3. Set the CD-ROM to master and the tape drive to slave if both are using the same IDE port.
4. Check the BIOS boot sequence; make sure it is not set to ATAPI (tape/CD-ROM) devices if the tape drive is configured as a master device or as a slave with no master.
5. Make sure the hard drive has sufficient free space; most backup programs temporarily use hard drive space as a buffer for data transfer.
6. Hard drive problems can cause the backup software to lock up. Check your hard disk for errors with SCANDISK or a comparable utility.

7. Check for viruses.
8. Check for previous tape drive installations; make sure any drivers from previous installations are removed.
9. Temporarily disable the current VGA driver and test with the standard 640×480×16 VGA driver supplied by Microsoft. If the problem does not reoccur, contact your graphics board manufacturer for an updated video driver.
10. Files in some third-party Recycle Bins can cause backup software to lock up. Empty the Recycle Bin before attempting a backup.
11. Disable antivirus programs and Advanced Power Management.
12. Try the tape drive on another computer system and different operating system, or try swapping the drive, card, and cable with known good, working equipment.

Other Tape Drive Problems

Other issues that might cause problems in general with tape backups include

- Corrupted data or ID information on the tape.
- Incorrect BIOS (CMOS) settings.
- Networking problems (outdated network drivers, etc.).
- The tape was made by another tape drive. If the other drive can still read the tape, this might indicate a head alignment problem or incompatible environment.

Tape Retensioning

Retensioning a tape is the process of fast forwarding and then rewinding the tape, to ensure there is even tension on the tape and rollers throughout the entire tape travel. Retensioning is recommended as a preventive maintenance operation when using a new tape or after an existing tape has been exposed to temperature changes or shock (for example, dropping the tape).

Retensioning restores the proper tension to the media and removes unwanted tight spots that can develop.

Some general rules for retensioning include the following:

- Retension any tapes that have not been used for over a month or two.
- Retension tapes if you have errors reading them.
- Retension any tapes that have been dropped.
- In some cases, it may be necessary to perform the retension operation several times to achieve the proper effect. Most tape drive or backup software include a Retension feature as a menu selection.

Optical Storage

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

What Is a CD-ROM?

What Types of Drives Are Available?

CD-ROM Disc and Drive Formats

Writable CD-ROM Drives

DVD (Digital Versatile Disc)

CD-ROM Software on Your PC

Loading CD-ROM Drivers

Creating a Bootable Disk with CD-ROM Support

Making a Bootable CD-ROM for Emergencies

Caring for Optical Media

Troubleshooting Optical Drives

What Is a CD-ROM?

Within minutes of inserting a plastic and aluminum, sandwich-coated data disc into your computer, you have access to information that might have taken you days or even weeks to find a few short years ago. Science, medicine, law, business profiles, and educational materials—every conceivable form of human endeavor or pursuit of knowledge—are making their way to CD-ROM, or *compact disc read-only memory*. Other formats such as CD-R and CD-RW are expanding the compact disc's capabilities by making them writable, and new technologies such as DVD are making it possible to store more data than ever on the same size disc.

CD-ROM drives are now considered standard equipment on most PCs. The primary exception to this rule is PCs that are intended for use on business networks. Server hard drives and shared network CD-ROMs can be much more economical than individual CD-ROM drives on every computer. However, nearly all standalone systems can benefit from some sort of optical storage device.

The CD-ROM is a read-only optical storage medium capable of holding up to 682MB of data (approximately 333,000 pages of text), 74 minutes of high-fidelity audio, or some combination of the two, on a single side of a five-inch disc. The CD-ROM is similar to the familiar audio compact disc and can, in fact, play in a normal audio player. The result, however, would be noise— unless audio tracks accompany the data on the CD-ROM (see the section “Enhanced Music CDs,” later in this chapter). Accessing data from a CD-ROM is quite a bit faster than from a floppy disk but considerably slower than a modern hard drive. The term CD-ROM refers to both the discs themselves and the drive that reads them.

Although only a few dozen CD-ROMs, or titles, were published for personal computer users in all of 1988, there are currently hundreds of thousands of individual titles containing data and programs, ranging from worldwide agricultural statistics to preschool learning games. Individual businesses, local and federal government offices, and small businesses also publish thousands of their own limited-use titles. As one example, consider that the storage space and expense that so many business offices once dedicated to the maintenance of a telephone book library can now be replaced by two discs containing the telephone listings for the entire United States.

CDs: A Brief History

In 1978, the Philips and Sony corporations joined forces to produce the current audio CD. Philips had already developed commercial laser-disc players, and Sony had a decade of digital recording research under its belt. The two companies were poised for a battle—the introduction of potentially incompatible audio laser disc formats—when they came to terms on an agreement to formulate a single audio technology.

Sony pushed for a 12-inch platter. Philips wanted to investigate smaller sizes, especially when it became clear that they could pack an astonishing 12 hours of music on the 12-inch discs.

By 1982, the companies announced the standard, which included the specifications for recording, sampling, and—above all—the 4.72-inch format you live with today. This size was chosen,

legend has it, because it could contain all of Beethoven's approximately 70-minute Ninth Symphony without interruption.

With the continued cooperation of Sony and Philips through the 1980s, additional specifications were announced concerning the use of CD technology for computer data. These recommendations evolved into the computer CD-ROM drives in use today, which use the same technology and disc format as audio CDs. Where engineers used to struggle to find the perfect fit between disc form and a great symphony, software developers and publishers began cramming these little discs with the world's information.

CD-ROM Technology

Although identical in appearance to audio CDs, CD-ROMs store data instead of (or in addition to) audio. The CD-ROM drives in PCs that read the data discs bear a strong resemblance to an audio CD player. The procedures for handling the CDs (inserting them into the CD drive and ejecting them when finished) are all familiar to anyone who has used an audio CD. Both forms of CDs operate on the same general mechanical principles.

The disc is made of a polycarbonate wafer, 120mm in diameter and 1.2mm thick, with a 15mm hole in the center. This wafer base is coated with a metallic film, usually an aluminum alloy. The aluminum film is the portion of the disc that the CD-ROM drive reads for information. The aluminum film or strata is then covered by a plastic polycarbonate coating that protects the underlying data. A label is usually placed on the top of the disc, and all reading occurs from the bottom. CD-ROMs are single-sided.

Note

CD-ROM media should be handled with the same care as a photographic negative. The CD-ROM is an optical device and degrades as its optical surface becomes dirty or scratched. If your drive uses a caddy—a container for the disc that does not require handling the disc itself—you might want to purchase a sufficient supply of these to reduce the handling of the actual discs. Most of the drives produced today no longer use caddies, however, and improper handling of the discs can shorten their life.

Mass-Producing CD-ROMs

Although a laser etches data onto a master disc, this technique would be impractical for the reproduction of hundreds or thousands of copies. Each production of a master disc can take over 30 minutes to encode. In addition, these master discs are made of materials that aren't as durable as a mass-produced disc for continued or prolonged use.

For limited-run CD production, an original master is coated with metal in a process similar to electroplating. After the metal is formed and separated from the master, the metal reverse image imprint of the original can be used to stamp copies, not unlike the reproduction of vinyl records. This process works effectively for small quantities; eventually the stamp wears out.

(continues)

To produce a large volume of discs, manufacturers use the following three-step process:

1. The master is once again plated and a stamp is produced.
2. This stamp creates a duplicate master, made of a more resilient metal.
3. The duplicate master can then be used to produce numerous stamps.

This technique makes it possible to create a great many production stamps from the duplicate master, preserving the original integrity of the first encoding. It also allows for mass production using inexpensive materials. The CDs you buy are coated with aluminum after they are stamped into polycarbonate, and then are protected with a thin layer of plastic. The thin aluminum layer that coats the etched pits as well as the smooth surfaces enables the reading laser to determine the presence or absence of strongly reflected light.

This mass-manufacturing process is identical for both data CD-ROMs and audio CDs.

Reading the information back is a matter of reflecting a low-powered laser off the aluminum strata. A receiver or light receptor notes where light is strongly reflected or where it is absent or diffused. Diffused or absent light is caused by the pits etched in the CD. Strong reflection of the light indicates no pit—this is called a *land*. The light receptors within the player collect the reflected and diffused light as it is refracted from the surface. As the light sources are collected from the refraction, microprocessors translate the light patterns back into data or sound.

The individual pits on a CD are 0.12 microns deep and about 0.6 microns wide (one micron equals one-millionth of a meter). The pits are etched into a spiral track with a spacing of 1.6 microns between turns, corresponding to a track density of nearly 16,000 tracks per inch. The pits and lands run from 0.9 to 3.3 microns long. The track starts at the inside of the disc and ends as close as 5mm from the edge of the disc. This single spiral track is nearly three miles long.

When a CD—audio or data—seeks out a specific datum on the disc, it looks up the address of the datum from a table of contents and positions itself near the beginning of this datum across the spiral, waiting for the right string of bits to flow past the laser beam.

CD-ROM data is recorded using a technique called *Constant Linear Velocity (CLV)*. This means that the track data is always moving past the read laser at the same linear speed. In other words, the disk must spin faster when reading the inner track area and slower when reading the outer track area. Because CDs were originally designed to record audio, the speed at which the drive reads the data had to be constant. Thus, each disc is broken up into blocks, or sectors, that are stored at the rate of 75 blocks per second on a disc that can hold a total of 74 minutes of information, resulting in a maximum of 333,000 blocks (sectors).

New multispeed CD-ROM readers still read the same CLV-recorded CDs, but play them back at a *Constant Angular Velocity (CAV)*. This means that the track data is moving past the read laser at a different speed, depending on where the track is physically located on the CD (inner or outer track). This type of drive reads the tracks at the edge of the disk faster than ones near the center because the CD is rotating at a constant speed, similar to old record players. CAV drives are also quieter than CLV drives, as a rule. A drive that combines CLV and CAV technologies is referred to as Partial-CAV or P-CAV. Table 13.1 compares CLV and CAV.

Table 13.1 CLV Versus CAV Technology Quick Reference

	CLV	CAV
Speed of CD rotation	Varies with data position on CD—faster on inner tracks than on outer tracks	Constant
Data Transfer rate	Constant	Varies with data position on CD—faster on inner tracks than on outer tracks
Noise level	High	Low
Price	High	Low
Availability	Limited	Common

At one time, people wanting the fastest CD-ROM drives preferred to purchase CLV drives, but a better option is available today: drives using Zen Research's TrueX drive technology, which uses multiple laser beams to achieve constant high transfer rates without the limitations or very high expense of CLV technology.

▶▶ See "TrueX/MultiBeam Technology," p. 709.

In an audio disc, each block stores 2,352 bytes. In a CD-ROM, 304 of these bytes are used for Sync (Synchronizing bits), ID (Identification bits), ECC (Error Correcting Code), and EDC (Error Detection Code) information, leaving 2,048 bytes for user data. Because these blocks are read at a constant speed of 75 per second, this results in a standard CD-ROM transfer rate of 153,600 bytes per second, which is exactly 150KB/sec.

Because a typical disc can hold a maximum of 74 minutes of data, and each second contains 75 blocks of 2,048 bytes each, you can calculate the absolute maximum storage capacity of a CD-ROM at 681,984,000 bytes (rounded as 682 million bytes or 650MB—megabytes—a.k.a. *binary megabytes*).

TrueX/MultiBeam Technology

As you've seen in previous sections, choosing a CD-ROM drive on the basis of its X-rating (speed multiple of the original 1x CD-ROM drive) can be highly misleading. Because CAV or P-CAV drives are common, most high-speed drives (16x or faster) don't achieve their rated maximum speed until the outer areas of the CD-ROM are read. Vibration can cause conventional CD-ROMs to reduce their spin rates to get reliable data reading, but at a sacrifice in speed.

A new approach to high-speed CD-ROM and DVD mechanisms changes the way that high speeds are achieved: instead of reading one track at a time, why not read more? This method, known as TrueX/MultiBeam, was developed by a company called Zen Research, which licenses the technology to CD-ROM and DVD drive makers, similar to the way that motherboard and video card

chipset vendors license their technology to other companies. Thus, drives using this technology won't be sold under the Zen Research name.

CD-ROM and forthcoming DVD drives based Zen's TrueX/MultiBeam technology work in a completely different manner than typical CAV drives, which increase their transfer rates by increasing their spin rates. Instead, TrueX drives use a relatively modest constant spin rate and split the data-reading laser beam into seven paths, allowing the beam to read seven tracks at the same time, rather than only one as with conventional drives (hence the term MultiBeam). Figure 13.1 illustrates how the data is split into seven paths.

Figure 13.1 MultiBeam technology allows seven tracks to be read at once.

By using a lower spin rate, the problems of vibration are avoided. By using CLV, the problems of variable data-transfer rates across the CD surface are avoided. And, by reading seven tracks at once, TrueX/MultiBeam drives can achieve true, constant X-ratings of 40x, 52x, or higher. Also,

transfer rates are at a high, constant speed. In Table 13.1, the transfer rates listed for 40x and 52x drives (40x@6,000KB per second, 52x@7,500 KB per second) represent seldom-achieved rates for conventional CAV 40x Max and 52x Max drives from most vendors. However, drives using TrueX/MultiBeam technology achieve these transfer rates across the entire surface of the CD-ROM. Table 13.2 compares two CD ROM drives—one P-CAV and one TrueX.

Table 13.2 P-CAV and TrueX Compared

Drive	Factory X-Rating	Avg. X-Rating	Technology	CPU Utilization	Average Access Time
Acer CD-640A	40x	24-27x	P-CAV	8% (near center of CD) -> 82% (outer tracks of CD at 40x)	75ms
Kenwood 40x	40x	42-47x	TrueX	18% constant across CD	80ms

Source: *Emedia Professional*, January 1999

TrueX/MultiBeam products are available from various vendors. Kenwood Technologies (whose products are sold under both the Kenwood and HiVal names) was the first company to sell retail CD-ROM drives using the TrueX/MultiBeam technology. Some Compaq models also offer TrueX/MultiBeam drives. Because Zen Research doesn't manufacture drives but provides the technology to other drive makers it's likely that other drive vendors will offer both CD-ROM and DVD-type drives using this or improved versions of this technology in the future.

Note

DVD drives using a variation of this technology are expected to be released in 1999, and future versions might include as many as 20-beam reading, compared to the seven-beam reading now in use.

Inside Data CDs

The microprocessor that decodes the electrical impulses is the key difference between audio CD players and CD-ROM drives. Audio CDs convert the digital information stored on the disc into analog signals for a stereo amplifier to process. In this scheme, some imprecision is acceptable because it would be virtually impossible to hear in the music. CD-ROMs, however, cannot tolerate any imprecision. Each bit of data must be read accurately. For this reason, CD-ROM discs have a great deal of additional Error Correcting Code (ECC) information written to the disc along with the actual stored information. The ECC can detect and correct most minor errors, improving the reliability and precision to levels that are acceptable for data storage.

CD-ROM drives operate in the following manner (see Figure 13.2):

1. The laser diode emits a low-energy infrared beam toward a reflecting mirror.
2. The servo motor, on command from the microprocessor, positions the beam onto the correct track on the CD-ROM by moving the reflecting mirror.
3. When the beam hits the disc, its refracted light is gathered and focused through the first lens beneath the platter, bounced off the mirror, and sent toward the beam splitter.
4. The beam splitter directs the returning laser light toward another focusing lens.
5. The last lens directs the light beam to a photo detector that converts the light into electric impulses.
6. These incoming impulses are decoded by the microprocessor and sent along to the host computer as data.

Figure 13.2 Typical components inside a CD-ROM drive.

The pits that are etched into the CD-ROM vary in length. The reflected light beam changes in intensity as it crosses over from a land to a pit area. The corresponding electrical signal from the photodetector varies with the reflected light intensity. The transitions between high and low signals, physically recorded as the start and end of each pit area, form a signaling code that the drive interprets as data bits.

Because a single bit error can be disastrous in a program or data file, the error detection and correction algorithms used by a CD-ROM drive are extensive. These routines allow for the probability of an undetected error to be fewer than 1 in 1,025. In more physical terms, this means that there would be only one undetected error in 2 quadrillion discs (this would form a stack 1 billion miles high!).

The error-correction data alone requires 288 bytes for every 2,048 bytes of informational content on the disc. This allows for the correction of numerous bad bits, including bursts of bad data over 1,000 bits long. This powerful error-correction capability is required because physical defects can

cause errors and because the CD medium was originally designed for audio reproduction, in which minor errors or even missing data are tolerable.

In the case of an audio CD, missing data can be interpolated—that is, the information follows a predictable pattern that enables the drive to guess the missing values. For example, if three values are stored on an audio disc, say 10, 13, and 20 appearing in a series, and the middle value is missing—due to damage or dirt on the CD's surface—you can interpolate a middle value of 15, which is midway between 10 and 20. Although this might not be exactly correct, in the case of audio recording it will not be noticeable to the listener. If those same three values appear on a CD-ROM in an executable program, there is no way to guess at the correct value for the middle sample. Interpolation cannot work because executable program instructions or data must be exact or the program will crash or improperly read data needed for a calculation. To guess 15 is not merely slightly off; it is completely wrong.

Because of the need for such precision, CD-ROM drives for use on PCs were later to market than their audio counterparts. When first introduced, CD-ROM drives were too expensive for widespread adoption. In addition, drive manufacturers were slow in adopting standards, causing a lag time for the production of CD-ROM titles. Without a wide base of software to drive the industry, acceptance was slow.

After the production costs of both drives and discs began to drop, however, CD-ROMs were rapidly assimilated into the PC world. This was particularly due to the ever-expanding size of PC applications. Virtually all software is now supplied on CD-ROM, even if the disc doesn't contain data representing a tenth of its potential capacity. As the industry stands now, if a software product requires more than two or three floppy disks, it is more economical to put it on a CD-ROM.

For large programs, the advantage is obvious. The Windows 98 operating system would require more than 70 floppy disks, and even that is only when Microsoft uses its proprietary 1.71MB disk format. The cost of producing, packaging, and shipping that many floppy disks instead of a single CD-ROM would drive up the price of the product substantially.

What Types of Drives Are Available?

When purchasing a CD-ROM drive for your PC, you should consider three distinct sets of criteria, as follows:

- The drive's performance specifications
- The interface the drive requires for connection to your PC
- The physical disc-handling system the drive uses

The variance in all these categories is enormous; in fact, single vendors offer entire lines of drives that vary in performance specifications, disc-handling mechanisms, and type of interface to the PC. For these reasons, drive prices can also vary widely. Before you buy, know the drive's characteristics.

CD-ROM Drive Specifications

Drive specifications tell you the drive's performance capabilities. If you're shopping for a sports car, for example, and the dealer tells you the car can accelerate from a standing stop to 60 miles per hour in five seconds, you know you've got a hot car. You can use the car's horsepower, weight, suspension design, and other specifications to understand more about the vehicle's performance.

CD-ROM drive specifications tell the shopper much the same thing. Typical performance figures published by manufacturers are the data transfer rate, access time, internal cache or buffers (if any), and the interface the drive uses.

Data Transfer Rate

The data transfer rate tells you how much data the drive can read from a CD-ROM and transfer to the host computer in a given amount of time. Normally, transfer rates indicate the drive's capability for reading large, sequential streams of data.

The standard measurement in the industry is kilobytes per second, usually abbreviated as KB/sec or, for today's faster drives, megabytes per second (MB/sec). If a manufacturer claims a drive can transfer data at 150KB/sec, it means that a drive reading a sequential stream of data from the CD will achieve 150KB/sec after it has come up to speed. Note that this is a sustained and sequential read, as of a single large file, not access across the data disc from different portions of the platter. Obviously, the data transfer specification is meant to convey the drive's peak data-reading capabilities. A higher rate of transfer might be better, but a number of other factors come into play as well.

The standard compact disc format dictates that there should be 75 blocks (or sectors) of data per second, with each block containing 2,048 bytes of data. This gives a transfer rate of exactly 150KB/sec. This is the standard for CD-DA (Digital Audio) drives and is also called single-speed in CD-ROM drives. The term *single-speed* refers to the original 150KB/sec drives because CDs are recorded in a Constant Linear Velocity (CLV) format, which means that the rotational speed of the disc varies to keep the track speed constant. This is also the rate at which music CDs are played by any speed of CD-ROM drive. A double-speed (or 2x) drive simply attains a transfer rate of 300KB/sec, two times that of the single-speed drive.

Because CD-ROM drives do not read and play data in real-time as audio drives do, it is possible to speed up the data transfer rate by spinning the disc at a higher linear velocity. CD-ROM drive speeds have accelerated rapidly over the years, and many different drive speeds are currently available, all of which are multiples of the original single-speed drives. Table 13.3 shows the speeds at which CD-ROM drives can operate.

Table 13.3 CD-ROM Drive Speeds and Data Transfer Rates

Drive Speed	Transfer Rate (bps)	Transfer Rate (KB/sec)
Single-speed (1x)	153,600	150
Double-speed (2x)	307,200	300
Triple-speed (3x)	460,800	450
Quad-speed (4x)	614,400	600
Six-speed (6x)	921,600	900
Eight-speed (8x)	1,228,800	1,200
Ten-speed (10x)	1,536,000	1,500
Twelve-speed (12x)	1,843,200	1,800
Sixteen-speed (16x)	2,457,600	2,400
Eighteen-speed (18x)	2,764,800	2,700
Twenty-four-speed (24x)	3,686,400	3,600
Thirty-two-speed (32x)	4,915,200	4,800
Thirty-six-speed (36x)	5,529,600	5,400
Forty-speed (40x)	6,144,000	6,000
Forty-eight-speed (48x)	7,372,800	7,200
Fifty-two-speed (52x)	7,987,200	7,500
One-hundred-speed (100x)	15,360,000	15,000
CAV drives (12x–24x)	1,843,200–3,686,400	1,800–3,600

bps = bytes per second

KB/sec = kilobytes per second

Note

Starting with 16x drives and above, the rated speeds for conventional (CAV) drives are maximum speeds. For example, a so-called 32x CD-ROM drive will achieve this 32x speed only on the outer edges of a CD-ROM platter. Depending on the drive model, most of the CD will be read at 12x–16x speeds. Because CD-ROMs can hold over 650MB of information, but most CD-ROMs are used to distribute information that occupies only a fraction of the total CD space, this maximum speed is seldom reached because CDs are created from the center of the disc outwards.

Note

So-called 100x CD-ROM drives actually achieve these high transfer rates by copying the contents of the CD-ROM to your hard disk and then running the copy from the (much faster) hard drive. This treats the hard drive as a very large CD-ROM cache. The “100x” drive-caching technology and Smart100 CD-ROM were developed by Taiwan’s Elitetgroup.

The 32x and faster drives are currently the most popular, and are standard equipment in most new PCs on the market today. A 4x drive is the minimum required to meet the MPC-3 (Multimedia Personal Computer) standard, and the fact that 48x and faster drives are now available goes to show that the hardware industry moves much more quickly than the standards-making process. In fact, it would probably be relatively difficult to find a new 4x drive today. New systems typically include a 32x or faster CD-ROM drive.

The way that CD-ROM drive speeds have constantly increased makes the thought of performing upgrades problematic. The drive speed of a CD-ROM has a different effect on different types of users. If you use CDs primarily to install applications or look up textual information in reference products such as dictionaries and telephone directories, the speed of the drive is not critical. A few more seconds spent performing a one-time program installation is not worth making sure you always have the fastest drive on the market.

Multimedia and game titles that contain a lot of music, animation, and video are another story, however. The multimedia experience can be greatly enhanced by a faster CD-ROM drive, and some software products specify a recommended minimum drive speed. It certainly is not necessary, however, to buy a new drive each time a faster speed is introduced. For gamers and other heavy CD-ROM users, a good rule of thumb is that an upgrade is not worthwhile unless you would be at least doubling your present speed. For light CD-ROM users, upgrading might never be necessary, because quad-speed drives are adequate for almost any application. Of course it is virtually impossible to purchase anything less than a 12x drive today because the manufacturers have discontinued all the slower drives due to competition in the marketplace making them uneconomical to produce. When installing a large office suite such as Microsoft Office 2000, Corel WordPerfect Office 2000, or an operating system such as Windows 98 or Windows 2000, using at least a 12x drive will greatly speed up the installation process.

