

GNU Readline Library

Edition 2.0, for Readline Library Version 2.0.
July 1994

Brian Fox, Free Software Foundation
Chet Ramey, Case Western Reserve University

This document describes the GNU Readline Library, a utility which aids in the consistency of user interface across discrete programs that need to provide a command line interface.

1 Command Line Editing

This chapter describes the basic features of the GNU command line editing interface.

1.1 Introduction to Line Editing

The following paragraphs describe the notation used to represent keystrokes.

The text **C-K** is read as ‘Control-K’ and describes the character produced when the Control key is depressed and the **K** key is struck.

The text **M-K** is read as ‘Meta-K’ and describes the character produced when the meta key (if you have one) is depressed, and the **K** key is struck. If you do not have a meta key, the identical keystroke can be generated by typing **ESC** *first*, and then typing **K**. Either process is known as *metafying* the **K** key.

The text **M-C-K** is read as ‘Meta-Control-k’ and describes the character produced by *metafying* **C-K**.

In addition, several keys have their own names. Specifically, **DEL**, **ESC**, **LFD**, **SPC**, **RET**, and **TAB** all stand for themselves when seen in this text, or in an init file (see Section 1.3 [Readline Init File], page 4, for more info).

1.2 Readline Interaction

Often during an interactive session you type in a long line of text, only to notice that the first word on the line is misspelled. The Readline library gives you a set of commands for manipulating the text as you type it in, allowing you to just fix your typo, and not forcing you to retype the majority of the line. Using these editing commands, you move the cursor to the place that needs correction, and delete or insert the text of the corrections. Then, when you are satisfied with the line, you simply press **RETURN**. You do not have to be at the end of the line to press **RETURN**; the entire line is accepted regardless of the location of the cursor within the line.

1.2.1 Readline Bare Essentials

In order to enter characters into the line, simply type them. The typed character appears where the cursor was, and then the cursor moves one space to the right. If you mistype a character, you can use your erase character to back up and delete the mistyped character.

Sometimes you may miss typing a character that you wanted to type, and not notice your error until you have typed several other characters. In that case, you can type **C-B** to move the cursor to the left, and then correct your mistake. Afterwards, you can move the cursor to the right with **C-F**.

When you add text in the middle of a line, you will notice that characters to the right of the cursor are ‘pushed over’ to make room for the text that you have inserted. Likewise, when you delete text behind the cursor, characters to the right of the cursor are ‘pulled back’ to fill in the blank space created by the removal of the text. A list of the basic bare essentials for editing the text of an input line follows.

C-B	Move back one character.
C-F	Move forward one character.
DEL	Delete the character to the left of the cursor.
C-D	Delete the character underneath the cursor.
Printing characters	
	Insert the character into the line at the cursor.
C-_	Undo the last thing that you did. You can undo all the way back to an empty line.

1.2.2 Readline Movement Commands

The above table describes the most basic possible keystrokes that you need in order to do editing of the input line. For your convenience, many other commands have been added in addition to **C-B**, **C-F**, **C-D**, and **DEL**. Here are some commands for moving more rapidly about the line.

C-A	Move to the start of the line.
C-E	Move to the end of the line.
M-F	Move forward a word.
M-B	Move backward a word.

C-L Clear the screen, reprinting the current line at the top.

Notice how **C-F** moves forward a character, while **M-F** moves forward a word. It is a loose convention that control keystrokes operate on characters while meta keystrokes operate on words.

1.2.3 Readline Killing Commands

Killing text means to delete the text from the line, but to save it away for later use, usually by *yanking* (re-inserting) it back into the line. If the description for a command says that it ‘kills’ text, then you can be sure that you can get the text back in a different (or the same) place later.

When you use a kill command, the text is saved in a *kill-ring*. Any number of consecutive kills save all of the killed text together, so that when you yank it back, you get it all. The kill ring is not line specific; the text that you killed on a previously typed line is available to be yanked back later, when you are typing another line.

