Packet Level I/O under Release 2

by Dale Larson and John Orr

Normally when an application needs to perform I/O using DOS, it uses functions from the *dos.library* to open, read, write, and close any I/O channels. These functions take care of talking to the underlying DOS device (see the ‘‘About Devices’’ section below), shielding the programmer from most of the grunt work it takes to carry out the I/O. These functions are adequate for most I/O needs.

One of the reasons these functions are only adequate is because they are synchronous. When an application attempts to transfer data using one of these functions, the I/O function waits for the entire transfer to finish before returning. Ideally, the application should be able to perform I/O asynchronously, so it can do something else while the data transfer takes place.

Another reason that these functions are only adequate is because they don’t implement all of the features built into DOS devices. To utilize these features, an application has to work on a lower level. The application has to talk directly to the DOS device.

About ‘‘Devices’’

The term ‘‘DOS devices’’ is confusing because the term ‘‘device’’ is a bit overloaded. There are three entities on the Amiga that are referred to as a device. There is the Exec device (for example trackdisk.device and console.device) the AmigaDOS device (such as DF0: and RAM:), and the logical AmigaDOS device name (for example, SYS:, C:, and S:). The Exec level device is basically a subset of an Exec library. Exec devices are described in the *RKRM: Devices* book. The AmigaDOS device is a higher level entity than the Exec device (AmigaDOS devices often utilize Exec devices). An AmigaDOS device has a process associated with it, normally referred to as a handler, that controls the AmigaDOS I/O stream via a FileHandle. The AmigaDOS logical device name (better known as an ‘‘assign’’) is made to look like an AmigaDOS device, but is a higher level entity than the AmigaDOS device. Both the AmigaDOS device and the logical device name are referred to by a name ending in a colon (':'). The logical device can refer to any directory on an AmigaDOS device (as long as the AmigaDOS device supports having files). The user can change the directory to which logical device name refers from a command line. This article deals primarily with AmigaDOS devices.

The Packet Level

When DOS functions talk to devices such as the floppy drive or the serial port, they talk to a special process called a *handler*. Every DOS device (like CON:, SER:, DF0:, and PIPE:) has a handler process. The handler process is responsible for receiving and carrying out a standard set of DOS device commands. It provides a standard programming interface to a lower-level I/O software or hardware entity (such as an Exec device). The packet interface abstracts the lower-level entity so that *dos.library* functions don't have to deal with a lot of bothersome details such as moving a disk head or reading serial registers. The interface to every handler is the same, so every DOS device operates in the same manner, regardless of any underlying software or hardware. Theoretically, to the *dos.library* functions, writing to the console handler (CON:) should be no different than writing to the serial port handler (SER:) or the DF0: handler. The handler lets *dos.library* functions treat all DOS devices in the same way.

Typically, the handler talks directly to an underlying Exec device. Two examples are the CON: and the DF0: handlers. The CON: handler process talks directly to the console.device. When trying to access a floppy in DF0:, the DF0: handler talks directly to the trackdisk.device. These handlers accept handler level commands (for example, `ACTION_READ` and `ACTION_WRITE`) and hide any Exec level I/O from the *dos.library* functions and subsequently, the application.

In cases like the DF0: handler, which is a special type of handler called a file system, the handler has to take care of organizing the lower-level medium into directories and files. The DF0: handler takes care of translating directory and file names into terms the trackdisk.device can understand (disk blocks). The only requirement of a handler to be a file system is that the handler must support files. A file system does not have to support a directory structure to be considered a file system. Handlers which are not file systems are called stream handlers.

Some handlers do not have any underlying software or hardware. Handlers such as RAM: have no underlying software or hardware. These kinds of handlers take care of implementing everything necessary to carry out the I/O rather than delegating to an Exec device.