Despite these speed increases, however, even the fastest CD-ROM drives pale in comparison to hard disk drive transfer rates, which can be as high as 21MB/sec. The SCSI or ATA/IDE interfaces that CD-ROM drives use today support data transfer rates reaching 80MB/sec, meaning that they are more than up to the task of maintaining CD-ROM transfer rates. If you expect to run a variety of CD-based software on your system, you need a drive with a high data-transfer rate. Applications that employ full-motion video, animation, and sound require high transfer rates, and you'll be disappointed in the results with a slower drive.

Vibration problems can cause high-speed drives to drop to lower speeds to allow reliable reading of CD-ROMs. Your CD-ROM can become unbalanced if you apply a small paper label to its surface to identify the CD or affix its serial number or code for easy reinstallation. For this reason, some 40x and faster CD-ROM drives such as the Plextor UltraPleX 40max and Acer CD-640A come with auto-balancing or vibration-control mechanisms to overcome these problems.

As drive makers seek to increase maximum speed ratings above 50x by increasing spin rates, vibration can become an even greater problem.

Access Time

The access time for a CD-ROM drive is measured the same way as for PC hard disk drives. In other words, the access time is the delay between the drive receiving the command to read and its actual first reading of a bit of data. The time is recorded in milliseconds; a typical manufacturer's rating for a 24x drive would be listed as 95ms. This is an average access rate; the true access rate depends entirely on where the data is located on the disc. When the read mechanism is positioned to a portion of the disc nearer to the narrower center, the access rate is faster than when it is positioned at the wider outer perimeter. Access rates quoted by many manufacturers are an average taken by calculating a series of random reads from a disc.

Obviously, a faster (that is, a lower) average access rate is desirable, especially when you rely on the drive to locate and pull up data quickly. Access times for CD-ROM drives are steadily improving, and the advancements are discussed later in this chapter. Note that these average times are significantly slower than PC hard drives, ranging from 200ms to below 100ms, compared to the 8ms access time of a typical hard disk drive. Most of the speed difference lies in the construction of the drive itself. Hard drives have multiple-read heads that range over a smaller surface area of the medium; CD-ROM drives have only one laser-read beam, and it must be able to access the entire range of the disc. In addition, the data on a CD is organized in a single long spiral. When the drive positions its head to read a track, it must estimate the distance into the disc and skip forward or backward to the appropriate point in the spiral. Reading off the outer edge requires a longer access time than the inner segments, unless you have a Constant Angular Velocity (CAV) drive, which spins at a constant rate so the access time to the outer tracks is equal to that of the inner tracks.

Access times have been falling since the original single-speed drives came out. With each increase in data transfer speed, you have usually seen an increase in access time as well. But as you can see in Table 13.4, these improvements are much less significant because of the physical limitation of the drive's single-read mechanism design.

Table 13.4 Typical CD-ROM Drive Access Times

Drive Speed	Access Time (ms)
Single-speed (1x)	400
Double-speed (2x)	300
Triple-speed (3x)	200
Quad-speed (4x)	150
Six-speed (6x)	150
Eight-speed (8x)	100
Ten-speed (10x)	100
Twelve-speed (12x)	100

(continues)

Table 13.4 Continued

Drive Speed	Access Time (ms)
Sixteen-speed (16x)	90
Eighteen-speed (18x)	90
Twenty-four-speed (24x)	90
Thirty-two-speed (32x)	85
Forty-speed (40x)	75
Forty-eight-speed (48x)	75
CAV (12/24x)	150–90

The times listed here are typical examples for good drives; within each speed category some drives are faster and some are slower.

Buffer/Cache

Most CD-ROM drives include internal buffers or caches of memory installed on-board. These buffers are actual memory chips installed on the drive's circuit board that enable it to stage or store data in larger segments before sending it to the PC. A typical buffer for a CD-ROM drive is 256KB, although drives are available that have either more or less (more is usually better). Generally, the faster drives come with more buffer memory to handle the higher transfer rates. However, many low-cost (under \$100) CD-ROM drives are shipping with buffers as small as 128KB, which saves money but can limit performance. The Kenwood drives using the Zen Research TrueX/MultiBeam technology, discussed earlier in the chapter, use a 2MB cache buffer, but this is required in part because the seven different data streams from the seven-beam laser must be recombined before transfer to the CPU.

Having buffer or cache memory for the CD-ROM drive offers a number of advantages. Buffers can ensure that the PC receives data at a constant rate; when an application requests data from the CD-ROM, the data can be found in files scattered across different segments of the disc. Because the drive has a relatively slow access time, the pauses between data reads can cause a drive to send data to the PC sporadically. You might not notice this in typical text applications, but on a drive with a slower access rate coupled with no data buffering, it is very noticeable—and even irritating—during the display of video or some audio segments. In addition, a drive's buffer, when under the control of sophisticated software, can read and have ready the disc's table of contents, speeding up the first request for data. A minimum size of 512KB for a built-in buffer or cache is recommended, and is standard on many 24x and faster drives. However, keep in mind that large buffers don't always result in faster data transfer rates overall.

CPU Utilization

A once-neglected but very real issue in calculating computer performance is the impact that any piece of hardware or software has on the CPU (central processing unit). This CPU utilization

factor refers to how much attention the CPU (such as Pentium III, K6-3, and so on) must provide to the hardware or software to help it work. A low CPU utilization percentage score is desirable because the less time a CPU spends on any given hardware or software process provides more time for other tasks, and thus greater performance for your system. On CD-ROM drives, three factors influence CPU utilization: CAV drive speed, drive buffer size, and interface type.

A good example of the impact of CAV drive speed can be seen in comparing the CPU utilization rates of the Acer and Kenwood 40x drives I looked at earlier.

Drive	Type	Minimum CPU-Utl	Maximum CPU-Utl
Acer 40x	P-CAV	8% (inner tracks)	82% (40x reads)
Kenwood 40x	TrueX	18% at all times	

The Acer 40x drive required most of the CPU's attention when reading at 40x, but the Kenwood used less than 20 percent of the CPU's attention no matter where the data was on the CD.

Drive buffer size also influences CPU utilization. For CD-ROM drives with similar performance ratings, the drive with a larger buffer is likely to require less CPU time (lower CPU Utilization percentage) than the one with a smaller buffer.

A third factor influencing CPU utilization is the interface type. Traditionally, SCSI-interface CD-ROM drives have had far lower CPU utilization rates than IDE/ATAPI drives of similar ratings. One review of 12x drives done several years ago rated CPU utilization for IDE/ATAPI CD-ROM drives at 65–80 percent, whereas SCSI CD-ROM drives checked in at less than 11 percent.

DMA (Direct Memory Access)

Today, the introduction of bus-mastering IDE controller circuits on current-model Pentium-class motherboards has substantially changed the picture. Bus-mastering IDE controllers use Direct Memory Access (DMA) transfers to improve performance and reduce CPU utilization. Now, CPU utilization for IDE/ATAPI and SCSI CD-ROM drives is about equal at around 11 percent. Thus, it's to your benefit to enable DMA access for your CD-ROM drives (and your IDE hard drives, too) if your system permits it.

Most recent IDE/ATAPI CD-ROM drives (12x and above) support DMA transfers, as does Windows 95 and above and most recent Pentium-class motherboards. To determine whether your Win9x system has this feature enabled, check the System Properties' Device Manager tab and click the + mark next to Hard Disk Controllers. A drive interface capable of handling DMA transfers will list Bus Master in the name. Next, check the hard drive and CD-ROM information for your system. You can use the properties sheet for your system's CD-ROM drives under Windows 9x to find this information; you might need to open the system to determine your hard drive brand and model. Hard disk drives and CD-ROM drives that support MultiWord DMA Mode 2 (16.6MB/second), UltraDMA Mode 2 (33MB/second), or faster can use DMA transfers. Check your product literature or the manufacturer's Web sites for information.

To enable DMA transfers if your motherboard and drives support it, open the System Properties sheet in Windows 9x, click the Device Manager tab, and open the Properties sheet for your hard drive. Click the Settings tab, and place a check mark in the box labeled DMA.

Repeat the same steps to enable DMA transfers for any additional hard drives and ATAPI/IDE CD-ROM drives in your computer. Restart your computer after making these changes.

Note

I strongly recommend that you back up your drives and your Windows 9x Registry before you enable DMA support or before you install and enable the driver to allow DMA support. If your system hangs up after you enable this feature, you'll need to replace the Registry after enabling DMA with the pre-DMA copy. Otherwise, you'll be faced with editing Registry keys by hand to start your system again. Because DMA transfers bypass the CPU to achieve greater speed, DMA problems could result in data loss. Make backups first, instead of wishing you had later.

Drive interfaces that don't mention bus mastering can't perform this speedup or need to have the correct driver installed. Windows 95 OSR 2.x and Windows 98 will automatically install the correct driver for Intel chipsets that support bus mastering. However, if you have a non-Intel chipset, or have Windows 95 (original version) or Windows 95a (OSR1), you will need to determine whether your system can support bus mastering and download the correct drivers. A good Web site for both Intel and non-Intel chipset support of this important feature is www.bmdrivers.com. Follow the links at this site to the motherboard chipset vendors, their technical notes (to determine whether your chipset supports bus mastering), and the drivers you need to download. Table 13.5 provides a list of chipsets that support DMA.

Table 13.5 Bus-Mastering Chipsets by Vendor and Operating System

Vendor	Chipsets	Driver Source by Operating System
Intel	430FX 430HX 430VX 440FX 430TX 440LX 440BX 440EX 440GX 440ZX 440ZX-66 450NX	(Same driver for all Intel chipsets) Windows 95 original & OSR1 (95a): Download from the Intel Web site Windows 95B, 95C (OSR 2.x), Windows 98: included on Windows CD-ROM
VIA	MVP3 VP3 VP2 VPX VP1	For Windows 95 (any version) and NT 3.51 & higher: Download the drivers from the VIA Web site. For Windows 98: included on CD-ROM

Vendor	Chipsets	Driver Source by Operating System
SiS	611 85c496 5513, 5571, 5581/5582, 5591, 5597/5598, 5600 IDE Driver* SiS530/5595 & SiS620/5595 IDE Driver	Download the drivers from the SiS Web site. *(For SiS chipsets 5511/5512/ 5513, 5596/5513, 5571, 5581/5582, 5598/5597, 5591/5595, 600/5595)
ETEQ	Various motherboard models	See www.soyo.com.tw to look up models and drivers; download there or from related FTP site.
PCChips	TXPRO	Download DOS, Windows 3.1, Windows 95, and Windows NT 4 drivers from the PCChips FTP site
	HXPRO	Download DOS, Windows 3.1, Windows 95, Windows NT 3.51 and 4.0 drivers from the PCChips FTP site.
	VXPRO	Download DOS, Windows 3.1, Windows 95, UNIX, OS/2, Windows NT 3.5, or NetWare drivers from the PCChips FTP site
Ali	See note at right	Drivers are available from the motherboard makers using Ali chipsets.

All Intel chipsets which contain a PIIXn device (PIIX, PIIX3, PIIX4, PIIX4E, and so on) are bus-mastering chipsets.

Although PCChips chipset names are similar to certain Intel Pentium chipsets (Triton series TX, HX, and VX), the drivers listed are strictly for PCChips chipsets, not Intel's.

A replacement for manufacturer-specific bus-mastering drivers is available from HighPoint Technologies. This product, XStore Pro, supports bus-mastering chipsets made by Intel, Via, SiS, and ALi, and has proven to more than double disk performance as measured by the Ziff-Davis Business WinMark 98. For more information, visit the HighPoint Web site.

Interface

A CD-ROM's interface is the physical connection of the drive to the PC's expansion bus. The interface is the data pipeline from the drive to the computer, and its importance shouldn't be minimized. There are four different types of interfaces available for attaching a CD-ROM, CD-R, or CD-RW drive to your system:

- SCSI/ASPI (Small Computer System Interface/Advanced SCSI Programming Interface)
- IDE/ATAPI (Integrated Drive Electronics/AT Attachment Packet Interface)
- Parallel port
- USB port

The following sections examine these different interface choices.

SCSI/ASPI

SCSI (pronounced *scuzzy*), or the Small Computer System Interface, is a name given to a special interface bus that allows many different types of peripherals to communicate. The current implemented version of the standard is called SCSI-3, which actually consists of several standards, each defining a part of the interface.

A standard software interface called ASPI (Advanced SCSI Programming Interface) enables CD-ROM drives (and other SCSI peripherals) to communicate with the SCSI host adapter installed in the computer. SCSI offers the greatest flexibility and performance of the interfaces available for CD-ROM drives, and can be used to connect many other types of peripherals to your system as well.

The SCSI bus enables computer users to string a group of devices along a chain from one SCSI host adapter, avoiding the complication of installing a separate adapter card into the PC bus slots for each new hardware device, such as a tape unit or additional CD-ROM drive added to the system. These traits make the SCSI interface preferable for connecting a peripheral such as a CD-ROM to your PC.

Not all SCSI adapters are created equal, however. Although they might share a common command set, they can implement these commands differently, depending on how the adapter's manufacturer designed the hardware. ASPI was created to eliminate these incompatibilities. ASPI was originally developed by Adaptec, Inc., a leader in the development of SCSI controller cards and adapters who originally named it the Adaptec SCSI Programming Interface before it became a de facto standard. ASPI consists of two main parts. The primary part is an ASPI-Manager program, which is a driver that functions between the operating system and the specific SCSI host adapter. The ASPI-Manager sets up the ASPI interface to the SCSI bus.

The second part of an ASPI system is the individual ASPI device drivers. For example, you would get an ASPI driver for your SCSI CD-ROM drive. You can also get ASPI drivers for your other SCSI peripherals, such as tape drives and scanners. The ASPI driver for the peripheral talks to the ASPI-Manager for the host adapter. This is what enables the devices to communicate together on the SCSI bus.

The bottom line is that if you are getting an SCSI interface CD-ROM, be sure that it includes an ASPI driver that runs under your particular operating system. Also, be sure that your SCSI host adapter has the corresponding ASPI-Manager driver as well. There are substantial differences between different SCSI adapters because SCSI can be used for a wide variety of peripherals. Low-cost, SCSI-3 compliant ISA or PCI adapters can be used for CD-ROM interfacing, but higher-performance PCI adapters that support more advanced SCSI standards such as Wide, Ultra, UltraWide, Ultra2Wide, and so on can be used with both CD-ROM drives and other devices such as CD-R/CD-RW drives, hard drives, scanners, tape backups, and so forth. To help you choose the appropriate SCSI adapter for both your CD-ROM drive and any other SCSI-based peripheral you're considering, visit Adaptec's Web site.

The SCSI interface offers the most powerful and flexible connection for CD-ROMs and other devices.

It provides better performance, and seven or more drives can be connected to a single host adapter. The drawback is cost. If you do not need SCSI for other peripherals and intend on connecting only one CD-ROM drive to the system, you will be spending a lot of money on unused potential. In that case, an IDE/ATAPI interface CD-ROM drive would be a more cost-effective choice.

IDE/ATAPI

The IDE/ATAPI (Integrated Drive Electronics/AT Attachment Packet Interface) is an extension of the same ATA (AT Attachment) interface most computers use to connect to their hard disk drives. Specifically, ATAPI is an industry-standard enhanced IDE interface for CD-ROM drives. ATAPI is a software interface that adapts the SCSI/ASPI commands to the IDE/ATA interface. This enables drive manufacturers to take their high-end CD-ROM drive products and quickly adapt them to the IDE interface. This also enables the IDE CD-ROM drives to remain compatible with the MSCDEX (Microsoft CD-ROM Extensions) that provide a software interface with DOS. With Windows 9x, the CD-ROM extensions are contained in the CDFS (CD File System) VxD (virtual device) driver.

ATAPI drives are sometimes also called enhanced IDE (EIDE) drives because this is an extension of the original IDE (technically the ATA) interface. In most cases, an IDE/ATA CD-ROM drive will connect to the system via a second IDE interface connector and channel, leaving the primary one for hard disk drives only. This is preferable because IDE does not share the single channel well and would cause a hard disk drive to wait for CD-ROM commands to complete and vice versa. SCSI does not have this problem because a SCSI host adapter can send commands to different devices without having to wait for each previous command to complete.

Caution

If you decide to purchase a writable CD-ROM drive, such as a CDR or CD-RW, the SCSI interface is most definitely recommended over IDE/ATA because of IDE's problems in sharing a channel between two devices. Writing to a compact disc requires a steady stream of data that the IDE interface often is not capable of delivering.

The IDE/ATAPI interface represents the most cost-effective and high-performance interface for CD-ROM drives. Most new systems that include a CD-ROM drive will have it connected through IDE/ATAPI. To prevent performance problems, be sure that your CD-ROM drive is connected on the secondary IDE channel, which is separate from the primary channel used by your hard disk drives. Some sound cards include an ATAPI interface driver and the requisite secondary IDE interface connector specifically for a CD-ROM drive. You can connect up to two drives to the secondary IDE connector; for more than that, SCSI is your only choice, and provides better performance as well.

Many systems on the market today can use the IDE/ATAPI CD-ROM drive as a bootable device, which allows the vendor to supply a recovery CD that can restore the computer's software to its factory-shipped condition. Later, you'll see how bootable CDs differ from ordinary CDs and how you can use low-cost CD-R/CD-RW drives, CD-R mastering software, and imaging software to make your own bootable CDs with your own preferred configuration.

Parallel Port

One of the easiest types of CD-ROM drive to install is one that uses a parallel port interface, and parallel port drives can be used on virtually any computer running Windows 9x.

Rather than opening the case to insert an SCSI adapter or connect an internal drive, you can install some CD-ROM drives simply by connecting a cable to the PC's parallel port and loading the appropriate software.

Obviously, the advantages of CD-ROMs that use the parallel port interface are their ease of installation and their portability. In an office environment where the primary function of CD-ROMs is to install software, you can easily move one parallel port drive from machine to machine, rather than purchase a drive for each system. If you use an operating system that supports Plug and Play (PnP), such as Windows 9x, simply plugging a PnP drive into the parallel port causes the OS to detect the new hardware and load the appropriate driver for you automatically.

For best performance, it's recommended that you set your printer port to use IEEE-1284 standards such as ECP/EPP or ECP before connecting your parallel-port CD-ROM. These are bidirectional, high-speed extensions to the standard Centronics parallel-port standard and will provide better performance for virtually any recent parallel device, including printers, tape backups, and Zip and LS-120 drives (also known as SuperDrives), as well as CD-ROM, CD-R, and CD-RW drives.

Using the IEEE-1284 enhanced settings can make a tremendous difference in parallel-port CD-ROM performance. For example, bidirectional (PS/2 style) can achieve data transfer rates of 100 to 530KB/second, whereas EPP can achieve rates of about 1,200Kb/second—12 times that of standard (unidirectional).

▶▶ See "IEEE 1284 Parallel Port Standard," p. 884.

Note

Parallel port CD-ROM drives nearly always include a cable with a pass-through connector. This connector plugs into the parallel port and, if necessary, a printer cable can plug into the connector. This enables you to continue using the port to connect to your printer while sharing the interface with the CD-ROM drive.

Not surprisingly, you pay a price for all this convenience. Parallel port drives typically have somewhat lower data-transfer rates and higher access times than their SCSI or IDE/ATA counterparts, they are slightly more expensive, and, of course, they require their own power supply. Parallel port devices can also be subject to compatibility problems, particularly on older systems. These performance levels can make the drives unsuitable for high-end gaming and multimedia applications, but for general use they are more than adequate.

I generally do not recommend that you purchase a parallel port device simply to save the trouble of opening up the computer. Installing an internal drive is not terribly difficult, and the performance increase is more than worth the extra effort. However, if you can take advantage of the portability that these devices provide, they are an excellent CD-ROM solution.

USB Interface

The newest type of interface, USB, the Universal Serial Bus, has proven to be extremely flexible and has been used for everything from keyboards and joysticks to CD-RW drives from several vendors. These drives can function as CD-ROM drives for data reading, but their real benefit comes in their transportability to different computers for use as a backup or archiving device with CD-R or CD-RW media.

USB CD-RW drives provide read and write transfer rates that match the fastest rates possible with IEEE-1284 parallel ports, with read rates on typical 6x models ranging from 1,145 to 1,200KB/second. They offer the same PnP ease of other modern peripherals used on a Windows 9x system. USB also provides a benefit that no parallel-port drive can match: hot-swappability, the capability to be moved from one computer to another without powering down either system.

For Windows 98 systems with USB ports, USB-based CD-RW drives are an excellent solution for backup and archiving of data onto low-cost, durable optical media. Although Windows 95 OSR 2.1 and above also support USB, at least in theory, USB device support with Windows 95 is chancy at best. This operating-system limitation should be a minimal issue as time passes and Windows 95 is replaced by Windows 98 and Windows 2000.

▶▶ See “USB and 1394 (i.Link) FireWire—Serial and Parallel Port Replacements,” p. 891.

Loading Mechanism

There are two distinctly different mechanisms for loading a CD into a CD-ROM drive: the tray and the caddy. Each one offers some benefits and features. Which type you select has a major impact on your use of the drive because you interact with this mechanism every time you load a disc.

Multiple CD-ROM drives on the market allow you to insert more than one disc at a time. Some of these use a special cartridge that you fill with discs, much like a multidisc CD player used in automobiles. Newer models are slot-loading, allowing you to push a button to select which internal cartridge slot you want to load with a CD. The drive’s door opens and you slide in the CD, which the drive mechanism grabs and pulls into place. Typical capacities range from 3–5 CDs or more, and these are available in both SCSI and IDE/ATAPI interfaces.

Tray

Most current SCSI and IDE/ATAPI CD-ROM drives use a tray loading mechanism. This is similar to the mechanism used with a stereo system. Because you don’t need to put each disc into a separate caddy, this mechanism is much less expensive overall. However, it also means that you have to handle each disc every time you insert or remove it.

Tray loading is more convenient than a caddy system (see the section, “Caddy,” later in this chapter) because you don’t need a caddy. However, this can make it much more difficult for young children to use the discs without smudging or damaging them due to excess handling.

The tray loader itself is also subject to damage. The trays can easily break if bumped or if something is dropped on them while they are extended. Also, any contamination you place on the tray or disc is brought right into the drive when the tray is retracted. Tray-loaded drives should not be used in a harsh environment such as a commercial or industrial application. Make sure both the tray and the data surface of the CD are clean whenever you use a tray-loading CD.

Note

One of the classic legends among PC technical support engineers is that of the user who called to complain that the cup holder on his computer retracted every time he restarted the machine. After careful questioning, the puzzled engineer determined that the caller had been using the CD-ROM tray to hold his coffee cup. Needless to say, this practice is not recommended.

The tray mechanism also does not hold the disc as securely as the caddy. If you don't have the disc placed in the tray properly when it retracts, the disc or tray can be damaged. Even a slight misalignment can prevent the drive from reading the disc properly, forcing you to open the tray and reset the disc.

Some tray drives cannot operate in a vertical (sideways) position because gravity prevents proper loading and operation. Check to see whether the drive tray has retaining clips on the outer edge of the CD seat, such as the Hitachi drive I have in my HP Vectra. If so, you can run the drive in either horizontal or vertical position.

Some CD-ROM drives equipped with retaining clips still aren't able to run CD-ROMs reliably in the vertical position. If this is a critical feature for you, be sure to test a unit before you install it in a system, or make sure you can return it if it doesn't work properly.

Apart from the convenience, the other advantage of the tray mechanism over the caddy system is in cost, and that is a big factor. If you do not have young children and you plan to use the drive in a clean environment where careful handling and cleanliness can be assured, the tray mechanism is recommended due to its significantly lower cost.