Here is the list of commands for killing text.

C-K Kill the text from the current cursor position to the end of the line.

M-D Kill from the cursor to the end of the current word, or if between words, to the end of the next word.

M-DEL Kill from the cursor the start of the previous word, or if between words, to the start of the previous word.

C-W Kill from the cursor to the previous whitespace. This is different than **M-DEL** because the word boundaries differ.

And, here is how to *yank* the text back into the line. Yanking means to copy the most-recently-killed text from the kill buffer.

C-Y Yank the most recently killed text back into the buffer at the cursor.

M-Y Rotate the kill-ring, and yank the new top. You can only do this if the prior command is **C-Y** or **M-Y**.

1.2.4 Readline Arguments

You can pass numeric arguments to Readline commands. Sometimes the argument acts as a repeat count, other times it is the *sign* of the argument that is significant. If you pass a negative argument to a command which normally acts in a forward direction, that command will act in a backward direction. For example, to kill text back to the start of the line, you might type **M- - C-K**.

The general way to pass numeric arguments to a command is to type meta digits before the command. If the first ‘digit’ you type is a minus sign (-), then the sign of the argument will be negative. Once you have typed one meta digit to get the argument started, you can type the remainder of the digits, and then the command. For example, to give the **C-D** command an argument of 10, you could type **M-1 0 C-D**.

1.3 Readline Init File

Although the Readline library comes with a set of Emacs-like keybindings installed by default, it is possible that you would like to use a different set of keybindings. You can customize programs that use Readline by putting commands in an *init* file in your home directory. The name of this file is taken from the value of the environment variable **INPUTRC**. If that variable is unset, the default is ‘`~/inputrc`’.

When a program which uses the Readline library starts up, the init file is read, and the key bindings are set.

In addition, the **C-x C-r** command re-reads this init file, thus incorporating any changes that you might have made to it.

1.3.1 Readline Init Syntax

There are only a few basic constructs allowed in the Readline init file. Blank lines are ignored. Lines beginning with a **#** are comments. Lines beginning with a **\$** indicate conditional constructs (see Section 1.3.2 [Conditional Init Constructs], page 7). Other lines denote variable settings and key bindings.

Variable Settings

You can change the state of a few variables in Readline by using the `set` command within the init file. Here is how you would specify that you wish to use `vi` line editing commands:

```
set editing-mode vi
```

Right now, there are only a few variables which can be set; so few, in fact, that we just list them here:

`editing-mode`

The `editing-mode` variable controls which editing mode you are using. By default, Readline starts up in Emacs editing mode, where the keystrokes are most similar to Emacs. This variable can be set to either `emacs` or `vi`.

`horizontal-scroll-mode`

This variable can be set to either `On` or `Off`. Setting it to `On` means that the text of the lines that you edit will scroll horizontally on a single screen line when they are longer than the width of the screen, instead of wrapping onto a new screen line. By default, this variable is set to `Off`.

`mark-modified-lines`

This variable, when set to `On`, says to display an asterisk (*) at the start of history lines which have been modified. This variable is `off` by default.

`bell-style`

Controls what happens when Readline wants to ring the terminal bell. If set to `none`, Readline never rings the bell. If set to `visible`, Readline uses a visible bell if one is available. If set to `audible` (the default), Readline attempts to ring the terminal's bell.

`comment-begin`

The string to insert at the beginning of the line when the `vi-comment` command is executed. The default value is `"#"`.

`meta-flag`

If set to `on`, Readline will enable eight-bit input (it will not strip the eighth bit from the characters it reads), regardless of what the terminal claims it can support. The default value is `off`.

`convert-meta`

If set to `on`, Readline will convert characters with the eighth bit set to an ASCII key sequence by stripping the eighth bit and prepending an `ESC` character, converting them to a meta-prefixed key sequence. The default value is `on`.