Handlers receive commands through an Exec message port. Every handler process has a message port for receiving commands. A handler accepts a command in the form of a DosPacket structure (defined in <*dos/dosextens.h*>), which is an extension of an Exec Message structure:

```
struct DosPacket {
   struct Message *dp_Link;
   struct MsgPort *dp_Port;  /* Reply port for the packet */
                             /* Must be filled in each send. */
   LONG dp_Type;
   LONG dp_Res1;             /* Result #1 */
   LONG dp_Res2;             /* For file system calls this is what would
                              * have been returned by IoErr() */
   LONG dp_Arg1;             /* Argument list */
   LONG dp_Arg2;
   LONG dp_Arg3;
   LONG dp_Arg4;
   LONG dp_Arg5;
   LONG dp_Arg6;
   LONG dp_Arg7;
}; /* DosPacket */
```

The dp_Type field contains an identifier corresponding to the command. The identifiers for each of the standard commands are defined in *<dos/dosextens.h>*. For example, the command to write data is `ACTION_WRITE`. Each packet type has different parameters, which the programmer supplies in the ‘‘dp_Arg’’ fields.

After a handler finishes with a packet, it returns the packet to the message port in dp_Port. The handler places return values (including any error codes) in the result fields dp_Res1 and dp_Res2. If there was an error, dp_Res2 contains the corresponding DOS error code.

The packet types are described in the Amiga Mail article ‘‘AmigaDOS Packet Interface Specification’’ on page II-5 and also in *The AmigaDOS Manual, 3rd Edition.* Since its original publication, the ‘‘AmigaDOS Packet Interface Specification’’ has been updated numerous times in Amiga Mail to correct errors. The information in that article (plus its errata) should appear in the next edition of *The AmigaDOS Manual*.

Finding the Handler

There are various ways to find the address of the target handler’s Message port, which is also called a process identifier by some documentation. When working with an open FileHandle, the handler’s port address is in the FileHandle’s fh_Type field. Note that the *dos.library* functions normally access a FileHandle using a BPTR, so to get to the fh_Type field an application has to do something like this:

```
my_handler_port = ((struct FileHandle *)BADDR(FileHandle))->fh_Type);
```

Because the AmigaDOS device NIL: has no handler process, the fh_Type field of any of its file handle’s will be NULL. The application must account for this case.

When working with a device or assign name, an application can get to the handler’s message port by using the *dos.library* function GetDeviceProc():

```
struct DevProc *GetDeviceProc(UBYTE *dev_name, struct DevProc *prev_devproc);
```

This function returns a pointer to the following structure:

```
struct DevProc {
        struct MsgPort *dvp_Port;     /* The handler’s Message port     */
        BPTR            dvp_Lock;     /*           (send packets there) */
        ULONG           dvp_Flags;
        struct DosList *dvp_DevNode;  /* DON’T TOUCH OR USE! */
};
```

This function is intended to improve on the DeviceProc() function as it also deals with multiple assigns. GetDeviceProc() must be countered by FreeDeviceProc(). See the GetDeviceProc() Autodoc for more details.

The Old Way

Prior to Release 2, sending packets was relatively complicated. Some of the early disks from the Fred Fish Library (disks 35, 56, and 66) contain complete examples of using DOS packets synchronously and asynchronously. As of Release 2.04, *dos.library* contains functions which make it easier to use DOS packets synchronously and asynchronously.

Synchronous Packet Calls

Performing synchronous packet I/O is now very simple. Simply call the *dos.library* function DoPkt():

```
LONG DoPkt(struct MsgPort *handler_port, LONG action_id, LONG arg1,
           LONG arg2, LONG arg3, LONG arg4, LONG arg5);
```

This function allocates and fills out a DosPacket using the packet type ('action_id') and arguments ('arg1', 'arg2', etc.) you supply. This function then sends off the packet to the 'handler_port' and waits for the packet to return. DoPkt() returns the value from the packet's dp_Res1 field. To get the value from the packet's dp_Res2 field, call the *dos.library* function IoErr(). Assembly language programmers can also get dp_Res2 from register D1.