Caddy

At one time, the caddy system was used on most high-end CD-ROM drives as well as the early CD-R (recordable CD) drives. It has since declined in popularity due to the convenience of the tray. The caddy system requires that you place the CD itself into a special caddy, which is a sealed container with a metal shutter. The caddy has a hinged lid that you open to insert the CD, but after that the lid remains shut. When you insert the caddy containing the CD into the drive, the drive opens a metal shutter on the bottom of the caddy, allowing access to the CD by the laser.

The caddy is not the most convenient loading mechanism, although if all your CDs are in their own caddies, all you have to do is grab the caddy containing the disc you want and insert it into the drive. This makes the CD operate much like a 3.5-inch disk. You can handle the caddy without worrying about touching or contaminating the disc or the drive, making this the most

accurate and durable mechanism as well. Young children can easily handle the caddies and don't have to touch the compact discs themselves.

Because the caddy is sealed, the discs are protected from damage caused by handling. The only time you actually handle the disc is when you first put it into the caddy. The caddy loading system also ensures that the disc is properly located when inside the drive. This allows for more accurate laser-head positioning mechanisms, and caddy drives generally have faster access times, as well.

The drawbacks to the caddy system are the expense and the inconvenience. You only get one caddy with the drive, so if you want to store your CD-ROMs in their own caddies, you must buy many more. Additional caddies can cost from \$4–\$10 each, which can lead to a significant expense if you have a large number of CD-ROMs. Most people do not buy caddies for all their discs. The alternative is that each time you insert a new disc into the drive, you first have to eject the caddy/disc, remove the disc from the caddy, put the disc back into the original jewel case, open the jewel case for the new disc, put the new disc into the caddy, and finally insert the caddy/disc back into the drive.

A final advantage of caddy-loaded drives is that they can function when mounted either horizontally or vertically, meaning that the drive can be installed sideways. You cannot do this with the cheaper tray-loaded drives, although some newer tray-loaded drives have small retaining tabs that allow both horizontal or vertical mounting.

Caddy-based CD-ROM and CD-R systems have declined drastically in popularity in recent years.

Other Drive Features

Although drive specifications are of the utmost importance, you should also consider other factors and features when evaluating CD-ROM drives. Besides quality of construction, the following criteria bear scrutiny when making a purchasing decision:

- Drive sealing
- Self-cleaning lenses
- Internal versus external drive

Drive Sealing

Dirt is your CD-ROM's biggest enemy. Dust or dirt, when it collects on the lens portion of the mechanism, can cause read errors or severe performance loss. Many manufacturers seal off the lens and internal components from the drive bay in airtight enclosures. Other drives, although not sealed, have double dust doors—one external and one internal—to keep dust from the inside of the drive. All these features help prolong the life of your drive.

Caddy-loaded drives are inherently sealed better and are much more resistant to the external environment than tray-loaded drives. Always use a caddy-loaded drive in harsh industrial or commercial environments.

Self-Cleaning Lenses

If the laser lens gets dirty, so does your data. The drive will spend a great deal of time seeking and reseeking or will finally give up. Lens-cleaning discs are available, but built-in cleaning mechanisms are now included on virtually all good-quality drives. This might be a feature you'll want to consider, particularly if you work in a less-than-pristine work environment, or you have trouble keeping your desk clean, let alone your CD-ROM drive lens.

Internal Versus External Drives

When deciding whether you want an internal or external drive, think about where and how you're going to use your CD-ROM drive. What about the future expansion of your system? Both types of drives have advantages and disadvantages, such as the following:

- *External enclosure.* These tend to be rugged, portable, and large—in comparison to their internal versions. Buy an external drive only if you lack the space inside the system or if your computer's power supply cannot support the additional load. You might also consider an external if you want to be able to move the drive from one PC to another easily. Parallel port drives are very portable and supported on a broad range of machines, but USB drives are a better choice for Windows 98 systems that have USB ports. SCSI drives can also be portable. If each PC has its own SCSI adapter with an external connection, all you need to do is unplug the drive from one adapter and plug it in to the other. Parallel port and USB-based drives must be external, and SCSI CD-ROM drives can be external, so if you are looking for an IDE type interface, you must use the internal IDE connector.
- *Internal enclosure.* Internal drives will clear off a portion of your desk. Buy an internal drive if you have a free drive bay and a sufficient power supply and you plan to keep the CD-ROM drive exclusively on one machine. The internal drives are also nice because you can connect the audio connector to your sound card and leave the external audio connectors free for other inputs. Internal drives can be IDE or SCSI.

CD-ROM Disc and Drive Formats

Compact discs are pitted to encode the binary bit values 0 and 1. Without a logical organization to this disc full of digits, the CD-ROM drive and PC would be at a loss to find any discernible data amid all those numbers. To this end, the data is encoded to conform to particular standards. When a drive encounters particular patterns, it—and the PC—can recognize the organization of the disc and find its way around the platter. Without standard data formats, the CD-ROM industry would be dead in the water; vendors of discs and disc drives would produce hardware and software that was incompatible with that of other vendors, thereby limiting the number of units that could be sold.

Formats are also needed to advance the technology. For example, hard rubber wheels and no suspension were fine for the first automobiles as they cruised along at the breakneck speed of 30mph. But hitting a pothole at 60mph could cause serious damage to the vehicle—and the riders. Inflatable tires and shock absorbers became necessary components of the modern car.

Similarly, the standards for disc formats have evolved as well. The first compact data discs stored only text information, which is relatively easy to encode. Graphics produced a greater challenge, and the standards evolved to accommodate them. The use of animation with synchronized sound and live-motion video called for other expansions to the standards by which data is stored on CDs.

It is extremely important to note that advanced CD-ROM standards are in the process of evolution right now. Multiple vendors are deploying a number of different techniques for expanding the capabilities of CD-ROM technology. They might be incompatible with each other or immature in their development, but acceptance of these newer standards by software vendors is essential to the widespread use of these standards. It is important that you be familiar with these issues before you purchase a drive. Consider the formats it is capable of reading now—and in the future.

The majority of drives available today, however, do comply with earlier CD-ROM formats, ensuring that the vast library of CD-ROM titles available today can be used on these drives.

Table 13.6 describes the differing CD-ROM formats.

Table 13.6 CD-ROM Formats

Format	Used For	Notes
Red Book	Digital audio CDs	This standard, a.k.a. CDDA (Compact Disc Digital Audio), was codeveloped by Philips and Sony
Yellow Book	Computer CDs	Specifies physical arrangement of sectors. ISO Mode 1:9660 Level 1: PC, Apple, UNIX, DVI Level 2: CDTV ISO 9660, HFS, and HFS-ISO are used with Yellow Book to define file and directory structures. See also Mode 1, Mode 2, and CD-ROM/XA, which define sector formats.
White Book	VideoCD	Stores MPEG-1, MPEG-2, and similar video sources. Has replaced VHS video in southeast Asia for film distribution.
Orange Book	Writable CDs including CD-R, magneto-optical, single and multisession recording and packet writing	Part I—Magneto-Optical Drives Part II—CD-R
Green Book	Combination of Red Book and Yellow Book—for CD-I (Interactive CD)	CD-ROM/XA can be played on either CD-I or CD-ROM drives; CD-I has been used for interactive sales presentations and kiosks
CD+ (Enhanced CD)	Combines music and computer data on single CD	Used by musical artists to incorporate videos and interviews on music CDs

Data Standard: ISO 9660

Manufacturers of the first CD-ROM data discs produced their discs for one particular drive. In other words, a data disc produced for company A's drive could not be read by anyone who had purchased company B's CD-ROM drive—the disc needed to be formatted for each manufacturer's drive. Obviously, this stalled the development of the industry. Philips and Sony developed the “Yellow Book” specifications for data CD-ROMs.

When Philips and Sony first published the audio CD specifications, the material was released in a red binder and became known as the “Red Book.” Subsequent CD-ROM specifications have been dubbed by color as well, such as the “Orange Book” and the “Green Book.”

The Yellow Book specifications are an extension of the way in which audio data can be stored on disc, and detail how data—rather than audio—can be organized on a disc for its later retrieval. The International Organization for Standardization (ISO) refined this specification (called ISO 9660) so that every vendor's products could expect to find a table of contents in the same place on a data disc. This is known as a Volume Table of Contents, and is quite similar in theory to a printed book's table of contents. ISO 9660 did not completely solve compatibility problems, however. The method for incorporating additional data to aid and refine the disc search process and even the format of the data blocks was still left to each separate vendor's design.

High Sierra Format

It was in all manufacturers' interests to resolve this standardization issue. In a meeting in 1985 at the High Sierra Hotel and Casino in Lake Tahoe, California, leading manufacturers of CD-ROM drives and CD-ROM discs came together to resolve the differences in their implementation of the ISO 9660 format. The agreement has become known as the High Sierra format and is now a part of the ISO 9660 specification document. This agreement enabled all drives to read all ISO 9660-compliant discs, opening the way for the mass production of CD-ROM software publishing. Adoption of this standard also enabled disc publishers to provide cross-platform support for their software, easily manufacturing discs for DOS, UNIX, and other operating system formats. Without this agreement, the maturation of the CD-ROM marketplace would have taken years longer and stifled the production of CD-ROM-based information.

The exact and entire specifications for how to format the compact disc medium are complex, strewn with jargon you might never need, and superfluous to your understanding of a drive's capabilities. You should know the basics, however, because you get a glimpse into the inner workings of how data can be retrieved so quickly from such an enormous well.

To put the basic High Sierra format in perspective, the disc layout is roughly analogous to that of a floppy disk. A floppy disk has a system track that not only identifies itself as a floppy disk and reveals its density and operating system, but also tells the computer how it's organized—into directories, which are made up of files.

Basic CD-ROM formats are much the same. The initial track of a data CD identifies it as a CD and begins the synchronization between the drive and the disc. Beyond the synchronization lies a

system area that details how the entire disc is structured. This system area identifies the location of the volume area—where the actual data is stored. The system area also lists the directories in this volume, with pointers or addresses to various named areas, as illustrated in Figure 13.3. A significant difference between the CD directory structure and that of DOS is that the CD's system area also contains direct addresses of the files within the subdirectories, allowing the CD to seek specific locations on the spiral data track.

Because the CD data is all on one long spiral track, when speaking of tracks in the context of a CD, I'm actually talking about sectors or segments of data along that spiral.

Figure 13.3 A diagram of CD-ROM basic file organizational format.

CD-DA (Digital Audio)

Data drives that can read both data and audio are called CD-DA. Virtually all the data drives now being sold read both types of discs. When you insert a disc, the drive reads the first track to determine what type of disc you've loaded. Most drives ship with audio CD software that enables you to play music CDs from your PC; Windows 9x and Windows NT have this capability built in. You can use headphones or, with an installed sound card, connect speakers to the system. Some external drives ship with standard Left/Right audio plugs; simply plug them into any external amplifier.

CD-ROM XA or Extended Architecture

CD-ROM XA, or Extended Architecture, is backward-compatible with the earlier High Sierra or ISO 9660 CD-ROMs. It adds another dimension to the world of CD-ROM technology: multiple-session recording.

Multiple Sessions

You will remember from the High Sierra format discussion that each CD-ROM disc has a VTOC (or Volume Table of Contents) in its system area, which tells the CD reader where and how the data is laid out on disc. Until this point, CD data was single-session in its encoding. In other words, when a CD was mastered, all the data that will ever reside on the disc had to be recorded in one session. The format, or the medium, had no provision for returning later to append more information.

Single-session CDs are no longer the only option, however. The CD-ROM XA format includes the capability to create multiple sessions on a single disc, each with its own VTOC. A drive that is CD-ROM XA-compliant is capable of finding the multiple VTOCs located on different areas of the disc and reading the data from those multiple sessions. This means that you can record a small amount of data on a CD, remove the CD from the drive, and then return to it later to record more data until the disc is filled. This is a vast improvement over the single-session concept, which forced you to wait until you had a sufficient amount of data to make burning a disc worthwhile. This technique is used by photofinishers who provide you with a CD with your pictures and ask you to return the CD to them with your next roll until the CD is full of electronic versions of your photos.

Multisession CD-ROMs Versus CD-RW

Although CD-ROM XA recording (see the section “CD-R” later in this chapter) allows you to reuse a CD-R until it’s full by multisession recording, there is no way to remove data from the CD-R but to simply replace it with updated versions until the CD-R is full. CD-RW (Rewritable CD) drives allow you to add, edit, and delete data from CD/RW media, as well as use CD-R media as with CD-R-only drives.

Interleaving

CD-ROM XA drives employ a technique known as interleaving. The specification calls for the capability to encode on disc whether the data directly following an identification mark is graphics, sound, or text. Graphics can include standard graphics pictures, animation, or full-motion video. In addition, these blocks can be interleaved, or interspersed, with each other. For example, a frame of video can start a track followed by a segment of audio, which would accompany the video, followed by yet another frame of video. The drive picks up the audio and video sequentially, buffering the information in memory, and then sending it along to the PC for synchronization.

In short, the data is read off the disc in alternating pieces and then synchronized at playback so that the result is a simultaneous presentation of the data. Without interleaving, it would be necessary for the drive to read and buffer the entire video track before it could read the audio track and synchronize the two for playback.

Mode 1 and Mode 2, Form 1 and Form 2

To achieve this level of sophistication, the CD format is broken up so that the data types are layered. Mode 1 is the standard Yellow Book CD sector format with error correction. Each 2,352-byte sector consists of four fields (see Figure 13.4), as follows:

- Synchronization (12 bytes)
- Header (8 bytes)
- User Data (2,048 bytes)
- Error Correction Code (ECC) and Error Detection Code (EDC) (284 bytes)

Figure 13.4 CD-ROM Yellow Book (Mode 1) sector format.

Mode 2, which was newly defined for the XA format, is CD data without error correction. The Mode 2 track, however, allows what are called Form 1 and Form 2 tracks to exist one after the other on the Mode 2 track, thereby permitting the interleaving. These interleaved tracks can include their own error correction and can contain any type of data. Figure 13.5 shows a visual representation of the breakdowns of Mode and Form structure.

Figure 13.5 A diagrammatic view of Mode and Form format for CD-ROM XA.

A Mode 2, Form 1 sector contains six fields (see Figure 13.6), as follows:

- Synchronization (12 bytes)
- Header (8 bytes)
- Subheader (8 bytes)
- User Data (2,048 bytes)
- Error Correction Code (280 bytes)
- Error Detection Code (4 bytes)

Figure 13.6 CD-ROM Yellow Book (Mode 2, Form 1) sector format.

A Mode 2, Form 2 sector contains only five fields (see Figure 13.7), as follows:

- Synchronization (12 bytes)
- Header (8 bytes)
- Subheader (8 bytes)
- User Data (2,324 bytes)
- Error Detection Code (4 bytes)

Synchronization (12 bytes)	Header (8 bytes)	Subheader (8 bytes)	User Data (2324 bytes)	EDC (4 bytes)
-------------------------------	---------------------	------------------------	---------------------------	------------------

Figure 13.7 CD-ROM Yellow Book (Mode 2, Form 2) sector format.

Both sector formats add a subheader field that identifies the type of information (such as audio or video) carried in the user data field. The Form 2 sector lacks the Error Correction Code of the Form 1 sector and increases the size of the user data field instead.

Because they use less control data, CD-ROMs that use the Mode 2, Form 2 sector format (such as MPEG video CDs) can hold more user information than other CD-ROM types in the same number of sectors, resulting in a data transfer rate of 172KB/sec instead of the standard 150KB/sec.

For a drive to be truly XA-compatible, the Form 2 data encoded on the disc as audio must be Adaptive Differential Pulse Code Modulation (ADPCM) audio—specially compressed and encoded audio. This requires that the drive or the SCSI controller have a signal processor chip that can decompress the audio during the synchronization process.

What all this translates into is that many of the CD-ROM drives currently available are only partially XA-compliant. They might be capable of reading the interleaved data and multisession discs but might not have the ADPCM audio component on the disc or its controller.

Presently, the only drives with full XA compliance are produced by Sony and IBM. The Sony drive incorporates the ADPCM chip on its drive. The IBM XA drive is for IBM's proprietary Micro Channel bus and is designed for its high-end PS/2 Model computers.

Manufacturers might claim that their drives are XA-ready, which means that they are capable of multisession and Mode 1 and Mode 2, Form 1 and Form 2 reading, but they do not incorporate the ADPCM chip. This is not a devastating shortcoming, however, because the CD-ROM XA format has not been very successful in itself. Software developers have not produced many XA software titles. IBM has a few under its Multimedia program, but when compared to the thousands of CD-ROM titles produced each year, very few of them take full advantage of XA capabilities.

However, although you might not find many XA discs on the market, the multisession capabilities and the Mode 2 sector formats defined by the standard are the basis for other CD-ROM formats that have been somewhat more successful, such as CD Extra (or CD PLUS) and PhotoCD.

If you purchase a drive that is fully mode- and form-compatible and is capable of reading multiple sessions, you have the technology needed to take advantage of the most popular formats available at this time. Audio and video interleaving is possible without full XA compliance, as MPC (Multimedia PC) applications under Microsoft Windows demonstrate.

Mixed-Mode CDs

There are several CD-ROM formats that combine different mode sectors on a single disc. Usually, these discs include both standard CD audio and CD-ROM data sectors and originate from the

music side (rather than the data side) of the compact disc industry. The intention is for a user to be able to play only the audio tracks in a standard audio CD player while remaining unaware of the data track. However, a user with a PC or a dedicated combination audio/data player can access both the audio and data tracks on the same disc. The audio portion of the disc can consist of up to 98 standard Red Book audio tracks, whereas the data track is typically composed of XA Mode 2 sectors, and can contain video, song lyrics, still images, or other multimedia content.

The fundamental problem with these mixed-mode CDs is that when an audio player tries to play the data track, the result is static that could conceivably damage speakers. Different manufacturers have addressed this problem in different ways, resulting in a number of format names, including CD-ROM Ready, Enhanced Music CDs, CD Extra, and CD Plus.

CD-ROM Ready

One solution, the CD-ROM Ready disk, hides the data track in a pause before the first audio track on the disc. Inserting the CD into an audio player and pressing the Play button simply skips past the pause and plays the first audio track. However, if you start the audio playing and then rewind past the beginning of the first audio track, the player will access the data track, possibly with disastrous results (depending on the volume level). CD-ROM Ready is therefore not a completely effective solution.

Enhanced Music CDs

Philips and Sony, in conjunction with other companies such as Microsoft and Apple, have developed another solution, the Enhanced Music CD specification, as defined in the Blue Book standard. Enhanced music CDs are often marketed under the names CD Plus (CD PLUS) or CD Extra and use the multisession technology defined in the CD-ROM XA standard to separate the audio and data tracks. Sometimes the markings are quite obscure, and you might not know that an audio CD contains data tracks until you play it in a CD-ROM drive.

The first session on an Enhanced Music CD contains up to 98 standard Red Book audio tracks, whereas the second session contains a single track of CD-ROM XA Mode 2 sectors. Because audio CD players are only single-session capable, they play only the audio tracks and ignore the additional session containing the XA data. An XA-ready CD-ROM drive in a PC, however, can see both of the sessions on the disc and access both the audio and data tracks.

PhotoCD

First announced back in 1990 but not available until 1992, CD drives or players that display your own CD-ROM-recorded photographs over your television are now being sold by Kodak. You simply drop off a roll of film at a participating Kodak developer; later you take home a PhotoCD and drop it into your PC or a Kodak PhotoCD-compatible disc player.

A PhotoCD-compatible player is a home A/V (audio/visual) entertainment system component that is designed to play both PhotoCDs and audio CDs.

Because virtually all data-ready CD drives can also interpret audio, it was not difficult for Kodak to design the CD players to play audio discs as well. The player merely reads the first track and determines what type of disc you've fed it.

Using the PhotoCD player, you can view your photographs at any one of several resolutions; with a PC, you can both view your images and manipulate them using standard graphics software packages.

When you drop off your roll of film, the Kodak developers produce prints, as they normally do. After prints are made, however, the process goes high-tech. Using high-speed SUN SPARCstations, they scan the prints with ultra-high-resolution scanners. To give you an idea of the amount of information each scan carries, one color photograph can take 15–20MB of storage. The compressed, stored images are then encoded onto special writable CDs. The finished product is packaged in a familiar CD case and shipped back to your local developer for pickup.

PhotoCD Disc Types

The images on the disc are compressed and stored using Kodak's own PhotoYCC encoding format, which includes up to six different resolutions for each image, as shown in Table 13.7. Kodak has defined several different types of PhotoCD discs to accommodate the needs of different types of users. The PhotoCD Master disc is the standard consumer format, and contains up to 100 of your photos in all the resolutions shown in the table except for base x64.

Table 13.7 PhotoCD Resolutions

Base	Resolution (pixels)	Description
/16	128×192	Thumbnail
/4	256×384	Thumbnail
x1	512×768	TV resolution
x4	1024×1536	HDTV resolution
x16	2048×3072	Print size
x64	4096×6144	Pro PhotoCD master only

The different resolutions supply you with images appropriate for different applications. If, for example, you want to include a PhotoCD image on a Web page, you would choose a low-resolution image. A professional photographer shooting photos for a print ad would want to use the highest resolution possible.

The Pro PhotoCD Master disc is intended for professional photographers using larger film formats, such as 70mm, 120mm, or 4×5 inch. This type of disc adds an even higher-resolution image (4,096×6,144 pixels) to those already furnished on the PhotoCD Master disc. Because of this added high-resolution image, this type of disk can hold anywhere from 25–100 images, depending on the film format.

The PhotoCD Portfolio disc is designed for interactive presentations that include sound and other multimedia content. The high-resolution images that take up the most space are not needed here, so this type of disc can contain up to 700 images, depending on how much other content is included.

The PhotoCD Catalogue disc uses even lower-resolution images, designed for use in thumbnail displays. Up to 600 images of this type can be stored on a single disc.

The Print PhotoCD disc is intended for users in the printing industry and includes the same five resolutions as the PhotoCD Master disc, plus a platform-independent CMYK image that can be used by virtually any imaging software or publishing system.

Multiple Session Photo CDs

One of the breakthroughs of the PhotoCD concept is that each of the disc types is capable of containing multiple sessions. Because the average consumer would not usually have enough film processed to fill an entire disc, you can bring back your partially filled CDs each time you have more film to develop. A new session is then added to your existing CD until the entire disc is filled. You pay less for the processing because a new CD is not needed, and all your images are stored on a smaller number of disks.

Any XA-compliant or XA-ready CD-ROM drive can read the multiple sessions on a PhotoCD disc, and even if your drive is not multisession capable, it can still read the first session on the disc. If this is the case, you'll have to purchase a new disc for each batch of film you process, but you can still take advantage of PhotoCD technology.

Kodak provides software that enables you to view the PhotoCD images on your PC, and licenses a PhotoCD import filter to the manufacturers of many different desktop publishing, image editing, and paint programs. This means that you can modify your PhotoCD images using a program such as Adobe Photoshop and integrate them into documents for printing or electronic publication with a page layout program such as Adobe PageMaker.

Picture CD

Although Kodak still offers PhotoCD services, its high cost has led to limited popularity. Kodak now offers the simpler Picture CD and Picture Disk services. Unlike PhotoCD, these services use the industry-standard JPEG file format. Picture CD uses a CD-R, with images stored at a single medium-resolution scan of 1,024 by 1,536 pixels. This resolution is adequate for 4×6 and 5×7 prints. The less-expensive Picture Disk service stores images on a 1.44MB floppy disk at a resolution of 400×600, suitable for screensavers and slide shows.

The software provided with Picture CD allows the user to manipulate images with various automatic or semiautomatic operations, but unlike PhotoCD, the standard JPEG (JPG) file format used for storage allows any popular image-editing program to work with the images without conversion. Although the image quality of Picture CD isn't as high as with Photo CD, the much lower price of the service should make it far more popular with amateur photographers.