`output-meta`

If set to `on`, Readline will display characters with the eighth bit set directly rather than as a meta-prefixed escape sequence. The default is `off`.

completion-query-items

The number of possible completions that determines when the user is asked whether he wants to see the list of possibilities. If the number of possible completions is greater than this value, Readline will ask the user whether or not he wishes to view them; otherwise, they are simply listed. The default limit is 100.

keymap

Sets Readline's idea of the current keymap for key binding commands. Acceptable **keymap** names are **emacs**, **emacs-standard**, **emacs-meta**, **emacs-ctlx**, **vi**, **vi-move**, **vi-command**, and **vi-insert**. **vi** is equivalent to **vi-command**; **emacs** is equivalent to **emacs-standard**. The default value is **emacs**. The value of the **editing-mode** variable also affects the default keymap.

show-all-if-ambiguous

This alters the default behavior of the completion functions. If set to **on**, words which have more than one possible completion cause the matches to be listed immediately instead of ringing the bell. The default value is **off**.

expand-tilde

If set to **on**, tilde expansion is performed when Readline attempts word completion. The default is **off**.

Key Bindings

The syntax for controlling key bindings in the init file is simple. First you have to know the name of the command that you want to change. The following pages contain tables of the command name, the default keybinding, and a short description of what the command does.

Once you know the name of the command, simply place the name of the key you wish to bind the command to, a colon, and then the name of the command on a line in the init file. The name of the key can be expressed in different ways, depending on which is most comfortable for you.

keyname: function-name or macro

keyname is the name of a key spelled out in English. For example:

```
Control-u: universal-argument
Meta-Rubout: backward-kill-word
Control-o: ">&output"
```

In the above example, 'C-u' is bound to the function **universal-argument**, and 'C-o' is bound to run the macro expressed on the right hand side (that is, to insert the text '>&output' into the line).

"keyseq": function-name or macro

keyseq differs from *keyname* above in that strings denoting an entire key sequence can be specified, by placing the key sequence in double quotes.

Some GNU Emacs style key escapes can be used, as in the following example, but the special character names are not recognized.

```
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
"\e[11~": "Function Key 1"
```

In the above example, ‘C-u’ is bound to the function `universal-argument` (just as it was in the first example), ‘C-x C-r’ is bound to the function `re-read-init-file`, and ‘ESC [1 1 ~’ is bound to insert the text ‘Function Key 1’. The following escape sequences are available when specifying key sequences:

```
\C-      control prefix
\M-      meta prefix
\e       an escape character
\\       backslash
\"       "
\'       ,
```

When entering the text of a macro, single or double quotes should be used to indicate a macro definition. Unquoted text is assumed to be a function name. Backslash will quote any character in the macro text, including " and '. For example, the following binding will make C-x \ insert a single \ into the line:

```
"\C-x\\": "\\\""
```

1.3.2 Conditional Init Constructs

Readline implements a facility similar in spirit to the conditional compilation features of the C preprocessor which allows key bindings and variable settings to be performed as the result of tests. There are three parser directives used.

- \$if** The `$if` construct allows bindings to be made based on the editing mode, the terminal being used, or the application using Readline. The text of the test extends to the end of the line; no characters are required to isolate it.
- mode** The `mode=` form of the `$if` directive is used to test whether Readline is in `emacs` or `vi` mode. This may be used in conjunction with the ‘`set keymap`’ command, for instance, to set bindings in the `emacs-standard` and `emacs-ctlx` keymaps only if Readline is starting out in `emacs` mode.

term The **term=** form may be used to include terminal-specific key bindings, perhaps to bind the key sequences output by the terminal's function keys. The word on the right side of the '=' is tested against the full name of the terminal and the portion of the terminal name before the first '-'. This allows *sun* to match both *sun* and *sun-cmd*, for instance.

application

The *application* construct is used to include application-specific settings. Each program using the Readline library sets the *application name*, and you can test for it. This could be used to bind key sequences to functions useful for a specific program. For instance, the following command adds a key sequence that quotes the current or previous word in Bash:

```
$if bash
# Quote the current or previous word
"\C-xq": "\eb"\ef\"
$endif
```

\$endif This command, as you saw in the previous example, terminates an **\$if** command.