Asynchronous Packet Calls

To do asynchronous packet calls, things are a little more complex, but they are still much better than they were before V37 (This subject was partially covered in Martin Taillefer's article, ''Fast AmigaDOS I/O'', page II-77, from the September/October 1992 issue of *Amiga Mail*). When using a DOS packet asynchronously, there are three things to do before sending the packet anywhere:

- ❏ Acquire a message port
- ❏ Allocate and initialize the packet
- ❏ Set up the packet's arguments

Acquiring the Message Port

It is possible for an application to use its process message port for packet transmissions rather than allocating a new one. It can get to its Process structure by calling FindTask() with an argument of NULL. The Process structure has an Exec MsgPort structure embedded in it, which an application can get to via the pr_MsgPort field. The bad thing about using this port is that many system functions also use it. Consequently, after sending an asynchronous packet, an application can not call any system functions that use pr_MsgPort. This includes most *dos.library* functions, many C compiler linker library functions, and many standard I/O functions (i.e., printf() and scanf()). The application has to wait for the asynchronous packet to return before calling such functions. If the application sent an asynchronous packet and inadvertently initiated some other packet level I/O

before the asynchronous packet came back, it is possible to cause an ‘‘unexpected packet received’’ system crash if the asynchronous packet returned at the wrong time. Also, an application should remove such a packet from the process message port using the WaitPkt() function. This function will take care of any system idiosyncrasies that the application would otherwise need to address itself. This applies to idiosyncrasies that exist now or new ones that may appear in the future.

As of V37, arguably the best and easiest way to acquire a message port is to create one with the *exec.library* call CreateMsgPort(). By allocating its own message port, the application doesn't have to worry about any problems with sharing the port.

Allocating and Initializing a Packet

The packet I/O system uses Exec's message passing system, so each DosPacket must also have an Exec Message structure. As both structures are necessary, they have been combined in a single StandardPacket structure (defined in *<dos/dosextens.h>*):

```
struct StandardPacket {
   struct Message   sp_Msg;
   struct DosPacket sp_Pkt;
}; /* StandardPacket */
```

To make a packet usable, the Exec Message and DosPacket structures have to be set up to point to each other. The DosPacket structure is straightforward about its link to its corresponding message. The DosPacket's dp_Link field must point to the packet's Message structure. However, the link from the Message to the DosPacket is a bit obscure. The Message contains an Exec Node structure which in turn contains a field called ln_Name. Although the Node structure defines ln_Name as a character array, the DOS packet I/O system instead requires that this field point to the Message's corresponding DosPacket:

```
my_standard_pkt->sp_Msg.mn_Node.ln_Name = (STRPTR)(my_standard_pkt->sp_Pkt);
```

As of V37, the *dos.library* function AllocDosObject() is usually the best way to allocate a StandardPacket. To allocate one, call:

```
mypacket = AllocDosObject(DOS_STDPKT, NULL);
```

This function takes care of linking the StandardPacket's Message and DosPacket. Note that the function call above does not return a pointer to a StandardPacket. This function allocates an entire StandardPacket structure, but it returns a pointer to the StandardPacket's sp_Pkt field. To access the sp_Msg portion of the StandardPacket, use the pointer in the dp_Link field.

Any structure allocated with AllocDosObject() must be freed with FreeDosObject(). To free 'mypacket' from the above AllocDosObject() call:

```
FreeDosObject(DOS_STDPKT, mypacket);
```

Filling in Packet Arguments

Before sending an asynchronous packet, an application needs to fill in its action and arguments. For example, a packet set up to read 4096 bytes from an open file handle might look something like this:

```
. . .

#define BUFSIZE 4096

. . .

BPTR myfh;
struct DosPacket *my_pkt;
UBYTE *buffer[BUFSIZE];

        . . .

        my_pkt->dp_Type = ACTION_READ;
        my_pkt->dp_Arg1 = ((struct FileHandle *)BADDR(myfh))->fh_Arg1;
        my_pkt->dp_Arg2 = buffer;
        my_pkt->dp_Arg3 = BUFSIZE;

        . . .
```

Sending the Asynchronous Packet

To send a packet asynchronously, use the *dos.library* SendPkt() function:

```
SendPkt(struct DosPacket *mypacket,
        struct MsgPort *handlerport, struct MsgPort *replyport)
```

This function sends 'mypacket' to 'handlerport' and exits without waiting for the packet to come back. When the packet returns, it will arrive at 'replyport'.