Writable CD-ROM Drives

It is now possible to create your own CD-ROMs—and audio CDs as well—using one of the new breeds of recordable CD-ROM devices. By purchasing writable CD-ROM disks and recording (or burning) your own CDs, you can store large amounts of data at a cost that is lower than any other removable, random-access medium.

You might find that cartridge drives such as Iomega's Zip and Jaz are priced comparably to writable CD-ROM drives, but recordable CD-ROM disks typically cost from \$1–\$10 each, whereas a 1GB Jaz cartridge costs about \$100. Also, if you want to transport the data, the other system must have the same type of drive, as there is no industry standard for cartridge data formats.

Magnetic tape media can provide a lower cost per megabyte, but tapes are linear-access devices. Accessing files from tape is a time-consuming process and does not provide anywhere near the convenience of a CD-ROM.

Compared with either tape or other removable media, using a CD-ROM burner is a very cost-effective and easy method for transporting large files or making archival copies. Another benefit of the CD for archiving data is that CDs have a much longer shelf life than tapes or other removable media.

Most writable CD-ROM drives are WORM (write-once, read many) devices, meaning that after you fill a CD with data, it is permanently stored. The de facto standard for this technology is the CD-R (CD-Recordable) drive. The write-once limitation makes this type of device less than ideal for system backups or other purposes in which it would be preferable to reuse the same media over and over. However, because of its low media costs, you might find that making permanent backups to CD-ROMs is as economically feasible as tape or other media.

In any case, there are now also CD-ROM burners on the market that are rewritable. CD-RW (CD-Rewritable) drives can reuse the same discs, making them suitable for almost any type of data storage task. All CD-RW drives can also be used to create CD-Rs. The following sections examine these two standards and how you can use them for your own data storage needs.

CD-R

CD-R drives are indeed WORM devices; however, they use a special recordable CD-ROM disc that, once recorded, can be played back or read in any standard CD-ROM drive. CD-R drives are useful for archival storage or for creating master CDs, which can be duplicated for distribution within a company.

Note

Because of the technical changes in the way the CD is made, there can sometimes be problems reading CDs made by CD-R devices in a standard CD-ROM player. Most of these problems result in poor play performance as the CD-ROM drive tries to align itself to the CD. However, some very old CD-ROM drives can't handle CD-R media.

CD-Rs function using the same principle as standard CD-ROMs, by reading the light reflected by a laser striking the surface of the disc. Light is either returned from the disc or not, forming a binary code. However, the CD-R disc itself is different from a standard CD-ROM.

Instead of the recording beam burning pits into a metallic or glass strata, the CD-R media is coated with a photosensitive organic dye that has the same reflective properties as a *virgin* CD. In other words, a CD reader would see an unrecorded CD-R disc as one long land. When the recording laser begins to burn data into the CD-R media, it heats the gold layer and the dye layer beneath. The result of heating these areas causes the dye and gold areas to diffuse light in exactly the same way that a pit would on a glass master disc or a mass-produced CD. The reader is fooled into thinking a pit exists, but there is no actual pit, simply a spot of less-reflective disc caused by the chemical reaction of heating the dye and gold. This use of heat to create the pits in the disc is why the recording process is often referred to as *burning* a CD.

Most recordable CD-ROM drives can write discs using any of the formats discussed thus far—from ISO 9660 all the way through CD-ROM XA. In addition, these drives can read the formats as well, and therefore serve as general-purpose CD-ROM readers. Prices have been falling steadily and now can be \$250 or less for a drive, and under \$2 for the blank media.

CD-R Capacity

All CD-R drives can work with the standard 650MB CD-R media (equal to 74 minutes of recorded music), but recently some companies have developed 700MB capacity (equal to 80 minutes of recorded music) CD-R blanks. Although the extra 50MB of storage can be useful, current media cost (over \$4 each) makes them much more expensive per MB than the 650MB standard. Two other considerations are that a capacity beyond 650MB/74 minutes is beyond the Orange Book specification, according to Adaptec, so compatibility of these extra-large CD-Rs in many drives is questionable. Also, many CD-R/CD-RW drives can't handle the extra capacity, and an update to popular CD-R mastering programs such as Adaptec's Easy CD Creator Pro might be necessary for some users. If you're concerned about industry-standard compatibility, I'd recommend sticking with the standard 650MB/74 minute media.

CD-R Media Color

There's controversy among CD-R users about which colors of CD-R media provide the best performance. Table 13.8 shows the most common color combinations, along with which brands use them and some technical information.

Some brands are listed with more than one color combination, due to production changes or different product lines. You should check color combinations whenever you purchase a new batch of CD-R media if you've found that particular color combinations work better for you in your applications.

Table 13.8 CD-R Media Color and Its Effect on Recording

Media Color (first color is reflective layer; second is die layer)	Brands	Technical Notes
Gold-gold	Mitsui Kodak Maxell Ricoh	Phthalocyanine dye Less tolerance for power variations Might be less likely to work in a wide variety of drives Invented by Mitsui Toatsu Chemicals Works best in drives that use a Long Write Strategy (longer laser pulse) to mark media
Gold-green	Imation (nee 3M) Memorex Kodak BASF TDK	Cyanine dye; more forgiving of disk-write and disk-read variations Has a rated lifespan of 10 years Color combination developed by Taiyo Yuden Used in the development of the original CD-R standards De facto standard for CD-R industry and was the original color combination used during the development of CD-R technology Works best in drives that use a Short Write Strategy (shorter laser pulse) to mark media
Silver-blue	Verbatim DataLifePlus HiVal Maxell TDK	Process developed by Verbatim Azo dye Similar performance to green media plus rated to last up to 100 years A good choice for long-term archiving

Ultimately, although the different color combinations each have their advantages, the best way to choose a media type is to try a major brand of media in your CD-R/CD-RW drive with both full-disk and small-disk recording jobs and then try the completed CD-R in as wide a range of CD-ROM drive brands and speeds as you can.

The perfect media for you will be the ones that offer you

- High reliability in writing
- No dye or reflective surface dropouts
- Durability through normal handling (scratch-resistant coating on media surface)
- Compatibility across the widest range of CD-ROM drives
- Lowest unit cost

Choosing the Best Media

After you determine which media works the best for you and your target drives, you might still be faced with a wide variety of choices, including conventional surface, printable surface, unbranded, jewel-case, bulk on spindle. The following list discusses these options:

- *Conventional surface.* Choose this type of media if you want to use a marker to label the CD rather than adding a paper label. This type of CD often has elaborate labeling, including areas to indicate CD title, date created, and other information as well as prominent brand identification. Because of the surface marking, it's not suitable for relabeling unless you use very opaque labels. It's a good choice for internal backups and data storage, though, where labeling is less important.
- *Printable surface.* Choose this type of media if you have a CD printer (a special type of inkjet printer that can print directly onto the face of the CD). Because the brand markings are usually low-contrast or even nonexistent (to allow overprinting), this type also works well with labeling kits such as NEATO and others.
- *Unbranded.* Usually sold in bulk on spindle, these are good choices for economy or use with labeling kits. They are not usually suitable for CD printers.
- *Jewel case.* Any of the preceding versions can be sold with jewel cases (the same type of case used for CD-ROM software and music CDs). This is a good choice if you plan to distribute the media in a jewel case, but it raises your costs if you plan to distribute or store the media in paper, Tyvek, or plastic sleeves. Hint: use extra jewel cases to replace your broken jewel cases on your CD software or music collection!
- *Bulk on spindle.* This media generally comes with no sleeves and no cases. It is usually the lowest-priced packaging within any brand of media. This is an excellent choice for mass duplication, or for those who don't use jewel cases for distribution.

CD-R Media Recording Speed Rating (X-Rating)

With CD-R mastering speeds ranging from 1x (now-discontinued first generation units) up through fast 4x and state-of-the-art 8x rates, it's important to check the speed rating of your CD-R media before you try the latest 4x and 8x units.

Most branded media on the market today is rated to work successfully at up to 4x recording speeds. Some brands indicate this specifically on their packaging, whereas you must check the Web sites for others to get this information.

If speed ratings are unavailable, assume the media is capable of reliable writing at no more than a 4x speed. Media that is 8x-rated is becoming more popular, but is often not available at retail stores. Check on the Web or with the drive vendor. At this point, 8x-rated media is somewhat more expensive than 4x or less-rated media. If you have problems recording at 4x on media of an unknown X-rating, try recording at 2x.

Writing a CD with a CD-R/CD-RW Drive

CD-R/CD-RW drives come in slower speeds than their CD-ROM reader counterparts. The fastest CD-R drives write at 8x normal speed—given the system performance to do so. However, some can read at up to 24x normal speed. This is obviously no competition for the 24x and 32x CD-ROM reader drives on the market today, but many CD-R users already have a read-only CD-ROM drive.

Whenever a CD-R drive writes data, it creates one long spiral track on the CD, alternating on and off to etch the pattern into the raw media. Because the CD-R can't realign itself like a hard drive, when it starts writing it must continue until it's finished with the track, or the CD is ruined. This means that the CD-R recording software, in combination with your system hardware, must be able to deliver a consistent stream of data to the CD-R drive while it's writing. To aid in this effort, the software uses a buffer that it creates on your hard disk to temporarily store the data as it is being sent to the CD-R drive.

You'll recall that the normal data transfer rate for a single-speed CD-ROM is 150KB/sec. When writing at a 4x speed, the computer must feed data to the CD-R drive at 600KB/sec. If any part of the computer isn't able to maintain that data rate, you'll receive a buffer under-run message, and the recording attempt will fail.

The buffer under-run message indicates that the CD-R drive had to abort recording because it ran out of data in its buffer to write to the CD. This is the biggest problem that people have with CD-R devices. Providing a fast source to write from—usually a fast SCSI drive—on a system with plenty of RAM will generally help avoid buffer under-runs.

How to Reliably Make CD-Rs

With typical burn times for full CD-Rs ranging from 10 minutes (8x) to as much as 80 minutes (1x), it is frustrating to have a buffer under-run turn your CD-R media to a coffee coaster—an unreadable blank.

Five major factors influence your ability to create a working CD-R: interface type, drive buffer size, the location and condition of the data you want to record to CD-R, the recording speed, and whether the computer is performing other tasks while trying to create the CD-R.

In general, SCSI-interface CD-R/CD-RW drives can burn CD-Rs at faster rates and more reliably than IDE/ATAPI drives. This is because the SCSI interface can work at higher sustained transfer rates, requires less CPU attention (lower CPU utilization rate), and can multitask multiple devices on the same SCSI interface card (daisy-chained devices). However, there are far more IDE/ATAPI CD-R/CD-RW drives than SCSI-interface drives on the market today, especially in the under-\$300 market. This is because IDE/ATAPI drives can use the standard IDE interfaces found on virtually all Pentium-class and higher motherboards. The drives are also lower in cost, due to their simpler design. Thus, with a “free” interface and low-cost drive design, a user willing to use a 2x writer can start CD-R mastering for less than \$200 in some cases.

To improve the odds of getting reliable CD-R creation with IDE/ATAPI drives, look for drives with

- *A large data buffer (1MB or larger).* The data buffer in the drive will hold information read from the original data source, so that even if there's a pause in data reading, there's no possibility of a buffer under-run until the on-drive buffer runs empty. A larger buffer minimizes the chance of "running out of data."
- *Drives that support DMA or UDMA operating modes.* As you've already seen, DMA/UDMA modes transfer data faster and with less CPU intervention than earlier versions of IDE. To use this feature, you'll also need a motherboard with a bus-mastering IDE interface with the appropriate drivers installed.

Tip

Also, if you have problems with reliable CD-R creation at the drive's maximum speed, try using a lower speed (2x instead of 4x, for example). Your mastering job will take twice as long, but better to create a working CD-R slowly than ruin a blank quickly.

An alternative approach is to use packet-writing software to create your CD-R. Many late-model CD-R/CD-RW drives support packet writing, which allows drag-and-drop copying of individual files to the CD-R rather than transferring all the files at once as with normal mastering software. This "a little at a time" approach means that less data must be handled in each write, and can make the difference between success and failure. If your drive supports this feature, it might come with Adaptec's DirectCD software (which performs packet writing), or you might need to buy it separately (about \$70.00 direct from Adaptec). Check Adaptec's Web site to see whether your drive can work with DirectCD. Note that although packet-written CDs can be read with Windows 95/98/NT/2000, they cannot be read with Windows 3.1/MS-DOS because these operating systems don't support packet-written CDs.

If your CD-R/CD-RW drive is SCSI-based, make sure you have the correct type of SCSI interface card! Although many drive vendors take the uncertainty out of this issue by supplying an appropriate card, others don't. When faced with SCSI interface card prices ranging from as little as \$50 to over \$500, it's easy to choose the lowest-priced adapter to save money. If your SCSI card isn't made for the task of creating CD-Rs, you'll also wind up with buffer under-runs and a nice collection of \$2.00 coffee coaster blanks instead of working CD-Rs.

If you must buy your own SCSI card for your recorder, follow these tips:

- *Forget about ISA cards.* Although ISA (Industry Standard Architecture) cards still work in today's Pentium III and AMD K6-3 computers, their long-term outlook is terminal. By the early 2000s, new computers built to the latest PC99 standards will no longer have any ISA slots. If you like to move expensive hardware to the new machines to get the longest lifespan from it, ISA will soon see a No Vacancy sign on new computers. Even for current machines, ISA cards with acceptable performance for CD-R mastering are far too expensive.
- *PCI is better, but not all PCI will work!* As discussed in Chapter 16, "Serial, Parallel, and Other I/O Interfaces," PCI's 32-bit data bus and 33MHz typical performance is far faster than ISA's 16-bit data bus and 8.33 MHz typical performance. Because PCI slots are now more common than ISA slots and are about to completely replace ISA slots your SCSI-based drive should be attached to a PCI card.

- *Any SCSI interface card used for CD-R/CD-RW drives should offer a feature called bus-mastering.* As discussed earlier in this chapter, bus-mastering allows data transfers to bypass the CPU for faster system performance. Very low-cost PCI-based SCSI cards don't offer this feature. Note that you can find some bus-mastering PCI cards that are less expensive than ISA bus-mastering cards, although they're faster.

You need to use a bus-mastering PCI-based card to get highly reliable CD-R creation at a low cost with your SCSI-based CD-R/CD-RW drive.

Tip

A number of CD-R manufacturers offer bus mastering SCSI cards for PCI slots, including Adaptec, Amedia, Promise Tech, SILG, Tekram, DTC, and Advansys.

CD-R/CD-RW Drive Buffer Size

When you purchase a CD-R/CD-RW drive, you should consider the size of the drive's internal RAM buffer. With otherwise identically configured systems, the drive with the larger RAM buffer should provide more reliable mastering.

Most CD-R/CD-RW drives offer buffer sizes of at least 1MB. I recommend purchasing drives that contain buffers of at least 2MB. Regardless of your interface type (IDE/ATAPI or SCSI), a buffer under-run (the drive's buffer runs out of data) is a fatal end to your CD-R mastering attempt.

Organizing Data for a CD-R

If you have the following conditions in place whenever you want to make a CD-R at highest speed, you'll seldom have any problems:

- High-speed DMA bus-mastering SCSI interface card
- SCSI-interface CD-R
- Data residing on a defragmented SCSI-interface local hard disk

If you're groaning because your CD-R mastering environment isn't anything like this, you're not alone. Many users don't have any SCSI-based devices, and yet a few simple precautions can help your IDE-based CD-R mastering attempts to succeed.

To ready your system for mastering a CD, follow these recommendations:

- Whenever possible, move all data you want to put onto a CD-R to a fast local hard drive. If you can't do this, avoid using the following sources for data: floppy drives, parallel-port Zip or other removable-storage drives, CD-ROM drives (especially 8x or slower), or Network drives (especially if you use ISA network cards on standard Ethernet or Token-Ring networks). These locations for data usually can't feed data quickly enough to maintain data flow to the CD-R drive.
- Before you master the CD-R, use disk-repair tools on your C: drive, CD-R mastering drive, CD-R data drive, and swap drives, followed by full defragmentation of each drive. This assures that disk errors or file fragmentation, both of which slow down disk access, won't be a factor in program or data search and retrieval.

- Avoid trying to master from active files or zero-byte files (often used for temporary storage). If you must master these files to make an archival copy of your current system configuration, use a program such as Norton Ghost or PowerQuest Drive Image, which create a single compressed file from your drive's contents. Then, master the CD-R using the resulting compressed file.
- Turn off power management for your hard disk and other peripherals. You can normally do this through the Power icon in Windows 9x. A few Seagate IDE drives require that you install a TSR program into AUTOEXEC.BAT to accomplish this because their built-in firmware does the power management.
- Make sure your temporary drive has at least twice the empty space of your finished CD-R. Your CD-R's estimated space requirements are shown during the mastering process with programs such as Adaptec Easy CD-Creator. Thus, if you're creating a CD-R with 500MB of data, your temporary drive must have at least 1GB of empty space.
- With Windows 9x, you'll improve disk caching by adjusting the typical role of the computer from workstation to server in the Performance tab of the System Properties dialog box. Note that this change works correctly with Windows 95B & 95C (OSR 2.x) and Windows 98, but the registry keys are incorrect in Windows 95 original retail and OSR1 (95a) versions. Check Microsoft's Web site for the correct registry key settings for Windows 95/95a, back up and edit the Registry, and restart the computer before making this change with those versions.
- If your original data is coming from a variety of sources, consider using the Create Disk Image option in Adaptec Easy CD-Creator or your software's most similar feature. This feature creates an image file on your hard drive that contains all the files you want to put onto a CD-R. Then, use Create CD from Disk Image to actually master the CD-R from that information.
- If you're uncertain of success, why waste a CD-R blank? Most mastering programs offer a test-then-create option that does a simulated burn of the CD-R before the actual creation. After the simulation, you're warned of any problems before the actual process begins. This option takes twice as long as the normal mastering process, so you might want to use it only when you're especially concerned about problems.
- Small files are harder to use in mastering a CD-R than large ones because of the excessive drive tracking necessary to find them and load them. You might want to use a packet-writing program such as Adaptec's DirectCD instead if your drive supports it.
- Keep your CD-R and other drives clean and free from dust. Use a cleaning CD if necessary. Dirty drives cause data-read errors or data-write errors if your CD-R drive is the dirty one.

Even with all these considerations, you might still have problems recording at your drive's top speed. In that case, it might be necessary to slow down the recording speed.

Setting the CD-R Recording Speed

The steady climb in CD-R mastering speeds from the old 1x to current 4x and 8x speeds has helped fuel the rush to CD-R mastering. But many users whose first CD-R drive was a slow-but-reliable 1x or 2x unit might have problems when switching to the newer 4x or faster recording rates. As the speed of the CD-R recording process increases, the likelihood of problems also increases. You've already seen that using the fastest interface and largest buffer size available can

help you create CD-Rs more reliably. Unfortunately, in some cases you might also want to reduce the recording rate of your drive.

If you're having buffer under-run problems despite taking all the precautions listed in the previous section, try dropping down a speed. CD-R mastering speeds run 1x, 2x, 4x, 8x. Go to the next lower speed and see how you do.

Using a lower speed than the drive is rated for can be frustrating, but it's preferable to take twice the time and actually get a CD-R than to ruin one in half the time.

Avoid Multitasking While Mastering a CD-R

Even with a fast hard drive, a fast host adapter, and a fast CD-R drive, you can still have buffer under-runs if you try to run more than one program while making your CD-R. If you run another program during the mastering process, the computer is forced to perform time-slicing, which causes it to start a process, switch away from it to start the next process, switch back to the first process, and so forth. This switching process could cause the CD-R drive to run out of data because it isn't receiving data in a steady stream. Forget about surfing the net, playing Solitaire, or creating a label for your new CD-R during the mastering process if you want reliable mastering.

CD-R Software

Another difficulty with CD-R devices is that they require special software to write them. Although most cartridge drives and other removable media mount as standard devices in the system and can be accessed exactly like a hard drive, the CD-R drive uses special CD-ROM burning software to write to the disk. This software handles the differences between how data is stored on a CD and how it is stored on a hard drive. As you learned earlier, there are several CD-ROM standards for storing information. The CD-ROM-burning software arranges the data into one of these formats so the CD can be read later by a CD-ROM reader.

At one time, CD recording technology required that you have what amounted to a replica of the CD on a local hard drive. In fact, some software packages even required a separate, dedicated disk partition for this purpose. You would copy all the files to the appropriate place on the hard drive, creating the directory structure for the CD, and then the software would create an exact replica of every sector for the proposed CD-ROM—including every file, all the directory information, and the volume information—and copy it to the CD-R drive. The result was that you had to have about 1.5GB of storage to burn a single CD ($650\text{MB}/\text{CD} \times 2 = 1.3\text{GB} + \text{overhead} = 1.5\text{GB}$). This is no longer a requirement because most software supports virtual images. You select the files and directories that you want to write to the CD from your hard drive and create a virtual directory structure for the CD-ROM in the software. This means that you can select files from different directories on different hard drives, or even files from network or other CD-ROM drives, and combine them any way you want on the CD-R. This works well provided the drives have adequate speed and your CD-R drive has a large buffer. If you have problems, follow the advice given earlier to overcome slow data sources.

The software assembles the directory information, burns it onto the CD, opens each file on the CD, and copies the data directly from the original source. This generally works well, but you must be aware of the access times for the media you select as data sources. If, for example, you select directories from a slow hard drive or from a busy network, the software might not be able to read the data fast enough to maintain a consistent stream to the recorder. This causes the write to fail, resulting in a wasted disc.

CD-R drives that support several writing speeds typically come equipped with software that can simulate the recording process for testing purposes. The software reads the source data from the various media you've selected and determines the maximum possible speed for the recording process. Even this is not foolproof, however. Conditions might change between the time of the test and the actual disc write process, resulting in a failed recording attempt. For this reason, it is best to burn CDs from source data on a local hard drive rather than network drives. SCSI is preferable to IDE for both the CD-R burner and the source drive because SCSI is better suited to devices sharing the same interface.

Don't Forget the Software!

If you have persistent problems with making CD-Rs, your mastering software might be to blame. Check the vendor's Web site for tips and software updates. Make sure that your mastering software is compatible with your drive and your drive's firmware revision. Some drives offer software-upgradable firmware similar to the motherboard's flash BIOS.

Each of the major CD-R/CD-RW drive vendors provides extensive technical notes to help you achieve reliable recordings. You can also find helpful information on SCSI adapter vendors' Web sites and the Web sites of the CD-R media vendors.

Creating Music CDs

Newer CD-R, CD-RW, and CD-ROM drives are making it possible for you to create a customized archive of your favorite prerecorded music. Adaptec's Easy CD-Creator Deluxe Edition, for example, features the SpinDoctor utility to build music CDs, and even removes pops, hiss, and other problems from old analog cassette tapes and vinyl LPs.

Digital audio extraction allows the digital tracks on commercial CDs to be transformed into WAV files by compatible mastering programs. Those WAV files, exactly like the ones created from older music sources via your sound card, can then create a CD-R, which can be played back in any popular CD stereo system.

A contributor to this chapter used this technique to combine several audio sources into a single rehearsal CD for a Christmas cantata at his church. Note that the church had purchased the music books and the original rehearsal cassette and CD recordings.

This exciting technology is not intended to give you a way to create a free music library. Instead, use it to give the music recordings you've paid for an extra dimension of usefulness.

Don't confuse this with the new breed of standalone digital CD copying machines, which don't require a computer and use a different, and more expensive, type of media.

Creating Digital Photo Albums

Photo-realistic printers from Epson, Canon, HP, and other vendors need a source for images. Scanners provide a start, but where will you store your photos? CD-Rs are the answer. Software such as the PhotoRelay utility bundled with Adaptec's Easy CD-Creator, Kai's Power Show, or customized solutions designed with Adobe Acrobat or other products provide a great place to store and show off your photos.