\$else Commands in this branch of the **\$if** directive are executed if the test fails.

1.4 Bindable Readline Commands

1.4.1 Commands For Moving

beginning-of-line (C-a)

Move to the start of the current line.

end-of-line (C-e)

Move to the end of the line.

forward-char (C-f)

Move forward a character.

backward-char (C-b)

Move back a character.

forward-word (M-f)

Move forward to the end of the next word. Words are composed of letters and digits.

backward-word (M-b)

Move back to the start of this, or the previous, word. Words are composed of letters and digits.

clear-screen (C-l)

Clear the screen and redraw the current line, leaving the current line at the top of the screen.

redraw-current-line ()

Refresh the current line. By default, this is unbound.

1.4.2 Commands For Manipulating The History

accept-line (Newline, Return)

Accept the line regardless of where the cursor is. If this line is non-empty, add it to the history list. If this line was a history line, then restore the history line to its original state.

previous-history (C-p)

Move ‘up’ through the history list.

next-history (C-n)

Move ‘down’ through the history list.

beginning-of-history (M-<)

Move to the first line in the history.

end-of-history (M->)

Move to the end of the input history, i.e., the line you are entering.

reverse-search-history (C-r)

Search backward starting at the current line and moving ‘up’ through the history as necessary. This is an incremental search.

forward-search-history (C-s)

Search forward starting at the current line and moving ‘down’ through the the history as necessary. This is an incremental search.

non-incremental-reverse-search-history (M-p)

Search backward starting at the current line and moving ‘up’ through the history as necessary using a non-incremental search for a string supplied by the user.

non-incremental-forward-search-history (M-n)

Search forward starting at the current line and moving ‘down’ through the the history as necessary using a non-incremental search for a string supplied by the user.

history-search-forward ()

Search forward through the history for the string of characters between the start of the current line and the current point. This is a non-incremental search. By default, this command is unbound.

history-search-backward ()

Search backward through the history for the string of characters between the start of the current line and the current point. This is a non-incremental search. By default, this command is unbound.

yank-nth-arg (M-C-y)

Insert the first argument to the previous command (usually the second word on the previous line). With an argument *n*, insert the *n*th word from the previous command (the words in the previous command begin with word 0). A negative argument inserts the *n*th word from the end of the previous command.

yank-last-arg (M-., M-_)

Insert last argument to the previous command (the last word on the previous line). With an argument, behave exactly like **yank-nth-arg**.

1.4.3 Commands For Changing Text

delete-char (C-d)

Delete the character under the cursor. If the cursor is at the beginning of the line, there are no characters in the line, and the last character typed was not C-d, then return EOF.

backward-delete-char (Rubout)

Delete the character behind the cursor. A numeric arg says to kill the characters instead of deleting them.

quoted-insert (C-q, C-v)

Add the next character that you type to the line verbatim. This is how to insert key sequences like C-Q, for example.

tab-insert (M-TAB)

Insert a tab character.

self-insert (a, b, A, 1, !, ...)

Insert yourself.

transpose-chars (C-t)

Drag the character before the cursor forward over the character at the cursor, moving the cursor forward as well. If the insertion point is at the end of the line, then this transposes the last two characters of the line. Negative arguments don't work.

transpose-words (M-t)

Drag the word behind the cursor past the word in front of the cursor moving the cursor over that word as well.

upcase-word (M-u)

Uppercase the current (or following) word. With a negative argument, do the previous word, but do not move the cursor.

downcase-word (M-l)

Lowercase the current (or following) word. With a negative argument, do the previous word, but do not move the cursor.

capitalize-word (M-c)

Capitalize the current (or following) word. With a negative argument, do the previous word, but do not move the cursor.