Waiting for the Asynchronous Packet

After calling SendPkt(), the application can go about its business, taking care of some other work while the DOS device handles the application's packet. Eventually, the application will have to test the reply port to see if the packet has come back yet. It can do this with WaitPort() or, if the application has to test for more than just the reply port's signal, it can use Wait(). If the application doesn't poll its signals too often, it can test its own signal bits using SetSignal() (see the *exec.library* Autodocs and the ''Introduction to Exec'' chapter of the Release 2 *RKRM: Devices* for more information on how to use these functions). Be sure to remove any and all packets from the message port using GetMsg().

If the application used its process message port (pr_MsgPort) as the reply port, it must use the WaitPkt() function to remove the packet from the message port. As mentioned earlier, this function will take care of any hidden system idiosyncrasies so the application never has to account for them. WaitPkt() will not necessarily clear the process message port's signal bit. Like SendPkt(), WaitPkt() assumes any DosPacket it works with is part of a StandardPacket structure.

The *dos.library* contains a function called AbortPkt() that, at a glance, looks like it might be useful to an application that needs to abort a packet (for example, upon receiving a break signal). This function, which was introduced in Release 2, is supposed to attempt to abort a packet that has already been sent to a handler. If the abort operation is successful, the aborted packet will arrive at its original reply port (the same place the packet would have arrived if it was successful). Unfortunately, the abort operation will never be successful, at least not under existing releases of the operating system. Currently, this function returns without doing anything (the most recent release is 3.0 or V39). In the future when AbortPkt() does do something, it will assume that any DosPacket it works with is part of a StandardPacket structure.

Interpreting the Packet Results

Upon returning to the application, for most packets, there will be result values in dp_Res1 and dp_Res2. For most packets, if dp_Res1 is `DOSTRUE`, the packet returned without a problem. If dp_Res1 is `DOSFALSE`, the handler experienced an error with the packet and there should be an error code in dp_Res2. The error codes are defined in <*dos/dos.h*>. Note that not all packets follow this error reporting convention. See the ''AmigaDOS Packet Interface Specification'' article on page II-5 for more information on how individual packets work.

Packets without dos.library Functions

Besides offering the ability to do asynchronous I/O, directly using DOS packets also allows applications to utilize features of certain handlers that are not available through a *dos.library* function.

The following packets are not available via a *dos.library* function as of Release 3.0:

```
ACTION_WRITE_PROTECT    ACTION_DISK_INFO (for console handlers)
```

If an application needs the feature that these packets provide, the application has to send the packet to the handler. The first two packets are fairly straightforward and are explained in the ''AmigaDOS Packet Interface Specification'' article on page II-5 of *Amiga Mail*.

The ACTION_DISK_INFO packet is peculiar because its function changes depending on the handler. When sent to a file system handler, it returns information about its media. The *dos.library* function Info() uses this packet. The ACTION_DISK_INFO packet has a different meaning to a console handler. When a console handler receives this packet, it returns a pointer to the window of the open console file handle. When an application needs this pointer, the only way to get it as of Release 3.0 is to send the console handler this packet.

There are two commonly used packets that an application could not call through a *dos.library* function under 1.3 that now have corresponding *dos.library* functions. The packet to rename a disk, ACTION_RENAME_DISK, is now available through the *dos.library* function Relabel(). Also the ACTION_SCREEN_MODE packet acquired a *dos.library* function, SetMode().

About the Examples

Two examples accompany this article. The first, *CompareIO.c*, uses packet level I/O to copy the standard input channel to the standard output channel (as set up by the standard startup code, *c.o*). *CompareIO* uses both synchronous and asynchronous I/O to perform the copy and reports the time it takes to do each. The other example, *InOutCTRL-C.c*, also uses packets to copy the standard input channel to the standard output channel, but it only uses asynchronous I/O. The second example does a better job checking for a user break.