Creating a Rescue CD

A number of programs on the market today allow you to make a compressed image file of the contents of any drive. These programs, such as the Ghost program sold by Symantec's Peter Norton group or PowerQuest's Drive Image, allow you to lock in the condition of any drive as of a particular time.

Note

See the CD accompanying this book for Que's edition of DriveImage.

This allows you to create an image file of your system when it's working and use the image-restore feature to reset your system when it fails.

Note

Don't confuse this with a popular Norton Utilities option called Norton Image. This program makes a backup copy of your drives' partition table, master boot record, FATs, and root directory to the end of each drive's data area. This very small file can recover from virus attacks or other problems with the first few sectors of a drive.

The perfect place to store a compressed image file is on a CD-R. At a minimum, your rescue disk should contain the compressed image file (a 650MB CD-R could contain the equivalent of a 1.5GB drive's normal contents if Drive Image's maximum compression option is used). It's also desirable to place a copy of the image-restore program on the CD-R. Mastering this type of rescue CD-R is done exactly the same as a conventional CD-R mastering process. To use the rescue CD-R, you must boot your system with drivers that allow the CD-ROM drive to work, run the restore program to read the data from the CD-R, and overwrite the drive's existing contents.

If you're looking for a single-CD solution to rescuing your system, one that won't require you to lug around a bootable floppy disk, I'll cover that later in this chapter after discussing the kinds of software a CD-ROM drive needs to operate.

►► See "Making a Bootable CD-ROM for Emergencies," p. 763.

Multiple Session CD-R Drives

Although it is true that a CD-R disc can only be filled with data once, most of the CD-R drives and software packages support multiple sessions on a single disk. This means you can partially fill a disk and then add other sessions later. As with any multisession disk, you must have an XA-

compliant or XA-ready CD-ROM drive to read all the sessions on a CD-R disc. Otherwise, your access is limited to the data in the first session.

About the only CD-ROM drives that can't read a multisession CD-R are first-generation single-speed and a few of the 2x drives. These drives are so old that they're extremely scarce and overdue for replacement (as are the computers they're found in). In practice, then, you can treat multisession CD-Rs as being as compatible as any other CD-R you create.

CD-RW

CD-RW (CD-Rewritable) drives, as defined in Part III of the Orange Book standard, are rapidly becoming a popular alternative to CD-Rs. CD-RWs use a different type of disc that the drive can rewrite at least one thousand times. Although they're slightly more expensive than CD-R media, CD-RWs are still far cheaper than optical cartridges and other removable formats. This makes CD-RW a viable technology for system backups, file archiving, and virtually any other data storage task.

Note

CD-RW drives are sometimes referred to as erasable CDs, or CD-E.

The drawback of the CD-RW is that the lower reflectivity of the disc itself limits its readability. Many standard CD-ROM and CD-R drives cannot read CD-RWs. However, a multiread capability is now found in virtually all CD-ROM drives of 24x speed or above, enabling them to read CD-RWs. Look for the "Multi-read" label on the drive to determine which of your drives have this capability. What's more, CD-RW drives are also capable of writing to CD-R discs and of reading standard CD-ROM discs. This means that by spending a little bit more for a CD-RW drive, you can get the best of both worlds: fully compatible WORM capability as well as rewritable storage.

The CD-RW Medium

The photosensitive dye within a CD-R disk changes from a reflective state to a nonreflective state when it is exposed to the laser recording beam of a CD-R drive. The change of state is permanent, which is why CD-R is a WORM medium. CD-RW disks also contain a substance that changes its reflective state when exposed to a laser, but unlike a CD-R, its change is not permanent.

The active layer of a CD-RW disk is an Ag-In-Sb-Te (silver-indium-antimony-tellurium) alloy that, in its original state, has a polycrystalline structure that makes it reflective. The active material is deposited on top of a polycarbonate substrate that is grooved in a spiral pattern to ensure precise servo guidance, resulting in accurate alignment of the lands and pits and absolute time information.

When the CD-RW drive writes to the disk, the laser uses its highest power setting, known as Pwrite, to heat the active material to a temperature between 500 and 700 degrees Celsius, causing it to liquefy. In its liquid state, the molecules of the active material flow freely, losing their polycrystalline structure and taking on an amorphous state. When the material solidifies in this

amorphous state, it loses its reflectivity. By selectively firing the laser, the drive leaves parts of the disc in the polycrystalline state, forming the lands, and parts in the amorphous state, forming the pits.

To reverse the phase of a specific area on a disc, the laser operates at a lower power setting (Perase) and heats the active material to approximately 200° Celsius, well below its liquefaction temperature, but above the temperature at which it reverts back from its amorphous to its polycrystalline state and becomes reflective again.

Note that despite the name of the Perase power setting, there is no explicit erasure performed to a CD-RW disk when it is rewritten. The drive pulses the laser at the appropriate power levels to produce polycrystalline and amorphous areas (lands and pits) at the appropriate locations, regardless of the previous state of those locations. Thus, the drive is writing both lands and pits. It is impossible to “erase” a CD-RW disk without writing new data over the old.

The formatting process for a CD-RW disk, which deletes the old contents and make the disk ready for new data, was very tedious with early CD-RW drives. New developments allow a rapid format in about 30 seconds, which is comparable to the quick format time on an ordinary floppy disk.

Reading CD-RW Discs

The original CD standards specify that on a compact disc the lands should have a minimum reflectance value of 70 percent, meaning that the area of a disc that represents a land should reflect back no less than 70 percent of the light directed at it. The pits should have a maximum reflectance value of 28 percent. In the early 1980s when these standards were developed, the photodiodes used in CD players were relatively insensitive, and these reflectance requirements were deliberately made stringent to accommodate them.

On a CD-RW disk, the reflectance of a land is approximately 15–25 percent, obviously well below the original minimum requirement. All the reflectance levels of CD-RW disks are approximately one-third of those defined in the original standard. However, the difference in the reflectance of a CD-RW disc's lands and the pits meets the 60 percent required by the original CD-ROM standard, and the photodiodes available today are more than capable of discerning between the CD-RW reflectance values. Thus, although some CD-ROM drives are not capable of reading CD-RW discs, it is not a difficult matter to modify the existing designs to make it possible for them to do so.

Philips, the company that is largely responsible for the development of CD-RW technology, in conjunction with Hewlett-Packard, has developed a multiread specification that has been approved by the Optical Storage Technology Association. This specification defines the levels of amplification needed for standard CD-ROM drives to read CD-RW discs.

Because only recent CD-ROM drives (many 24x drives and virtually all 32x and above) are multi-read (capable of reading CD-RW media), many early DVD drives can't read CD-RW, and because CD-RW media is about 3x the cost of CR-R blanks, I recommend using CD-R media in CD-RW drives when you want to send data to other users. Use the CD-RW media for drag-and-drop file

copying or for temporary backup storage. Remember, every CD-RW drive is also a CD-R drive. Many vendors of CD-RW/CD-R media sell CD-R/CD-RW bundle packages which feature both types of media, recognizing the dual nature of the drives and the different purposes of the two types of media—often at a savings that makes the CD-R media essentially free.

If you are wondering whether a CD-ROM drive can read a CD-RW disc, look for the “Multi-read” label on the drive—and, of course, test an actual CD-RW of your own creation if possible.

DVD (Digital Versatile Disc)

The future of CD-ROM is called DVD (Digital Versatile Disc). This is a new standard that dramatically increases the storage capacity of, and therefore the useful applications for, CD-ROM-size disks. A CD-ROM can hold a maximum of about 650MB of data, which might sound like a lot but is simply not enough for many up-and-coming applications, especially where the use of video is concerned.

One of the primary applications for DVDs is as a replacement for videotapes. DVDs can be rented or purchased like prerecorded VCR tapes, but offer much higher resolution and quality and greater content. DVD has applications not only in computers, but in the consumer entertainment market as well.

DVD History

DVD had a somewhat confusing beginning. During 1995, two competing standards for high-capacity CD-ROM drives emerged to compete with each other for future market share. A standard called Multimedia CD was introduced and backed by Sony and Philips Electronics, whereas a competing standard called the Super Density (SD) disk was introduced and backed by Toshiba, Time Warner, and several other companies. If both of these standards had hit the market as is, consumers as well as entertainment and software producers would have been in a quandary over which one to choose.

Fearing a repeat of the Beta/VHS situation, several organizations, including the Hollywood Video Disc Advisory Group and the Computer Industry Technical Working Group, banded together. They insisted on a single format and refused to endorse either competing proposal. With this incentive, both groups worked out an agreement on a single, new, high-capacity CD-ROM in September of 1995. The new standard combined elements of both previously proposed standards and was called DVD, which originally stood for Digital Video Disk, but which has since been changed to Digital Versatile Disc. The single DVD standard has avoided a confusing replay of the VHS/Beta fiasco and has given the software, hardware, and movie industries a single, unified standard to support.

DVD Specifications

DVD offers an initial storage capacity of 4.7GB of digital information on a single-sided, single-layer disc the same diameter and thickness of a current CD-ROM. With MPEG-2 (Motion Picture Experts Group—standard 2) compression, that’s enough to contain 135 minutes of video, enough

for a full-length, full-screen, full-motion feature film—including three channels of CD-quality audio and four channels of subtitles. With only one audio track, a single disk could easily hold 160 minutes of video or more. This initial capacity is no coincidence; the creation of DVD was driven by the film industry, which has long sought a storage medium cheaper and more durable than videotape.

Note

It is important to know the difference between the DVD-Video and DVD-ROM standards. DVD-Video discs contain only video programs and are intended to be played in a DVD player, connected to a television and possibly an audio system. DVD-ROM is a data storage medium intended for use by PCs and other types of computers. The distinction is much like that between an audio CD and a CD-ROM. Computers might be able to play audio CDs as well as CD-ROMs, but dedicated audio CD players cannot use a CD-ROM's data tracks.

Current models of DVD are compatible with 8.5GB dual-layer discs as well as double-sided discs that will store 9.4GB in a single layer and 17GB in a dual-layer format.

DVD's initial storage capacity is made possible by several factors, including

- A smaller pit length (~2.08x, from 0.972 to 0.4 microns)
- A reduced track pitch (~2.16x, from 1.6 to 0.74 microns)
- A larger data area on the disc (~1.02x, from 86 to 87.6 square centimeters)
- More efficient channel bit modulation (~1.06x)
- More efficient error correction code (~1.32x)
- Less sector overhead (~1.06x, from 2048/2352 to 2048/2060 bytes)

The DVD drive's data markings are much smaller and closer together than those on CD, allowing the same physical-sized platter to hold much more information (see Figure 13.8).

Figure 13.8 DVD data markings versus those of a standard CD-R or CD-RW.

The drive uses a shorter wavelength laser to read these smaller pits and lands. DVD can double its initial capacity by using both sides of the disc, and double it again by writing two separate layers of data on each side. The second data layer is written to a separate substrate below the first layer, which is semireflective to allow the laser to penetrate to the substrate beneath it. By focusing the laser on one of the two substrates, the drive can read roughly twice the amount of data from the same surface area.

With advancements coming in blue-light lasers, this capacity might be increased several-fold in the future. DVD drives are also very fast compared to current CD-ROM technology. The standard transfer rate is 1.3MB/sec, which is approximately equivalent to that of a 9x CD-ROM drive. Access times are typically in the 150–200ms range, with burst transfer rates of 12MB/sec or higher. DVD drives spin at a base speed that is about three times as fast as a single speed CD-ROM. 5x drives are now available. DVD drives use either the IDE/ATA or SCSI interface, exactly like CD-ROMs, and include audio connectors for playing audio CDs through headphones or speakers.

DVD drives are fully backward-compatible, and as such will be able to play today's CD-ROMs as well as audio CDs. When playing existing CDs, the performance of current models is equivalent to a 20x or faster CD-ROM drive. As such, users who currently own 4x CD-ROM drives might want to consider a DVD drive instead of upgrading to a faster CD-ROM drive. Several manufacturers have announced plans to phase out their CD-ROM drive products in favor of DVD. In a few years, DVDs might make CD-ROMs obsolete, in the same way that audio CDs displaced vinyl records in the 1980s.

The current DVD drives feature several improvements over the first-generation models of 1997. Those units were expensive, slow, and incompatible with either CD-R or CD-RW media. Many early units asked your overworked video card to try to double as a MPEG decoder to display DVD movies, with mediocre results in speed and image quality. As is often the case with “leading edge” devices, their deficiencies make them eminently avoidable.

Many PC vendors have integrated DVD-ROM drives into their new high-end computers, usually as an option. The typical package also includes an MPEG-2 decoder board for processing the compressed video on DVD disks. This offloads the intensive MPEG calculations from the system processor and makes it possible to display full-screen, full-motion video on a PC.

Some manufacturers of video display adapters have begun to include MPEG decoder hardware on their products. These adapters are called “DVD MPEG-2 accelerated,” and call for some of the MPEG decoding tasks to be performed by software. Any software decoding involved in an MPEG solution places a greater burden on the main system processor, and can therefore yield less satisfactory results.

Adding a DVD Drive to Your System

A DVD drive installs in a manner similar to that of a CD-ROM or any other type of drive. See Chapter 14, “Physical Drive Installation and Configuration,” to learn how to install a 5 1/4-inch DVD drive.

Following, are some basic principles to keep in mind when installing a DVD drive:

- Most DVD drives are IDE/ATAPI devices, meaning that you have the issue of master/slave setups on the dual-connector 40-pin IDE cable. If you're replacing an old CD-ROM drive, simply note its master-slave configuration when you remove it from your system, set the new DVD drive the same way, attach it to the data cable, connect the power, and you're finished.

- Many current DVD drives require that you connect them to a bus-mastering IDE interface. If your drive requires a bus-mastering interface, check out the tips earlier in this chapter.
- The other half of DVD, the MPEG decoder card, can be tougher. You must have an open PCI expansion slot, the card usually requires an IRQ (which might force you to disable an existing port to free up an IRQ), and you must connect the decoder card to your existing VGA card. Because of the high hardware demands that MPEG decoder cards place on many users' systems, new VGA video cards with high-quality MPEG movie playback are looking more and more interesting to users. Table 13.9 compares MPEG decoder cards to video cards with built-in MPEG players.

Table 13.9 MPEG Decoder Cards Versus Video Cards with MPEG Players

Consideration	MPEG Decoder	MPEG Player
PCI Slot usage	1 for decoder; 1 for VGA	1 slot only
Movie Image Quality	High	Varies
Playback Speed	High	Varies
MPEG Game Compatibility	Yes	No

DVD Standards

DVD is still a young technology, and the standards situation is more confused than usual. Just about the only certain element in the DVD picture is the DVD-ROM format itself. Nearly all other aspects of the technology are caught up in conflicts between rival standards.

DVD video currently exists as a standard supported by most of the movie industry. Movie titles and DVD players are widely available in North America and Japan. DVD's one-time rival, DIVX, which was supported by only a few major studios, was discontinued in the summer of 1999.

Why DIVX Died

DIVX required a different player—the DVD players available now cannot play DIVX discs—and, even more shocking, required that the player be connected to Digital Video Express's computerized billing system via a built-in modem to play a DIVX disc or go through an on-line payment system. Fortunately, every DIVX player can also play standard DVD and audio CDs.

DIVX had several shortcomings that contributed to its failure, including the rental system, which rendered the DIVX movie useless after 48 hours unless you paid to view it again or purchased it. Other shortcomings included modem and online ordering hassles, and the lack of outlets for DIVX movies (mostly Circuit City stores).

Low-cost rentals for DVD movies and the increasing popularity of DVD movies at public libraries give you plenty of places to find DVD movies to try, and they are sold by virtually every major consumer electronics store.

What to do with your DIVX player? Use it for DVD movies, and check with the Circuit City or DIVX Web sites for details about a \$100 rebate, which will compensate you for the extra cost of the now-useless DIVX enhancements in your player.

DVD Standards

In a war that brings back unhappy memories of the VHS/Beta struggle of the 1980s, the computer and movie industries are locked in a struggle to see which enhancements to the basic DVD standard will actually exist. Table 13.10 compares the competing DVD standards.

Table 13.10 DVD Standards

Standard	Capacity	Compatible With	Notes
DVD-RAM	2.6GB per side	Not compatible with DVD-ROM drives unless they are very recent models; check with your vendor	Most popular and lowest-priced recordable DVD-type technology; several models now shipping; media about \$25 per disk; requires Windows 95 OSR 2.x or Windows 98 with FAT-32 to exceed 2GB per side
DVD-R	3.95GB (original) 4.7GB (1999 version)	Almost all DVD players can read these	Original 3.95GB drives were \$17,000; new 4.7GB drives sell for under \$5500; media about \$40 per disk; future versions of the 1999-model drive are expected to work with DVD-RW media
DVD-RW (originally called DVD-R/W)	4.7GB	Almost all DVD players will be able to read these	Media about \$40 per disk; phase-change technology; first drives expected in late 1999
DVD+RW side	2.8GB per side	A few current DVD-ROM drives from Sony and Philips can read these	Media is about \$30 per disk; no cartridge is needed; HP, Philips and Sony introduced shipping models in mid-1999; list about \$700

There are also conflicts between standards for writable versions of DVD drives. Right now, the most likely candidates for acceptance are DVD-R and DVD-RAM, both based on specifications published in August 1997. DVD-R is comparable to CD-R in that it is a WORM technology that uses an organic dye as its active medium. The first DVD-R drives were released by Pioneer in October 1997 with a price of \$17,000; blank discs are now about \$40.

DVD-RAM is a rewritable drive type that uses a phase-change technology such as that of CD-RW. However, DVD-RAM discs cannot be read by standard DVD-ROM drives because of differences in both reflectivity of the medium and the data format. (DVD-R, by comparison, is backward-compatible with DVD-ROM.) DVD-ROM drives that can read DVD-RAM discs began to come on the market in early 1999. Neither DVD-R nor DVD-RAM can write disks using dual layers, but there will be double-sided DVD-RAM discs available. Some manufacturers have matched the standard 4.7GB capacity for a single-sided, single-layer disc with their DVD-R and DVD-RAM products, but most implementations hold slightly less.

Apart from DVD-R and DVD-RAM, several other writable DVD standards are in various stages of development. DVD+RW, also called DVD Phase Change Rewritable, is a competing rewritable

format championed by Philips, Sony, and Hewlett-Packard. It is more closely based on CD-RW and is incompatible with DVD-RAM, although DVD+RW drives can read DVD-ROMs and CDs. These drives began to ship in the summer of 1999.

Pioneer has its own rewritable format, originally called DVD-R/W and now referred to as DVD-RW, that also uses a phase-change technology and is somewhat more compatible than DVD-RAM. Drives based on this technology are expected in late 1999. Although newer DVD-type drives have become more compatible with the CD-R/CD-RW standards, there still exists a major problem in harmonizing the many different types of writable DVD formats. As with the old Beta versus VHS battle, even the introduction of a superior specification complicates the process of accepting a single specification as an industry standard.

CD-ROM Software on Your PC

After you've physically installed the drive, you're ready for the last step—installing the drivers and other CD-ROM/DVD-ROM software. As usual, this process can be simple with a PnP operating system such as Windows 9x or rather painful with DOS and Windows 3.1. The optical drive needs the following three software components for it to operate on a PC:

- A SCSI adapter driver (not needed for ATAPI IDE CD-ROM drives). Most popular SCSI adapter drivers are built into Windows 9x.
- A SCSI driver for the specific CD-ROM drive you've installed. An ASPI driver is built into Windows 9x, as is an ATAPI IDE CD-ROM driver.
- MSCDEX—Microsoft CD Extensions for DOS, which is built into Windows 9x as the CDFS VxD.

If you still use DOS, you can have the first two drivers—the SCSI adapter driver and CD-ROM driver—load into your system at startup by placing command lines in your CONFIG.SYS file. The MSCDEX, or DOS extension, is an executable file added into your system through your AUTOEXEC.BAT file. This is not required in Windows 9x; the operating system will autodetect the drive on startup and prompt you to install the correct drivers if it can't find them in its standard arsenal of device drivers.

Using Windows 9x along with a CD-ROM or DVD-ROM drive that conforms to the ATAPI (AT Attachment Packet Interface) IDE specification does not require you to do anything. All the driver support for these drives is built into Windows 9x, including the ATAPI driver and the CDFS VxD driver.

If you are running an SCSI CD-ROM drive under Windows 9x, you will still need the ASPI (Advanced SCSI Programming Interface) driver that goes with your drive. The ASPI driver for your drive will normally come from the drive manufacturer and is included with the drive in most cases. However, by arrangement with hardware manufacturers, Windows 9x usually includes the ASPI driver for most SCSI host adapters, and also automatically runs the CDFS VxD virtual device

driver. In some rare cases, you might have to install an updated driver that you have obtained from the manufacturer.

When you install a PnP SCSI host adapter in a Windows 9x system, simply booting the computer should cause the operating system to detect, identify, and install drivers for the new device.

When the driver for the host adapter is active, the system should detect the SCSI devices connected to the adapter and again load the appropriate drivers automatically.

The only problem you might encounter is if you are installing a new device, such as a DVD-ROM drive, on an older version of Windows. Windows 98 includes drivers for most of the DVD-ROM drives on the market, but Windows 95 was released before these devices existed. In this case, you will probably have to supply a device driver on floppy disk, in response to a request from the OS, during the installation process.

DOS SCSI Adapter Driver

For DOS users, of course, the installation process is not so easy. Each SCSI adapter model has a specific driver that enables communication between the PC and the SCSI interface. Normally, these drivers conform to the ASPI. The ASPI driver for the drive connects with the ASPI driver for the SCSI host adapter; this is how the adapter and the drive communicate. An ASPI driver should be provided both with your SCSI drive and with the host adapter. Documentation should also have been included that walks you through the installation of the software.

Most SCSI adapters come with an installation program that automates the process of installing the appropriate ASPI drivers, both for the adapter and for the devices connected to the SCSI bus. However, you can manually add the SCSI device driver to your CONFIG.SYS file. In the CONFIG.SYS file, add the name and path of the appropriate driver with the `DEVICE=` command (replace `C:\DRIVERS` with the actual location of your files, and `MYSCSI.SYS` with the actual name of your SCSI driver):

```
DEVICE=C:\DRIVERS\MYSCSI.SYS
```

`C:\DRIVERS` is the subdirectory into which you copied the SCSI ASPI device drivers. Some drivers have option switches or added commands that, for example, enable you to view the progress of the driver being loaded.

DOS CD-ROM Device Driver

This driver should be a part of your basic installation kit as well. If not, contact the drive's manufacturer for the proper device driver for your SCSI card.

The device driver should come with an installation program that prompts you for the memory I/O address for the SCSI adapter to which you've connected the CD-ROM drive. This device driver enables the adapter to communicate with the drive through the SCSI bus. Installation programs add a line similar to the following to your CONFIG.SYS file (replace `MYCDROM.SYS` with the actual name of your CD-ROM driver file, and `C:\DRIVERS` with the actual location of your files):

```
DEVICE=C:\DRIVERS\MYCDROM.SYS /D:miscd001
```

C:\DRIVERS is the subdirectory that contains the driver MYCDROM.SYS, the driver for your specific CD-ROM drive.

Note the /D:mscd001 option after the preceding statement. This designation, called the device signature, identifies this CD-ROM driver as controlling the first (001), and only, CD-ROM drive on the system. This portion of the device driver statement is for the Microsoft DOS Extensions driver, which designates CD-ROM drives in this fashion. In fact, you could use any designation here, as long as the MSCDEX command line uses the same one.

MSCDEX: Adding CDs to DOS

The Microsoft CD Extensions for DOS allow the DOS operating system (and by extension, Windows 3.1) to identify and use data from CD-ROMs attached to the system. The original DOS operating system had no provisions for this technology, so “hooks” or handling of this unique media are not part of the basic operating environment. Using these extensions is convenient for all involved, however. As CD-ROM technology changes, the MSCDEX can be changed, independently of DOS. For example, most PhotoCD, multiple-session CD-ROM drives require MSCDEX.EXE version 2.21 or higher, which has been modified from earlier versions to accommodate the newer CD-ROM format.

MSCDEX.EXE should be in your software kit with your drive. If not, you can obtain the latest copy directly from Microsoft. If you are a registered user of DOS or Windows 3.1, MSCDEX.EXE is free. Read the licensing agreement that appears on the disc or in your manual concerning the proper licensing of the MSCDEX files.

Your installation software should add a line similar to the following to your AUTOEXEC.BAT file:

```
C:\WINDOWS\COMMAND\MSCDEX.EXE /d:mscd001
```

C:\WINDOWS\COMMAND is the directory in which the MSCDEX.EXE file is located by default with Windows 95 and 98; with MS-DOS and Windows 3.1, it could be located in the \DOS directory, or in the directory containing the CD-ROM drivers. The /d:mscd001 portion of the command line supplies the MSCDEX extension with the device signature defined in the CD-ROM device driver of your CONFIG.SYS file.

Note*

The MSCDEX and CD-ROM device signatures must match. The defaults that most installations provide are used in this example. As long as the two names are the same, the drivers can find one another.

As long as you have these three drivers—the SCSI adapter driver, the CD-ROM driver, and the DOS CD extensions—loaded properly in your system, the CD-ROM drive will operate as transparently as any other drive in your system.

Table 13.11 lists the options that you can add to the MSCDEX.EXE command line.

Table 13.11 MSCDEX Command-Line Options

Switch	Function
<code>/V</code>	Called Verbose; when this option is added to the command line, it displays information about memory allocation, buffers, drive letter assignments, and device driver names on your screen at boot time.
<code>/L:<letter></code>	Designates which DOS drive letter you want to assign to the drive. For example, <code>/L:G</code> assigns the drive letter G: to your CD-ROM drive. Two conditions apply: First, you must not have another drive assigned to that letter; and second, your <code>lastdrive=</code> statement in your CONFIG.SYS file must be equal to or greater than the drive letter you're assigning. <code>LASTDRIVE=G</code> would be fine. <code>LASTDRIVE=F</code> would cause an error if you attempt to assign the CD-ROM drive to the G: drive with the <code>/L:</code> switch.
<code>/M:<buffers></code>	Enables you to buffer the data from the CD-ROM drive. This is useful if you want faster initial access to the drive's directory. Buffers of 10 to 15 are more than enough for most uses. Any more is overkill. Each buffer, however, is equal to 2KB of memory. So a <code>/M:10</code> buffer argument, for example, would take 20KB of memory. Note that this does not significantly increase the overall performance of the drive, just DOS's initial access to the drive and the access of large data blocks when the drive is reading live-motion video files, for example. You can't turn a 400ms drive into a speed demon by adding a 200KB buffer. With no <code>/M:</code> argument added, MSCDEX will add six buffers as a default. That might be fine for most PCs and CD-ROM drives.
<code>/E</code>	Loads the aforementioned buffers into DOS high memory, freeing up space in the conventional 640KB. Early versions of MSCDEX—anything below version 2.1—do not load into extended memory. You must have DOS 5.0 for this option to load.
<code>/K</code>	Provides Kanji (Japanese) language support.
<code>/S</code>	Enables you to share your CD-ROM drive on a peer-to-peer network, such as Windows for Workgroups.

Note that Windows 9x uses a built-in CDFS (CD File System) driver that takes the place of MSCDEX. It is configured through the Windows 9x Registry and requires no AUTOEXEC.BAT command. USB-based CD-ROM/CD-R/CD-RW drives are also configured through the Windows 9x Registry and use no CONFIG.SYS or AUTOEXEC.BAT commands.

Loading CD-ROM Drivers

As mentioned earlier, your drive should come with installation software that copies the device driver files to your hard drive. It should also add the necessary command lines to your CONFIG.SYS and AUTOEXEC.BAT files.

When the process is complete, you can reboot your machine and look for signs that all went smoothly in the software installation.

Following is a series of sample portions of your startup screens to give you an idea of what messages you'll receive when a given driver is properly loaded into the system.

When you're sure that the software is loaded correctly, try the drive by inserting a disc into the drive. Then get a directory of the disc from the DOS prompt by issuing the following command:

```
DIR/w G:
```

This command gives you a directory of the CD you've inserted, if your CD has been assigned the drive letter G.

You can log in to the CD-ROM drive, as you would any DOS drive. The only DOS commands not possible on a CD-ROM drive are those that write to the drive. Remember that CDs are media that cannot be overwritten, erased, or formatted.

If you logged in to the CD-ROM and received a directory of a sample CD, you're all set.

Now you can power down the PC and replace the cover.

CD-ROM in Microsoft Windows 3.x

When your drive is added to your system, Windows already knows about it through the device drivers and DOS. The CD-ROM drive is accessible through File Manager by double-clicking its file cabinet icon. You see your CD-ROM drive among the drive icons across the top. Windows knows that the drive is a CD-ROM drive through the DOS extensions discussed earlier.

You can set your CD-ROM player to play audio CDs while you are working in Windows. You need to hook up your drive to a sound card and speakers or connect the CD's audio ports to a stereo first. Go to Windows' control panel and select Drivers. If you do not see [MCI] CD Audio among the files in the driver's list, choose Add. Insert the Windows installation disk that contains the CDAUDIO driver and add the driver. When the driver appears on the list, close the Drivers and control panel windows.

Double-click the Media Player icon. Under Devices, select CD. A listing of the track numbers on your audio CD appears along the bottom edge of the Media Player. The controls on Media Player are similar to those of an audio CD player, including track select, continuous play, and pause.

Many drive manufacturers supply DOS-based CD audio players with their systems. Check your installation manual and software discs for these utilities.

Optical Drives in Windows 9x and Windows NT 4.0

As stated earlier, Windows 9x and Windows NT include virtually all the drivers you will need to run your optical drive, making the software installation automatic. Windows automatically recognizes most IDE drives, and with the addition of the appropriate drive-specific ASPI driver, most SCSI drives as well.

There are several new capabilities with CDs and DVDs in Windows 9x/NT. The most dramatic is the Autoplay feature, which is available on Windows 95/98 and some versions of Windows NT 4.0.

Autoplay is a feature integrated into Windows 9x that enables you to simply insert a disc into the drive, and Windows will automatically run it without any user intervention. It will also detect whether that particular disc has already been installed on your system, and if not, it will automatically start the install program. If the disc has already been installed, it will start the application program on the disc.

The Autoplay feature is simple. When you insert a disc, Windows 9x automatically spins it and looks for a file called AUTORUN.INF. If this file exists, Windows 9x opens it and follows the instructions contained within. As you can see, this Autoplay feature will only work on discs that have this file. Most software companies are now shipping CD-ROM and DVD-ROM titles that incorporate the Autoplay feature.

Tip

You can disable the Autoplay feature for all CD-ROMs by opening the Windows 9x System control panel to the Device Manager page, highlighting your CD-ROM drive, and clicking the Properties button. The Properties dialog box for the drive has a Settings page that contains an Auto Insert Notification checkbox. Clearing this box prevents the operating system from processing the AUTORUN.INF file.

If you want to use Autoplay for some CDs, but not others, hold down the Shift key when inserting a CD you don't want to Autoplay.

Windows 9x/NT includes a new version of the Media Player found in Windows 3.x called the CD Player. This application allows you to play audio CDs in your drive while you work at the computer. The CD Player features graphical controls that look like a standard audio CD-ROM drive and even has advanced features found in audio drives, such as random play, programmable play-back order, and the capability to save play list programs.

MS-DOS Drivers and Windows 9x

Many users have discovered that their CD-ROM drives didn't come with MS-DOS drivers at a very unfortunate time: when their Windows 9x system wouldn't start up. All too often, the "cure" for a "dead" Windows 9x system is a complete reinstallation from the Windows 9x CD, to replace defective files and settings with new copies. Of course, if Windows isn't working, its 32-bit CD-ROM device drivers aren't working either. And, if you don't have your CONFIG.SYS and AUTOEXEC.BAT files and the files listed earlier either, you can't reload Windows! You should have a bootable disk ready that has the appropriate drivers included to allow you to rebuild your Windows 9x installation in case of emergencies.

If you have Windows 98, the Emergency Startup disk that you create during installation or later already has the appropriate drivers, AUTOEXEC.BAT, and CONFIG.SYS included to run most popular SCSI and ATAPI/IDE-based CD-ROMs. However, a Windows 95 bootable disk doesn't include the AUTOEXEC.BAT, CONFIG.SYS, or drivers; you'll have to add these yourself (see the next section).

Note

If you can't find any references to the MS-DOS drivers needed for your CD-ROM drive on your Windows 9x computer, check for an installation disk that might have been shipped with the drive. To install the CD-ROM device driver files you need, use that disk to perform an MS-DOS/Windows 3.1 installation, which will add the appropriate lines to your CONFIG.SYS and AUTOEXEC.BAT files and copy the drivers to your system.

Creating a Bootable Disk with CD-ROM Support

If you use Windows 95 (any version), take a moment and create a bootable disk. I'll assume that your CD-ROM drive uses the following CD-ROM device driver: MYCDROM.SYS, located in C:\CDROM.

Note

Your actual CD-ROM device driver will have a different name, but it almost always has *CD* or *CD-ROM* in the name somewhere!

You need to copy the following files to your bootable disk in A: drive:

- MYCDROM.SYS

Use the actual driver name for your CD-ROM drive and copy it from the file's actual location.

- MSCDEX.EXE

Copy from C:\WINDOWS\COMMAND; same file for any CD-ROM drive.

Then, you need to create a CONFIG.SYS file that loads the CD-ROM device driver and an AUTOEXEC.BAT that loads the MSCDEX.EXE CD-ROM extensions for MS-DOS program. Use a text editor such as the Windows Notepad.

- Contents of CONFIG.SYS:

DEVICE=MYCDROM.SYS /D:mscd001

- Contents of AUTOEXEC.BAT:

MSCDEX.EXE /d:mscd001 (other optional switches if you like as noted earlier)

note

Note that the */d:* switch refers to the same device name, which could be "Charlie" or "Kumquat" or anything that matches! A mismatch would cause the loading process to fail.

Add these four files added to your bootable floppy (listed again here for clarity):

- MYCDROM.SYS (or whatever your CD-ROM driver is called)
- MSCDEX.EXE
- AUTOEXEC.BAT (references MSCDEX.EXE)
- CONFIG.SYS (references MYCDROM.SYS)

Also, add the COMMAND.COM file and the hidden boot files to the disk to complete your bootable disk that can both start your computer and give you access to the CD-ROM drive.

With the disk still in the A: drive, check your BIOS setup, change the drive boot order to allow A: to be first if needed, and then save any changes if necessary. The computer reboots, and if you've

done your work properly, you should boot up to an A: prompt and be able to access your CD-ROM drive at whatever drive letter was displayed when MSCDEX.EXE ran. This will be the next drive letter after your last hard drive letter. If your latest hard drive letter is C:, the CD-ROM is D:.

Put your Windows 95 CD-ROM in the CD-ROM drive and see whether you can display a directory listing. If you can, your bootable disk is a success! Put the disk away for a rainy day. Sooner or later, you'll need it.

Note

The same basic procedure works for MS-DOS and Windows 3.1 users.

Windows 98 users can normally use their Emergency Startup disk created during upgrade installation or through the Windows Programs tab in the Add/Remove Software dialog box. Unlike the Windows 95 version, the Windows 98 version has an elaborate multipart CONFIG.SYS file that tries the most common IDE and SCSI CD-ROM drivers to find one that works with your drive.

If you did not create an emergency disk when installing Windows 98 or have misplaced the disk, you can create one at any time by opening the Add/Remove Programs control panel, selecting the Startup Disk tab and choosing Create Disk.

If you use Windows 2000, your CD is bootable. Be sure to set the boot order in your BIOS so that your system scans your CD-ROM before your hard drive. See Chapter 5, "BIOS," for more information on accessing the BIOS Setup utility.

Making a Bootable CD-ROM for Emergencies

With the rise of low-cost CD-R/CD-RW drives and low-cost drive imaging products such as Norton's Ghost and PowerQuest's Drive Image, it's now possible for individual PC owners to create their own version of what is standard with more and more new computers: a bootable CD-ROM that can be used to start up a system and restore it to a previously saved state. This is a step beyond the rescue CD that I discussed earlier, in which the image file was placed on a standard data CD-R. To recover from a system crash with that type of CD, you'd need to boot your system with a boot disk similar to the one I described making in the previous section.

But wouldn't it be great if you didn't need a bootable disk? They're easy to erase, damage, or lose. What if the CD-R itself could be bootable? You might have even seen a computer manufacturer's recovery CD boot itself before restoring a drive. With most CD-R mastering software, you can make one too.

Bootable CDs contain a special version of the boot files found on any disk or hard drive used to start a system. Because these files take less than 100KB (in the case of Windows 95B), the remainder of the 650MB can be used to store a compressed image of the system hard drive (made with Ghost, Drive Image, or similar products), a copy of the original operating system installation files, or anything else that you'd find useful.

By creating a bootable CD, you can

- Have a bootable “super-sized floppy” that can’t be erased or altered (if you write-protect it during creation).
- Create your own recovery CD by creating a compressed image file of your system when it’s in top working condition and placing the image file on the CD along with the restore program. In the event of disaster, boot with the CD and restore the image file.
- Switch between operating systems by creating compressed image files of each operating system after you install it and copying each to a separate CD along with the recovery utility. It isn’t necessary to make the CD bootable with the same operating system because you’ll need to restart the computer after restoring the image file.

Files Needed for a Bootable CD

The minimum requirements for a bootable CD include

- A system in which the CD-ROM can be designated as a boot drive

Note

Check your BIOS under Advanced Setup or similar options. Recent and current BIOS code supplied by AMI, Award Software, and Phoenix Technologies typically support the CD-ROM as a bootable device.

- A CD-ROM drive which can be treated as a bootable device (see the sidebar after this list)
- A CD-R or CD-RW drive (you’ll use CD-R media in either case)
- Mastering software that allows creation of a bootable CD

Note

If your current CD-mastering software lacks this option, consider changing to Adaptec’s Easy CD-Creator Pro. This low-cost software program supports most CD-R/CD-RW drives, offers high performance, many features for creating music as well as data CDs, and can make bootable CD-Rs.

- A floppy disk containing your operating system boot files

Note

You can use the ERU disk created by Windows 95, the startup disk created by Windows 95/98, or any bootable disk made by your operating system. Note that you’ll need to add the CD-ROM drivers to the disk, or verify that the Windows 98 startup disk will work with your CD-ROM drive (discussed later in this chapter).

ATAPI/IDE Drives are Bootable

Most ATAPI/IDE drives connected to a motherboard IDE interface can be used as a bootable device if the BIOS permits it. If your CD-ROM is connected to a sound card, this procedure won’t work. If your CD-ROM is connected to an SCSI interface, you’ll need an SCSI interface with a BIOS chip that permits booting as well as a bootable CD.

Here's a quick test to see whether your system can handle treating an IDE/ATAPI CD as a bootable device:

1. Place a data CD into your CD-ROM drive.
 2. Start your computer.
 3. Enter the BIOS Setup program.
 4. Go to the appropriate screen (as mentioned earlier) and select CD-ROM as first boot device.
 5. Select first hard disk (a.k.a. C:) as second boot device.
 6. Exit BIOS setup screens and save changes.
 7. On computer restart, see whether CD-ROM drive is being read for boot files. If so, eject data CD and allow computer to boot from hard disk. You should be able to boot from a bootable CD if your system tries to read the boot files from the CD-ROM drive.
-

The basic procedure for creating a bootable CD is as follows:

- 1.** Create a bootable floppy for the operating system you want to install on the CD.
- 2.** Get a blank CD-R and place it into your CD-R/CD-RW drive.
- 3.** Start your mastering software.
- 4.** Under disk layout, make sure that ISO 9660 is selected. This CD format doesn't permit long filenames, so make sure that any additional files you add to the CD have no more than eight characters plus up to three characters for the filename extension.
- 5.** Make sure that the bootable option is enabled in the disk layout.
- 6.** When prompted, insert the disk containing boot files into A: drive.
- 7.** These files are copied to your CD layout. Note that the names of these files are not the same as the normal operating system boot files. The files are called BOOTCAT.BIN and BOOTIMG.BIN.
- 8.** Add any additional files (image files, operating system install files, and so on) you want to the layout.
- 9.** Start the CD Creation process.
- 10.** When the process is completed, view the contents of the finished CD-R.
- 11.** Close your mastering program, saving the layout if you desire.
- 12.** Insert the bootable CD you just created into your CD-ROM drive.
- 13.** Restart the computer and see whether your system boots from the CD.

If you follow these directions, you will discover two interesting things when you reboot:

- Your CD-ROM drive is called drive A:.
- You won't be able to see any of your files on drive A: (the CD-ROM) except for COMMAND.COM if you made the CD-R with Windows 9x boot files.

Even though the bootable CD was able to start the computer, a CD-ROM, regardless of BIOS version, is still primarily a software-controlled peripheral. Without the appropriate driver software (the CD-ROM device driver in CONFIG.SYS and the MSCDEX.EXE program in AUTOEXEC.BAT), the CD-ROM drive cannot function at all (normal mode) or cannot do any more than boot the computer as if it's a 650MB shiny round floppy disk (bootable CD mode).

The CONFIG.SYS and AUTOEXEC.BAT statements needed on a bootable CD are similar to the standard examples you saw earlier, but with special modifications that allow them to work on a CD and change the drive letter assignments back to normal.

1. Start with a bootable disk containing the AUTOEXEC.BAT, CONFIG.SYS, MYCDROM.SYS (substitute your driver for this one), and MSCDEX.EXE as I discussed earlier.

2. Edit the CONFIG.SYS to read:

```
Lastdrive=Z  
Device=mycdrom.sys /d:mscd001
```

3. Edit the AUTOEXEC.BAT to read:

```
MSCDEX /d:mscd001 /l:z
```

The /l:z statement “locks” your CD-ROM drive letter at Z.

4. Boot the computer with the modified boot disk, and make sure the CD-ROM drive is accessible as Z:.
5. Start the CD-R mastering software program.
6. Create your CD-layout. If you're trying to make a rescue CD from an image file made with Norton Ghost, Drive Image, and so on, place the image file into the CD layout, along with the image-file-restore program.
7. Open the File menu and select CD Properties. Check mark the box that says Bootable CD.
8. Under Data type, select ISO 9660 and select Any 8+3 Character MS-DOS Filename under Properties

Note that with ISO 9660 that any Windows 9x-style long file names are shortened to their MS-DOS alias names (“Program Files” = “Progra~1”, and so on).
9. Create the CD. Insert the bootable disk you created in steps 1–4 when prompted.
10. Note that even though the bootable floppy contains four additional files, the two files in the CD layout are still called BOOTCAT.BIN and BOOTIMG.BIN. These files contain all bootable information from the floppy.
11. Remove the bootable floppy, and restart the computer (change the boot sequence to CD-ROM first and hard disk second).
12. Success means the system boots from CD-ROM and CD-ROM drivers load to allow access to entire CD.

Caring for Optical Media

Some people believe that optical discs and drives are indestructible when compared to their magnetic counterparts. Actually, modern optical drives are far less reliable than modern hard disk drives. Reliability is the bane of any removable media, and CD-ROMs and DVD-ROMs are no exception.

By far the most common causes of problems with optical discs and drives are scratches, dirt, and other contamination. Small scratches or fingerprints on the bottom of the disc should not affect performance because the laser focuses on a point inside the actual disk, but dirt or deep scratches can interfere with reading a disc.

To remedy this type of problem, you can clean the bottom surface of the CD with a soft cloth, but be careful not to scratch the surface in the process. The best technique is to wipe the disc in a radial fashion, using strokes that start from the center of the disc and emanate toward the outer edge. This way, any scratches will be perpendicular to the tracks rather than parallel to them, minimizing the interference they might cause. You can use any type of solution on the cloth to clean the disc, so long as it will not damage plastic. Most window cleaners are excellent at removing fingerprints and other dirt from the disc and will not damage the plastic surface.

If there are deep scratches, they can often be buffed or polished out. A commercial plastic cleaner such as that sold in auto parts stores for cleaning plastic instrument cluster and tail-lamp lenses is very good for removing these types of scratches. This type of plastic polish or cleaner has a very mild abrasive that polishes scratches out of a plastic surface. Products labeled as cleaners are usually designed for more serious scratches, whereas those labeled as polishes are usually milder and work well as a final buff after using the cleaner. Polishes can be used alone if the surface is not scratched very deeply.

Read errors can also occur when dust accumulates on the read lens of your CD-ROM drive. You can try to clean out the drive and lens with a blast of “canned air,” or by using a drive cleaner (which can be purchased at most music stores that sell audio CDs).

If your discs and your drive are clean, but you still can't read a particular disc, your trouble might be due to disc capacity. Early CD-ROM discs had a capacity of about 550MB (equivalent to about 60 minutes of CD audio). More recently, the capacity of a standard CD has been pushed to 650MB (74 minutes of CD audio). Many older CD-ROM drives are unreliable when they try to read the outermost tracks of newer discs where the last bits of data are stored. You're more likely to run into this problem with a CD that has lots of data—including some multimedia titles. If you have this problem, you might be able to solve it with a firmware or driver upgrade for your CD-ROM drive, but it's possible that the only solution will be to replace the drive.

Sometimes too little data on the disc can be problematic as well. Some older CD-ROM drives use an arbitrary point on the disc's surface to calibrate their read mechanism, and if there happens to be no data at that point on the disc, the drive will have problems calibrating successfully. Fortunately, this problem can usually be corrected by a firmware or driver upgrade for your drive.

Many older drives have had problems working under Windows 9x. If you are having problems, contact your drive manufacturer to see whether there is a firmware or software-driver upgrade that might take care of your problem. With new high-speed drives available for well under \$100, it might not make sense to spend any time messing with an older drive that is having problems. It would be more cost-effective to upgrade to a new drive instead.

If you are having problems with only one particular disc and not the drive in general, you might find that your difficulties are in fact caused by a defective disc. See whether you can exchange the disc for another to determine whether that is indeed the cause.

Troubleshooting Optical Drives

Failure Reading a CD

If your CD fails to read a CD, try the following solutions:

- Check for scratches on CD data surface.
- Check drive for dust, dirt; use cleaning CD.
- Make sure drive shows up as working device in System Properties.
- Try a CD that you know to work.
- Restart computer (the magic cure-all).
- Remove drive from Device Manager in Windows 9x, allow system to redetect drive and reinstall drivers (if PnP-based system).

Failure to Read CD-R, CD-RW Disks in CD-ROM or DVD Drive

If your CD-ROM or DVD drive fails to read CD-R and CD-RW disks, try the following solutions:

- Check compatibility; some very old 1x CD-ROM drives can't read CD-R media. Replace drive with newer, faster, cheaper model.
- Many early-model DVD drives can't read CD-R, CD-RW media; check compatibility.
- CD-ROM drive must be Multi-Read compatible to read CD-RW due to lower reflectivity of media; replace drive.
- If some CD-Rs but not others can be read, check media color combination to see whether some color combinations work better than others; change brand of media.
- Packet-written CD-Rs (from Adaptec DirectCD and backup programs) can't be read on MS-DOS/Windows 3.1 CD-ROM drives due to limitations of operating system.

IDE/ATAPI CD-ROM Drive Runs Slowly

If your IDE/ATAPI CD-ROM drive performs poorly, check the following items:

- Check cache size in the Performance tab of the System Properties control panel. Select the quad-speed setting (largest cache size)
- Check to see whether the CD-ROM drive is set as the slave to your hard disk; move CD-ROM to the secondary controller if possible.

- Your PIO or UDMA mode might not be set correctly for your drive in the BIOS; check drive specs and use autodetect in BIOS for best results (see Chapter 5).
- Check to see that you are using bus-mastering drivers on compatible systems; install appropriate drivers for motherboard's chipset and operating system in use. See "DMA (Direct Memory Access)" earlier in this chapter.
- Check to see whether you are using the CD-ROM interface on your sound card instead of IDE connection on motherboard. Move drive connection to the IDE interface on motherboard and disable sound card IDE if possible to free up IRQ and I/O port address ranges.
- Open the System Properties control panel and select the Performance tab to see whether system is using MS-DOS Compatibility Mode for CD-ROM drive. If all IDE drives are running in this mode, see www.microsoft.com and query on "MS-DOS Compatibility Mode" for a troubleshooter. If only the CD-ROM drive is in this mode, see whether you're using CD-ROM drivers in CONFIG.SYS and AUTOEXEC.BAT. Remove the lines containing references to the CD-ROM drivers (don't actually delete the lines—REM them), reboot the system and verify that your CD-ROM drive still works and that it's running in 32-bit mode. Some older drives require at least the CONFIG.SYS driver to operate.

Poor Results When Writing to CD-R Media

If you are having problems successfully writing data to a CD-R disk, see "How to Reliably Make CD-Rs" earlier in this chapter.

Trouble Reading CD-RW Disks on CD-ROM

If you cannot read CD-RW disks in your CD-ROM, check the vendor specifications to see whether your drive is multi-read compliant. Some drives are not compliant.

If your drive is multi-read compliant, try the CD-RW disk on known-compliant CD-ROM drive (drive with multi-read feature).

Trouble Reading CD-R Disks on DVD Drive

If your DVD drive cannot read a CD-R disk, check drive compliance—original DVDs cannot read CD-R media. Newer, faster DVD drives support CD-R media.

Trouble Making Bootable CDs

If you are having problems creating a bootable CD, try these possible solutions:

- Check the contents of bootable floppy disk from which you copied the boot image. To access entire contents of a CD-R, a bootable disk must contain CD-ROM drivers, AUTOEXEC.BAT, and CONFIG.SYS.
- Use ISO 9660 format. Don't use Joliet format because it is for long-filename CDs and can't boot.
- Check your system's BIOS for boot compliance and boot order; CD-ROM should be listed first.
- Check drive for boot compliance.
- SCSI CD-ROMs need SCSI card with BIOS and bootable capability as well as special motherboard BIOS settings.

Physical Drive Installation and Configuration

SOME OF THE MAIN TOPICS IN THIS CHAPTER ARE

Hard Disk Installation Procedures
Hard Drive Physical Installation—Step by Step
Replacing an Existing Drive
Hard Disk Drive Troubleshooting and Repair
Installing an Optical Drive (CD-ROM, CD-R)
Floppy Drive Installation Procedures
Tape Drive Installation Issues

This chapter covers the actual installation of hard drives, optical drives (CD/DVD), floppy drives, and tape drives. This includes everything from the preparation of the components to setting jumpers to the actual cabling and physical installation. Also the initial system software configuration issues will be covered as well, right up until the start of the operating system installation. From that point on the steps you take would depend on which operating system you are installing.

For more information on drive interfaces, magnetic storage, drive operation, and operating system issues, see the following chapters:

- *Chapter 7. “The IDE Interface”*
- *Chapter 8. “The SCSI Interface”*
- *Chapter 9. “Magnetic Storage Principles”*
- *Chapter 10. “Hard Disk Storage”*
- *Chapter 11. “Floppy Disk Storage”*
- *Chapter 12. “High-Capacity Removable Disk Storage”*
- *Chapter 13. “Optical Storage”*
- *Chapter 26. “Operating System Software and Troubleshooting”*

Although most of the drives you would install in a PC are covered here, the primary emphasis is on hard disks.

Hard Disk Installation Procedures

This section describes the hard disk drive installation process, particularly the configuration, physical installation, and formatting of a hard disk drive.

To install a hard drive in a PC, you must perform some or all of the following procedures:

- Configure the drive
- Configure the host adapter
- Physically install the drive
- Configure the system
- Partition the drive
- High-level format the drive

As you perform the setup procedure, you may need to know various details about the hard disk drive, the host adapter, and the system ROM BIOS, as well as many of the other devices in the system. This information usually appears in the various OEM manuals that come with these devices. Make sure when you purchase these items that the vendor includes these manuals. (Many do not include the manuals unless you ask for them.) For most equipment sold today, you will get enough documentation from the vendor or reseller of the equipment to enable you to proceed.

If you are like me, however, and want all the technical documentation on the device, you will want to contact the original manufacturer of the device and order the technical specification

manual. For example, if you purchase a system that comes with a Western Digital IDE hard disk, the seller probably will give you some limited information on the drive, but not nearly the amount that the actual Western Digital technical specification manual provides. To get this documentation, you have to call Western Digital and order it. The same rule applies for any of the other components in most of the systems sold today. I find the OEM technical manuals to be essential in providing the highest level of technical support possible.

For reference, you can look up the hard disk manufacturer names in Vendor List, on the CD, and you will find numbers to call for technical support, as well as URLs for their Web sites.

Drive Configuration

Before you physically install a hard disk drive into the computer, you must be sure that it is properly configured. For an IDE drive, this generally means designating the drive as a master/slave or using the Cable Select feature and a special cable to determine the relationship. For SCSI drives, you must set the device's SCSI ID and possibly its SCSI bus termination state.

◀◀ These procedures are covered in "The IDE Interface," p. 509, and "The SCSI Interface," p. 529.

Host Adapter Configuration

Older hard disk drive types used separate disk controller cards that you had to install in a bus slot. The IDE and SCSI hard disk drives used in today's PCs have the disk controller integrated into the drive assembly. For IDE drives, the I/O interface is nearly always integrated into the system's motherboard, and you configure the interface through the system BIOS. There is no separate host adapter, therefore, if you have an IDE drive you can proceed to "Physical Installation," later in this chapter. Some systems might use ATA/IDE adapters in lieu of the built-in interface, because some of the motherboard-integrated ATA interfaces will not support the faster modes some newer drives (such as ATA/33 and ATA/66) are capable of achieving. In most cases, I would recommend upgrading the motherboard rather than getting an IDE host adapter, because there are other benefits to a new motherboard and the cost isn't much higher.

SCSI drives, however, usually require a host adapter card that you must install in a bus slot like any other card. A few motherboards have integrated SCSI adapters, but these are rare. Configuring a SCSI host adapter card involves setting the different system resources that the adapter requires. As with most expansion cards, a SCSI host adapter will require some combination of the following system resources:

- ROM addresses
- Interrupt requests (IRQ)
- DMA (Direct Memory Access) channel (DRQ)
- I/O port addresses

Not all adapters use every one of these resources, but some may use them all. In most cases, these resources will be automatically configured by the BIOS and your operating system.

When you install a host adapter that supports Plug and Play in a system with a Plug-and-Play BIOS and operating system, such as Windows 9x, the configuration process is completely

automatic. The computer sets the required hardware resource settings to values that do not conflict with other devices in the computer.

◀◀ See “Plug-and-Play BIOS,” p. 400.

If your hardware or operating system does not support Plug and Play, you have to manually configure the adapter to use the appropriate resources. Some adapters provide software that enables you to reconfigure or change the hardware resources, while others use jumpers or DIP switches.

◀◀ See “System Resources,” p. 311.

The IDE interface is part of the standard PC BIOS, which makes it possible to boot from an IDE drive. The BIOS provides the device driver functionality that the system needs to access the drive before any files can be loaded from disk. The SCSI interface is not part of the standard PC BIOS, so most SCSI host adapters have their own ROM BIOS that enables SCSI drives to function as boot devices.

Use of the SCSI BIOS is usually optional. If you are not booting from a SCSI drive, you can load a standard device driver for your operating system to access the SCSI devices. Most host adapters have DIP switches that you use to enable or disable SCSI BIOS support.

In addition to providing boot functionality, the SCSI BIOS can provide many other functions, including any or all of the following:

- Low-level formatting
- Drive-type (parameter) control
- Host adapter configuration
- SCSI diagnostics
- Support for nonstandard I/O port addresses and interrupts

If the adapter's onboard BIOS is enabled, it will use specific memory address space in the upper memory area (UMA). The UMA is the top 384KB in the first megabyte of system memory. The UMA is divided into three areas of two 64KB segments each, with the first and last areas being used by the video adapter circuits and the motherboard BIOS, respectively. Segments C000h and D000h are reserved for use by adapter ROMs such as those found on disk controllers or SCSI host adapters.

Note

You must ensure that any adapters using space in these segments of the HMA (high memory area) do not overlap with another adapter that uses this space. No two adapters can share this memory space. Most adapters have software, jumpers, or switches that can adjust the configuration of the board and change the addresses it uses to prevent conflict.

Physical Installation

The procedure for the physical installation of a hard disk drive is much the same as that for installing any other type of drive. You must have the correct screws, brackets, and faceplates for the specific drive and system before you can install the drive.

Some computer cases require plastic or metal rails that are secured to the sides of a hard disk drive so it can slide into the proper place in the system (see Figure 14.1). When you purchase a drive, vendors often give you the option to purchase a kit as opposed to the bare drive. For slightly more money, the kit includes mounting rails, screws, and often a ribbon cable that you should be able to use in most systems. Be careful when purchasing a SCSI drive, however, as the kit might include a host adapter that can add substantially to the price.

Because cables can vary for both IDE and SCSI interfaces, be sure you have the proper cable for both your drive and controller. For example, to run the newer Fast-ATA/66 modes, you need a special 80-conductor cable. This cable is also recommended if you are running Fast-ATA/33; it will work for all slower modes as well.

Figure 14.1 A typical hard disk with mounting rails.

If you cannot purchase a drive kit, there are several companies listed in the Vendor List (on the CD) that specialize in drive-mounting brackets, cables, and other hardware accessories. Also, many newer aftermarket computer cases have eliminated the need for drive rails altogether by building the expansion slot itself to the 3 1/2- or 5 1/4-inch drive specification, enabling you to bolt the new drive directly to the case. Most 3 1/2-inch hard drives sold in boxed packaging in retail outlets do include the mounting bracket required to mount a 3 1/2-inch drive in a 5 1/4-inch bay (as shown in Figure 14.2).

Note

You should also note the length of the drive cable itself when you plan on adding a hard disk drive. It can be very annoying to assemble everything that you think you'll need to install a drive, and then find that the drive cable is not long enough to reach the new drive location. You can try to reposition the drive to a location closer to the interface connector on the host adapter or motherboard, or just get a longer cable. IDE cables are limited to 18 inches in overall length; if they are shorter, that is all the better. This is most important if your drive is going to use the faster ATA/33 and ATA/66 modes. Using a cable that is too long will cause timing errors and signal degradation, possibly corrupting the data on your drive.

Figure 14.2 A typical bracket used to mount a 3 1/2-inch drive in a 5 1/4-inch drive bay. The bracket is screwed to the drive, and then mounted in the bay by using screws or rails as determined by the case.

Different faceplate, or bezel, options are also available. Make sure that you have the correct bezel for your application. Some systems, for example, do not need a bezel; if there is a bezel on the drive, you must remove it.

Caution

Make sure you use only the screws that come with your new drive. Many drives come with a special short-length screw that can have the same size thread as other screws you might use in your system. If you use screws that are too long, they might protrude too far into the drive casing and cause problems.

Hard Drive Physical Installation—Step by Step

The step-by-step procedures for installing a hard drive are as follows:

1. Check your computer for an unused IDE connector. Typical Pentium-class and above PCs have provision for four IDE devices; if you have less, add your drive to an unused 40-pin

- connector on an IDE cable. (You will need to attach a cable if you have only one IDE cable in the computer and both connectors on the cable already have drives or devices attached.)
2. Double-check the pin configuration. The colored (normally red or red-flecked) stripe on one edge of the cable goes to pin 1 of the hard drive's data connector. Reverse this, and the drive won't be capable of accepting any commands, such as `identify`, `FDISK`, or `FORMAT`. Most cables will be keyed to prevent improper installation, but many are not.
 3. Slide the drive carefully into a drive bay of the correct size. Most hard drives, except for a few very high-capacity SCSI drives meant for servers and the Quantum Bigfoot series, are 3 1/2-inch wide and 1-inch high. If you have no 3 1/2-inch drive bays left for your hard disk, attach a drive-adapter kit to the sides of the drive to make it wide enough to fit into a 5 1/4-inch wide drive bay (refer to Figure 14.2). Some case designs require that you attach rails to the side of the hard drive. If so, attach them to the drive using the screws supplied with either the case or the drive. Be sure the screws aren't too long, if you bottom the screws in the drive, you can damage it. Then slide the drive into the bay in the case until the rails latch into place. Note that most cases include the screws and rails to install drives, but if not you may have to purchase them separately.
 4. Attach the existing data cable connector to the back of the drive, unless you are adding the drive and cable at the same time. In that case, attach the cable to the drive before you slide it into the drive bay and fasten it into place (step 2 above).
 5. Attach the appropriate power connector to the drive. Most hard drives use the larger, or "Molex" four-wire power connector. If necessary, purchase a Y-splitter cable to create two power connectors from one (many computers have fewer power connectors than drive bays).
 6. Turn on the computer and listen for the new hard disk to spin up. While today's drives are very quiet compared to early hard disks, you should still hear a faint rattling or clicking as the new hard disk starts to run. If you don't hear anything from the drive, double-check the data and power cables.
 7. Restart the computer and access the BIOS setup screens to configure the new hard disk. At a minimum, you'll need to detect (or set) the following parameters: cylinders, heads, sectors per track, and write precompensation. If your BIOS has an autodetect or auto type setting, I recommend you use it as it will configure most parameters automatically. For IDE hard drives above 528 million bytes, you'll also need to set LBA translation to access the drive's full capacity. If autodetect was selected LBA translation should already be set correctly. Many systems have a Peripherals Configuration screen, which also allows you to set UDMA, PIO, and block mode configurations for maximum drive performance. See your drive's documentation for the correct settings. Save the BIOS configuration, and exit the BIOS setup screen to continue. The following section has more information on this step, as it can be complicated.
 8. Restart the computer, and prepare to run `FDISK` to prepare the hard drive for formatting and use. Or, you can use drive partitioning software, such as PowerQuest's Partition Magic to automatically create and manage disk partitions.

Note

See the CD accompanying this book for Macmillan editions of Partition Magic and Drive Image, which allows you to image a drive for emergency restoration or for multiple installations.

System Configuration

After your drive is physically installed, you have to provide the computer with basic information about the drive so the system can access it and boot from it. How you set and store this information depends on the type of drive and system you have. Standard (IDE) setup procedures apply for most hard disks except SCSI drives. SCSI drives normally follow a custom setup procedure that varies depending on the host adapter that you are using. If you have a SCSI drive, follow the instructions included with the host adapter to configure the drives.

Automatic Drive Typing

For IDE drives, virtually all new BIOS versions in today's PCs have automatic typing. The BIOS sends a special Identify Drive command to all the devices connected to the IDE interface during the system startup sequence; the drives are intelligent enough to respond with the correct parameters. The BIOS then automatically enters the parameter information returned by the drive. This procedure eliminates errors or confusion in parameter selection. However, even with automatic drive typing, some BIOSes will alert you that you need to enter the system Setup program and configure the drive. In these situations, just enter the system BIOS configuration utility and save the settings that the BIOS has detected for the drive. You don't need to enter any settings yourself.

If your system supports automatic drive typing but no drive information appears onscreen, you might have forgotten to attach the power cable to the drive, or you may have reversed the IDE interface cable at either the motherboard or the hard drive connections. The red stripe on the 40-pin IDE cable is supposed to be aligned with pin 1 at both ends. Without power or proper data connection the drive will never spin up and, therefore, cannot be detected.

Even though most new BIOSes support automatic drive typing at startup, there are a couple of benefits to performing this task within the BIOS configuration screen:

- In the event that you need to move the drive to another system, you'll know the drive geometry and translation scheme (such as LBA) that was used to access the drive. If the drive is moved to another computer, the identical drive geometry (cylinder, head, sectors per track) and translation scheme must be used in the other computer, or the data on the drive will not be accessible and can be lost. Because many systems with auto-configuration don't display these settings during the startup process, performing the drive-typing operation yourself might be the only way to get this information.
- Even if you never expect to move the drive, you'll gain several seconds on every startup by detecting the drive in the BIOS configuration screens and saving the setting there. You can also save time by setting unused drive interfaces to Not Installed. Otherwise, the computer will try to detect devices on all four IDE ports (primary master, primary slave, secondary master, and secondary slave) each time you start the computer.

Manual Drive Typing

If you are dealing with a motherboard that does not support automatic typing, you must enter the appropriate drive information in the system BIOS manually. The BIOS has a selection of pre-configured drive types, but these are woefully outdated in most cases, providing support only for drives holding a few hundred megabytes or less. In nearly every case, you will have to select the user-defined drive type and provide values for the following settings:

- Cylinders
- Heads
- Sectors per track
- Write precompensation

The values that you use for these settings should be provided in the documentation for the hard disk drive, or they might be printed on the drive itself. It's a good idea to check for these settings and write them down, because they may not be visible once you've installed the drive. You should also maintain a copy of these settings in case your system BIOS should lose its data due to a battery failure. One of the best places to store this information is inside the computer itself. Taping a note with vital settings like these to the inside of the case can be a lifesaver.

In the event that you are not able to determine the correct settings for your hard drive from either the drive case or from the Technical Reference, there are utility programs available from the Internet that can query the drive for this information. Western Digital's TBLCHK.EXE has been updated to handle LBA-mode hard drives, unlike many older utilities, and can be obtained from Western Digital's Web site.

Note

The setup parameters for over 1,000 popular drive models are included in the Technical Reference on the CD. Additionally, there is a generic table of parameters included in the appendix that will work (although they may not work optimally) with any IDE drive up to 528MB.

Depending on the maker and the version of your system BIOS, there may be other settings to configure as well, such as what transfer mode to use, and whether or not the BIOS should use logical block addressing.

◀◀ See "Increased Drive Capacity," p. 521.

Formatting

Proper setup and formatting are critical to a drive's performance and reliability. This section describes the procedures used to format a hard disk drive correctly. Use these procedures when you install a new drive in a system or immediately after you recover data from a hard disk that has been exhibiting problems.

There are three major steps in the formatting process for a hard disk drive subsystem:

1. Low-level formatting
2. Partitioning
3. High-level formatting

Low-Level Formatting

All new hard disk drives are low-level formatted by the manufacturer, and you do not have to perform another LLF before you install the drive. In fact, under normal circumstances, you should not ever have to perform a low-level format on an IDE or SCSI drive. Most manufacturers no longer recommend that you low-level format any IDE type drive.

This recommendation has been the source of some myths about IDE. Many people say, for example, that you cannot perform a low-level format on an IDE drive, and that if you do, you will destroy the drive. This statement is untrue! What can happen is that you may lose the optimal head and cylinder skew factors for the drive that were set by the manufacturer, as well as the map of drive defects. This situation is not good and will definitely have a negative effect on the drive's performance, but you still can use the drive with no problems.

However, there may be times when you must perform a low-level format on an IDE or SCSI drive. The following sections discuss the software that you can use to do this.

SCSI Low-Level Format Software

If you are using an SCSI drive, you must use the LLF program provided by the manufacturer of the SCSI host adapter. The design of these devices varies enough that a register-level program can work only if it is tailored to the individual controller. Fortunately, all SCSI host adapters include low-level format software, either in the host adapter's BIOS or in a separate disk-based program.

The interface to the SCSI drive is through the host adapter. SCSI is a standard, but there are no true standards for what a host adapter is supposed to look like. This means that any formatting or configuration software will be specific to a particular host adapter.

Note

Notice that SCSI format and configuration software is keyed to the host adapter and is not specific in any way to the particular SCSI hard disk drive that you are using.

IDE Low-Level Format Software

IDE drive manufacturers have defined extensions to the standard WD1002/1003 AT interface, which was further standardized for IDE drives as the ATA (AT Attachment) interface. The ATA specification provides for vendor-unique commands, which are manufacturer proprietary extensions to the standard. To prevent improper low-level formatting, many of these IDE drives have special codes that must be sent to the drive to unlock the format routines. These codes vary among manufacturers. If possible, you should obtain LLF and defect-management software from

the drive manufacturer; this software usually is specific to that manufacturer's products, and often is model-specific. Check the brand and model number of your hard disk to determine the utility program you need.

Most ATA IDE drives are protected from any alteration to the skew factors or defect map erasure because they are in a translated mode. Zoned bit recording drives are always in translation mode and are fully protected. Most ATA drives have a custom command set that must be used in the format process; the standard format commands defined by the ATA specification usually do not work, especially with intelligent or zoned bit recording IDE drives. Without the proper manufacturer-specific format commands, you can't perform the defect management by the manufacturer-specified method, in which bad sectors often can be spared.

Most manufacturers supply low-level format programs for their drives. Here are a few examples:

- *Seagate*. ftp://ftp.seagate.com/techsuppt/seagate_utils/sgatfmt4.zip
- *IBM*. <http://www.storage.ibm.com/techsup/hddtech/welcome.htm>
- *Quantum*. http://support.quantum.com/menus/soft_menu.htm
- *Western Digital*. http://www.wdc.com/service/ftp/wddiag/wd_diag.exe
- *Maxtor*. <http://www.maxtor.com/library/ide.html>

I would try the manufacturer specific format programs first. They are free and can often work at a lower level and handle defects in ways that the more generic ones can't. If formatting software is not available from your drive's manufacturer, I recommend Disk Manager by Ontrack and the MicroScope program by Micro 2000. Another excellent, inexpensive, general-purpose PC hardware diagnostic that includes low-level format capability is #1 TuffTEST Pro from #1-PC Diagnostics. These programs can format many IDE drives because they know the manufacturer-specific IDE format commands and routines. They also can perform defect-mapping and surface-analysis procedures.

Note

While Ontrack Disk Manager can be purchased in a "generic" version that works with any manufacturer's hard drives, brand-specific OEM versions are often available free of charge on the utility disks or CD-ROMs shipped with new retail-packaged hard disk drives. You should also check your drive maker's Web site for updated versions of Disk Manager. These OEM versions are designed to check for a particular brand's drive firmware, and will not work on any other brand than the one for which they were modified.

Nondestructive Formatters

General-purpose, BIOS-level, nondestructive formatters, such as Calibrate and SpinRite, are not recommended in most situations where a real LLF is required. These programs have several limitations and problems that limit their effectiveness; in some cases, they can even cause problems with the way that defects are handled on a drive. These programs attempt to perform a track-by-track LLF by using BIOS functions, while backing up and restoring the track data as they go. These programs do not actually perform a complete LLF, because they do not even try to low-level format the first track (Cylinder 0, Head 0) due to problems with some controller types that store hidden information on the first track.

These programs also do not perform defect mapping in the way that standard LLF programs do, and they can even remove the carefully applied sector header defect marks during a proper LLF. This situation potentially allows data to be stored in sectors that originally were marked defective and may actually void the manufacturer's warranty on some drives. Another problem is that these programs only work on drives that have already been formatted and can format only drives that are formattable through BIOS functions.

Note

Spinrite is, however, useful for recovering data found on drives with read errors, because of its thorough method of repeatedly rereading the errors and analyzing the results to reconstruct the missing data. This process is called *Dynastat Data Recovery*.

A true LLF program bypasses the system BIOS and sends commands directly to the disk controller hardware. For this reason, many LLF programs are specific to the disk controller hardware for which they are designed. It is virtually impossible to have a single format program that will run on all different types of controllers. Many hard drives have been incorrectly diagnosed as being defective because the wrong format program was used and the program did not operate properly.

Drive Partitioning with FDISK

Partitioning a hard disk is the act of defining areas of the disk for an operating system to use as a volume.

When you partition a disk, the partitioning software writes a master partition boot sector at Cylinder 0, Head 0, Sector 1—the first sector on the hard disk. This sector contains data that describes the partitions by their starting and ending cylinder, head, and sector locations. The partition table also indicates to the ROM BIOS which of the partitions is bootable and, therefore, where to look for an operating system to load.

▶▶ See "File Systems and Data Recovery," p. 1379.

The FDISK program is the accepted standard for partitioning hard disk drives for use with all versions of Windows 9x and DOS. Partitioning prepares the boot sector of the disk in such a way that the FORMAT.COM program or the Windows GUI format utility can operate correctly. FDISK also makes it possible for different operating systems to coexist on a single hard disk. No matter which operating system you use, it should come with an FDISK program that can be used to partition the drive.

Note

Because FDISK depends on BIOS information about the hard disk to determine the size and drive geometry of the hard disk, correct BIOS settings are vital to a correct operation of FDISK. If a 10GB hard drive is defined in the BIOS as a 10MB hard drive, for example, all that FDISK will prepare for use, and all that FORMAT will ultimately prepare, is 10MB.

With any version of Windows, as with MS-DOS, FDISK allows you to create two different types of disk partitions: primary and extended. A primary partition can be bootable but an extended partition cannot. If you have only a single hard disk in your system, at least part of the drive must be prepared as a primary partition if you want to start your computer from the hard disk (and who doesn't?). A primary partition equals a single drive letter (C: on one-drive systems), whereas an extended partition acts as a sort of logical container for additional drive letters (D: and beyond). A single extended partition can contain a single drive letter (also referred to as a *logical DOS drive*), or more than one logical DOS drive of different sizes.

Don't get hung up on the fact that FDISK calls partitions "DOS" partitions or "DOS" drives. This is true even though the operating system you are installing is Windows 95, 98, NT, 2000, Linux, etc.

Depending on the version of Windows in use (and with any version of MS-DOS), it might be necessary to subdivide a hard drive through the use of FDISK. The original release of Windows 95 and MS-DOS supports FAT16, which allows no more than 65,536 files per drive and a single drive letter of no more than 2.1GB in size. Thus, a 10.1GB hard disk prepared with MS-DOS or the original Windows 95 must have at a minimum of five drive letters, and could have more. See Figure 14.3.

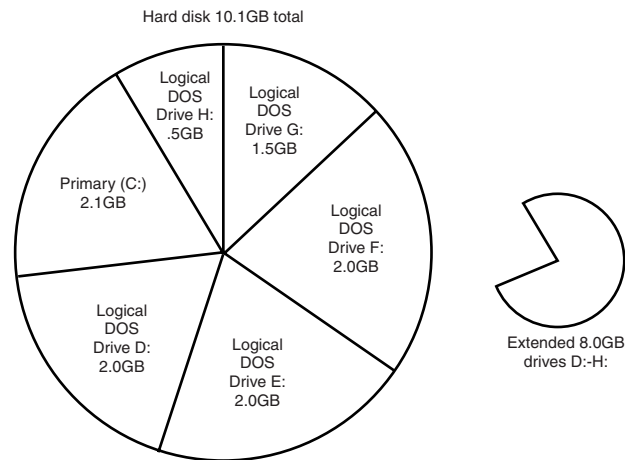

Figure 14.3 Adding a hard drive above 2.1GB in size to an MS-DOS or original Windows 95 computer forces the user to create multiple drive letters to use the entire drive capacity. The logical DOS drives are referenced like any other drive, although they are portions of a single physical hard disk.

▶▶ See "FAT Disk Structures" p. 1380.

Another reason for subdividing a single drive into letters is for increased data security. For example, PowerQuest (the creators of PartitionMagic) suggests a three-drive partitioning scheme that looks like this:

- C: for the operating system and utilities
- D: for applications
- E: and above for data

In this example, primary and extended partitions would be assigned as shown here:

- C: the primary partition
- D: and E: in the extended partition as logical DOS drives

If a catastrophic failure to the disk structure wipes out C: or D:, Drive E:, which contains the data, will normally still be intact. This method also makes backing up the data easier; just set the backup program to back up all of E:, or all the changed files on E:.

Large Hard Disk Support

If you use the Windows 95B or above (Win95 OSR 2.x) or Windows 98 versions of FDISK with a hard drive greater than 512MB, FDISK will offer to enable large disk support.

Choosing to enable large disk support provides several benefits:

- You can use a large hard disk (greater than 2.1GB) as a single drive letter; in fact, your drive can be as large as 2TB and still be identified by a single drive letter. This is due to the FAT32 file system, which allows for many more files per drive than FAT16.

▶▶ See "FAT32," p. 1399.

- Because of the more efficient storage methods of FAT-32, your files will use less hard disk space overall.

However, keep in mind that all disk operations must be done through Windows 95B or Windows 98 for any drive FDISKed with large hard drive support (FAT32). If you have old MS-DOS games or applications that require you to boot with MS-DOS rather than with Windows' command-prompt mode, they can't access a FAT32 drive.

A drive prepared with the large hard disk support (FAT32) option enabled can still be partitioned into primary and secondary partitions with FDISK, as with FAT16 for the data-security reasons listed earlier.

Another type of file system is NTFS, which is supported only by Windows NT and Windows 2000. This is a high performance file system with additional security and networking features. It is discussed in more detail in Chapter 27, "File Systems and Data Recovery". Note that Windows 9x cannot read NTFS partitions, and Windows NT cannot read FAT32 partitions. Windows 2000 can handle both FAT32 and NTFS.

Assigning Drive Letters with FDISK

There are many ways to use FDISK, depending on the number of hard drives you have in your system and the number of drive letters you want to create.

With a single drive, creating a primary partition (C:) and an extended partition with two logical DOS drives within it will result in the following drive letters:

Partition Type	Drive letter(s)
Primary	C:
Extended volumes	D: and E:

Most people would think that a second physical drive added to this system should have drive letters that follow the E: drive.

However, you need to understand how drive letters are allocated by the system to know how to use FDISK correctly in this situation. Table 14.1 shows how FDISK assigns drive letters by drive and partition type.

Table 14.1 Drive Letter Allocations by Drive and Partition Type

Drive	Partition	Order	First drive letter
1st	Primary	1st	C:
1st	Extended	3rd	E:
2nd	Primary	2nd	D:
2nd	Extended	4th	F:

How does this affect you when you add another hard drive? If you prepare the second hard drive with a primary partition and your first hard drive has an extended partition on it, the second hard drive will take the primary partition's D: drive letter. This moves all the drive letters in the first hard drive's extended partition up one drive letter.

In the first example, we listed a drive with C: (primary partition), D:, and E: (extended partition volumes) as the drive letters (D: and E: were in the extended partition). Table 14.2 indicates what happens if a second drive is added with a primary partition and an extended partition with two volumes (same setup as the first drive):

Table 14.2 Drive Letter Changes Caused by Addition of Second Drive with Primary Partition

Drive	Partition Type	Order	Original drive letter(s) (first drive only)	New drive letter(s) after adding second drive
1st	Primary	1st	C:	C:
1st	Extended	3rd	D:, E:	E:, F:
2nd	Primary	2nd		D:
2nd	Extended	4th		G:, H:

After adding the second drive, the original drive letters D: and E: have now become E: and F:. The primary partition on the new drive has become D:, and the extended partition volumes on the second drive are G: and H:. Confused? Well you better not be or you'll find yourself deleting or copying data to or from the wrong drive.

This principle extends to third and fourth physical drives as well: the primary partitions on each drive get their drive letters first, followed by logical DOS drives in the extended partitions.

One way to affect this is to only partition additional drives with extended partitions, in other words, do not create primary partitions on them. That way the new drive's partitions will be seen only as additional letters, and the letters used by the first drive's partitions will remain unchanged.

If you're *adding* a drive to your system, you should now understand why preparing that second, third, or fourth drive with a primary partition is a bad idea. If you're installing an additional hard drive (not a replacement), remember that it can't be a bootable drive. If it can't be bootable, there's no reason to make it a primary partition. FDISK will allow you to create an extended partition using 100 percent of the space on any drive. Table 14.3 shows the same example used in the Table 14.2 with the second drive installed as an extended partition:

Table 14.3 Drive Letter Allocations after Addition of Second Drive with Extended Partition Only

Drive	Partition Type	Order	Original drive letter(s) (first drive only)	New drive letter(s) after adding second drive
1st	Primary	1st	C:	C:
1st	Extended	3rd	D:, E:	D:, E:
2nd	Primary	2nd	—	—
2nd	Extended	4th		F:

When a new drive is added with only extended partition volumes, then you can see that the original drive letters remain undisturbed. This is a much easier to understand arrangement, and prevents accidents with data due to drive letters changing. This operating-system behavior also explains why some of the first computers with IDE-based (ATAPI) Iomega Zip drives had the Zip drive as D:, with a single hard disk identified as C: and E;; the Zip drive was treated as the second hard drive with a primary partition.

Drive Partitioning with Partition Magic

PowerQuest's Partition Magic allows you to take an existing hard drive and perform the following changes to it without loss of data:

- Change primary partition size (larger or smaller)
- Turn empty space on hard drive into additional drive letters
- Convert the inefficient FAT16 partition type into efficient FAT32 on systems with Windows 95B or Windows 98
- Move programs to new drive letters created with PM and change registry keys and other information automatically

Note

As mentioned earlier in the chapter, the CD accompanying this book contains the Que edition of Partition Magic. I still recommend FDISK be used for initial partitioning and setup of any drive, but Partition Magic can be very useful for reconfiguring a system that is already partitioned.

While the program recommends a full backup before starting, I've used Partition Magic many times to turn a single "big drive" into two or more drive letters in less than 10 minutes. Performing the same task with backup software and FDISK/FORMAT can take several hours.

High-Level (Operating System) Formatting

The final step in the installation of a hard disk drive is the high-level format. Like the partitioning process, the high-level format is specific to the file system you've chosen to use on the drive. On Windows 9x and DOS systems, the primary function of the high-level format is to create a FAT and a directory system on the disk so the operating system can manage files. You must run FDISK before formatting a drive. Each drive letter created by FDISK must be formatted before it can be used for data storage.

Usually, you perform the high-level format with the FORMAT.COM program or the formatting utility in Windows 9x Explorer. FORMAT.COM uses the following syntax:

```
FORMAT C: /S /V
```

This command high-level formats drive C:, writes the hidden operating system files in the first part of the partition, and prompts for the entry of a volume label to be stored on the disk at the completion of the process.

The FAT high-level format program performs the following functions and procedures:

1. Scans the disk (read only) for tracks and sectors marked as bad during the LLF, and notes these tracks as being unreadable.
2. Returns the drive heads to the first cylinder of the partition, and at that cylinder (Head 1, Sector 1) writes a DOS volume boot sector.
3. Writes a FAT at Head 1, Sector 2. Immediately after this FAT, it writes a second copy of the FAT. These FATs essentially are blank except for bad-cluster marks noting areas of the disk that were found to be unreadable during the marked-defect scan.
4. Writes a blank root directory.
5. If the /S parameter is specified, copies the system files, IO.SYS and MSDOS.SYS (or IBM-BIO.COM and IBMDOS.COM, depending on which DOS you run) and COMMAND.COM to the disk (in that order).
6. If the /V parameter is specified, prompts the user for a volume label, which is written as the fourth file entry in the root directory.

Now, the operating system can use the disk for storing and retrieving files, and the disk is a bootable disk.

During the first phase of the high-level format, the program performs a marked defect scan. Defects marked by the LLF operation show up during this scan as being unreadable tracks or sectors. When the high-level format encounters one of these areas, it automatically performs up to five retries to read these tracks or sectors. If the unreadable area was marked by the LLF, the read fails on all attempts.

After five retries, the DOS FORMAT program gives up on this track or sector and moves to the next one. Areas that remain unreadable after the initial read and the five retries are noted in the FAT as being bad clusters.

Note

Because the high-level format doesn't overwrite data areas beyond the root directory of the hard disk, it's possible to use programs such as Norton Utilities to unformat the hard disk that contains data from previous operations, provided no programs or data has been copied to the drive after high-level formatting. Unformatting can be performed because the data from the drive's previous use is still present.

If you create an extended partition, the logical DOS drive letters found there need a simpler FORMAT command, because system files aren't necessary. For example, `FORMAT D: /V` for drive D; `FORMAT E: /V` for drive E; etc.

FDISK and FORMAT Limitations

The biggest problem with FDISK is that it is destructive. If you change your mind about disk structure, you must back up your system and start over again. That alone is cause for using FDISK with care, but there are other limitations you should keep in mind:

- FDISK doesn't provide any help with issues of drive letter changes.
- FDISK requires FORMAT before the drive is ready for use.
- FORMAT must check the entire drive before making it ready for use. Its error management is rudimentary and can waste a lot of disk space with older drives that have disk errors.
- FDISK and FORMAT are designed for a single operating system environment, with no provision for multiboot options (Windows 9x and NT or Windows 9x and Linux, for example).
- FDISK and FORMAT offer no procedure for migrating data to a new drive, and XCOPY is tricky to use
- FDISK and FORMAT might cause conflicts with existing CD-ROM drives, which often use the next available drive letter after the existing hard drive

For these reasons, many drive vendors offer some sort of automatic disk installation software with their hard drives. These routines can make the task of disk migration a fast, easy, reliable operation.

Typical features of automatic disk installation programs include the following:

- *Replacement for FDISK and FORMAT.* A single program performs both functions more quickly than FDISK and FORMAT separately
- *Database of drive jumpers for major brands and models*

- *Drive copy function.* Copies contents of old MS-DOS or Windows 9x drive to new drive, retaining long filenames, file attributes, etc.
- *CD-ROM drive letter relocation utility.* Moves CD-ROM to new drive letter (to make room for new hard drive letters) and resets Windows Registry and INI file references to new drive letter so CD-ROM software works without reinstallation
- *Menu-driven or wizard-driven process for installing new hard drive*
- *Optional override of BIOS limitations for installation of large hard drives (>504MB, 2.1GB, 8.4GB, etc.)*

The two major vendors in the automated disk-utility business are Ontrack Data International, Inc. and StorageSoft. These companies sell their disk-installation products to OEM hard drive vendors for use with particular brands of drives. They also sell to the public “generic” versions that can be purchased for use with any brand or model of hard disk. Table 14.4 provides a basic overview of the most popular disk installation programs.

Table 14.4 Overview of Automatic Disk-Installation Programs

Vendor	Software	Current Version	OEM	Retail
Ontrack	Disk Manager	9.xx	Yes	Yes
	Disk Manager DiskGo!	2.5x	Yes	Yes
	StorageSoft	EZ Drive	9x	Yes
	DrivePro	3.x	No	Yes
Seagate ¹	DiscWizard	2.4x	Yes	No
Maxtor ²	MaxBlast!	9.x	Yes	No

1 Seagate's DiscWizard was codeveloped with Ontrack, and contains Ontrack Disk Manager v9.x.

2 Maxtor's MaxBlast! Software v9.x is a customized version of EZ-Drive. Version 7.x and 8.x of MaxBlast! were customized versions of Ontrack's Disk Manager

Disk Manager and EZ-Drive are DOS-based utility programs, whereas DiscWizard and Disk Manager DiskGo! offer a Windows-like interface. Seagate's DiscWizard actually analyzes the system, asks the user questions about the intended installation, and prepares a customized procedure based on the user's responses.

OEM versions of disk-installation programs are available from the drive makers' Web sites; retail versions usable with any combination of drives can be purchased from retail stores or at the vendors' online stores.

Replacing an Existing Drive

Previous sections discuss installing a single hard drive or adding a new hard drive to a system. While formatting and partitioning a new hard disk can be challenging, replacing an existing drive and moving your programs and files to it can be a lot more challenging.

Drive Migration for MS-DOS Users

When MS-DOS 6.x was dominant, many users used this straightforward method to transfer the contents of their old hard drive to their new hard drive:

1. The user created a bootable disk containing FDISK, FORMAT, and XCOPY.
2. The new hard drive was prepared with a primary partition (and possibly an extended partition, depending on the user's desires).
3. The new hard drive was formatted with system files, although the operating system identified it as D:.
4. The XCOPY command was used to transfer all non-hidden files from C:\ (the old hard drive) to D:\ thus:

```
XCOPY C:\ D:\ /S/E
```

The XCOPY command also was used as necessary to transfer files from any remaining drive letters on the old hard drive to the corresponding drive letters on the new drive.

Because the only hidden files such a system would have were probably the operating system boot files (already installed) and the Windows 3.1 permanent swap file (which could be recreated after restarting Windows), this "free" data transfer routine worked well for many people.

After the original drive was removed from the system, the new drive would be jumpered as master and assigned C:. You will need to run FDISK from a floppy and set the primary partition on the new C: drive as Active. Then exit FDISK and the drive will boot.

Drive Migration for Windows 9x Users

Windows 95 and 98 have complicated the once simple act of data transfer to a new system by their frequent use of hidden files and folders (such as \Windows\Inf, where Windows 9x hardware drivers are stored). The extensive use of hidden files was a major reason for a greatly enhanced version of XCOPY to be included in Windows 9x.

Note

XCOPY32 is automatically used in place of XCOPY when XCOPY is started within a DOS session under Windows.

XCOPY32 for Windows 9x Data Transfer

Compared to "classic" XCOPY, XCOPY32 can copy hidden files; can preserve file attributes such as system, hidden, read-only, and archive; can automatically create folders, and is compatible with long filenames. Thus, it is possible to use it to duplicate an existing drive, but with these cautions:

1. The XCOPY32 command is much more complex.
2. There may be errors during the copy process because of Windows' use of temporary files during normal operation, but XCOPY32 can be forced to continue.

This command line will call XCOPY32 and transfer all files and folders with their original attributes intact from the original drive (C:) to the new drive (D:). This command must be run from an MS-DOS session under Windows 95 or 98.

```
xcopy32 c:\. d:\ /e/c/h/r/k
```

The command switches are explained here:

- /E. Copies folders, even if empty, also copies all folders beneath the starting folder
- /C. Continues to copy after errors (The Windows swap file can't be copied due to being in use.)
- /H. Copies hidden and system files
- /R. Overwrites read-only files
- /K. Preserves file attributes

Repeat the command with appropriate drive-letter changes for any additional drive letters on your old drive.

After the original drive is removed from the system, the new drive needs to be jumpered as master (or single) and the operating system will assign it C:. You will need to run FDISK from a floppy and set the primary partition on the new C: drive as Active. Then exit FDISK, and the drive will boot.

Note that although the XCOPY method has worked for me, some people have problems with it. A much more automated and easy approach to cloning drives is to use commercial software designed for that purpose, such as Drive Copy by PowerQuest or Norton Ghost by Symantec.

While many users have prepared new hard drives for use with nothing but FDISK and FORMAT, today's more complex systems are presenting increasingly good reasons for looking at alternatives.

Hard Disk Drive Troubleshooting and Repair

If a hard drive has a mechanical problem inside the sealed HAD (head disk assembly), repairing the drive is usually not feasible. It may be doable, but financially it will be far less expensive to purchase a new drive. If the failure is in the logic board, that board can be replaced with one from a donor drive. Normally this is done only for the purposes of reading the information on the failed drive, because you will have to purchase a complete second drive to cannibalize for the logic board. None of the drive manufacturers normally sell spare parts for their drives anymore.

Most hard disk drive problems are not mechanical hardware problems; instead, they are "soft" problems that can be solved by a new LLF and defect-mapping session. Soft problems are characterized by a drive that sounds normal but produces various read and write errors.

Hard problems are mechanical, such as when the drive sounds as though it contains loose marbles. Constant scraping and grinding noises from the drive, with no reading or writing capability, also qualify as hard errors. In these cases, it is unlikely that an LLF will put the drive back into service. If a hardware problem is indicated, first replace the logic-board assembly. You can make this repair yourself and, if successful, you can recover the data from the drive.

If replacing the logic assembly does not solve the problem, contact the manufacturer or a specialized repair shop that has clean-room facilities for hard disk repair. (See the Vendor's List on the CD for a list of drive manufacturers and companies that specialize in hard disk drive repair.) Because of the costs, it will probably be more economical to simply purchase a new drive.

Testing a Drive

When accessing a drive, it is easy to tell if the drive has been partitioned and formatted properly. A simple test will tell you if a stored drive is in its "raw" condition or has been partitioned and formatted properly. These tests work best if you have a boot disk available and if the spare hard drive is the only hard drive attached.

First, attach the drive to your system. If you can attach power and data cables to it, you need not install it into a drive bay unless you are planning to use it immediately. If the drive will be run loose, I recommend placing it on a non-conductive foam pad or other soft surface. This will insulate the drive from potential shocks and other hazards. After detecting the drive in the BIOS and saving the changes, start your operating system from the boot disk.

Then, from the A: prompt, enter the following command:

```
DIR C:
```

This will produce one of the following responses:

- *Invalid Drive Specification.* This indicates the drive does not have a valid partition (created by FDISK), or that the existing Master Boot Sector or partition tables have been damaged. No matter what, the drive must be partitioned and FORMATTed before use. You will also get this warning on a FAT32 or NTFS partitioned drive if you use a Windows 95 (original version) or MS-DOS boot disk when checking. Use a Windows 95B, Windows 98, or Windows 2000 boot disk to avoid this false message from FAT32 partitions. Or use a Windows NT or Windows 2000 boot disk to detect NTFS partitions.
- *Invalid media type.* This drive has been partitioned but not FORMATTed, or the format has been corrupted. You will want to use FDISK's #4 option to examine the drive's existing partitions, and either delete them and create new ones or keep the existing partitions and run FORMAT on each drive letter.
- *Directory of C:....* The contents of C: drive are listed, indicating the drive was stored with a valid FDISK and FORMAT structure and data.

Installing an Optical Drive (CD-ROM, CD-R)

Installation of a CD-ROM or DVD-ROM drive can be as difficult or as easy as you make it. If you plan ahead, the installation should go smoothly.

This section walks you through the installation of a typical internal (SCSI or IDE) and external (SCSI only) optical drive, with tips that often aren't included in the manufacturer's installation manuals. After you install the hardware, your job may be finished if you are running Windows 9x and using a Plug-and-Play drive, or you may have to manually load the software needed to access the drive.

Note

CD-ROM and DVD-ROM drives use the same IDE and SCSI system interfaces and can be installed using the same basic procedures. Some DVD-ROM drives come with an MPEG-2 decoder board that enables you to view DVD movies and video on your PC. This board installs in a PCI bus slot like any other expansion card and performs the video decoding process that would otherwise fall to the system processor.

Avoiding Conflict: Get Your Cards in Order

Regardless of the type of installation—internal or external drive—you must have a functioning IDE or SCSI host adapter before the drive can function. In most cases, you will be connecting the optical drive to an existing IDE or SCSI adapter. If so, the adapter should already be configured not to conflict with other devices in your system. All you have to do is connect the drive with the appropriate cable and proceed from there.

Most computers today have an IDE adapter integrated into the motherboard. However, if you are adding SCSI to your system for the first time, you must install a SCSI host adapter into an expansion slot and make sure it is configured to use the appropriate hardware resources, such as the following:

- IRQ
- DMA channel
- I/O port address

As always, Windows 9x and PnP hardware can completely automate this process, but if you're using another operating system, you may have to configure the adapter manually.

Drive Configuration

Configuration of your new optical drive is paramount to its proper functioning. Examine your new drive (see Figure 14.4) and locate any jumpers. For an IDE drive, here are the typical ways to jumper the drive:

- As the primary (master) drive on the secondary IDE connection
- As the secondary (slave) drive to a current hard disk drive

If the drive is to be the only device on your secondary EIDE interface, the factory settings are usually correct. Consult the manual to make sure this is so.

When you use the CD-ROM or DVD-ROM as a secondary drive—that is, the second drive on the same ribbon cable with another device—make sure it is jumpered as the slave drive, and configure the other device so it is the master drive (see Figure 14.5). In most cases, the drive will show up as the next logical drive, or the D: drive.

Caution