1.4.4 Killing And Yanking

kill-line (C-k)

Kill the text from the current cursor position to the end of the line.

backward-kill-line (C-x Rubout)

Kill backward to the beginning of the line.

unix-line-discard (C-u)

Kill backward from the cursor to the beginning of the current line. Save the killed text on the kill-ring.

kill-whole-line ()

Kill all characters on the current line, no matter where the cursor is. By default, this is unbound.

kill-word (M-d)

Kill from the cursor to the end of the current word, or if between words, to the end of the next word. Word boundaries are the same as **forward-word**.

backward-kill-word (M-DEL)

Kill the word behind the cursor. Word boundaries are the same as **backward-word**.

unix-word-rubout (C-w)

Kill the word behind the cursor, using white space as a word boundary. The killed text is saved on the kill-ring.

delete-horizontal-space ()

Delete all spaces and tabs around point. By default, this is unbound.

yank (C-y)

Yank the top of the kill ring into the buffer at the current cursor position.

yank-pop (M-y)

Rotate the kill-ring, and yank the new top. You can only do this if the prior command is yank or yank-pop.

1.4.5 Specifying Numeric Arguments

`digit-argument (M-0, M-1, ... M--)`

Add this digit to the argument already accumulating, or start a new argument. `M-` starts a negative argument.

`universal-argument ()`

Each time this is executed, the argument count is multiplied by four. The argument count is initially one, so executing this function the first time makes the argument count four. By default, this is not bound to a key.

1.4.6 Letting Readline Type For You

`complete (TAB)`

Attempt to do completion on the text before the cursor. This is application-specific. Generally, if you are typing a filename argument, you can do filename completion; if you are typing a command, you can do command completion, if you are typing in a symbol to GDB, you can do symbol name completion, if you are typing in a variable to Bash, you can do variable name completion, and so on.

`possible-completions (M-?)`

List the possible completions of the text before the cursor.

`insert-completions ()`

Insert all completions of the text before point that would have been generated by `possible-completions`. By default, this is not bound to a key.

1.4.7 Keyboard Macros

`start-kbd-macro (C-x)`

Begin saving the characters typed into the current keyboard macro.

`end-kbd-macro (C-x)`

Stop saving the characters typed into the current keyboard macro and save the definition.

`call-last-kbd-macro (C-x e)`

Re-execute the last keyboard macro defined, by making the characters in the macro appear as if typed at the keyboard.

1.4.8 Some Miscellaneous Commands

re-read-init-file (C-x C-r)

Read in the contents of your init file, and incorporate any bindings or variable assignments found there.

abort (C-g)

Abort the current editing command and ring the terminal's bell (subject to the setting of `bell-style`).

do-uppercase-version (M-a, M-b, ...)

Run the command that is bound to the corresponding uppercase character.

prefix-meta (ESC)

Make the next character that you type be metafied. This is for people without a meta key. Typing 'ESC f' is equivalent to typing 'M-f'.

undo (C-_, C-x C-u)

Incremental undo, separately remembered for each line.

revert-line (M-r)

Undo all changes made to this line. This is like typing the `undo` command enough times to get back to the beginning.

tilde-expand (M-~)

Perform tilde expansion on the current word.

dump-functions ()

Print all of the functions and their key bindings to the readline output stream. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an *inputrc* file.

1.5 Readline vi Mode

While the Readline library does not have a full set of **vi** editing functions, it does contain enough to allow simple editing of the line. The Readline **vi** mode behaves as specified in the Posix 1003.2 standard.

In order to switch interactively between **Emacs** and **Vi** editing modes, use the command M-C-j (`toggle-editing-mode`). The Readline default is **emacs** mode.

When you enter a line in **vi** mode, you are already placed in 'insertion' mode, as if you had typed an 'i'. Pressing **ESC** switches you into 'command' mode, where you can edit the text of the

line with the standard `vi` movement keys, move to previous history lines with ‘`k`’, and following lines with ‘`j`’, and so forth.

2 Programming with GNU Readline

This chapter describes the interface between the GNU Readline Library and other programs. If you are a programmer, and you wish to include the features found in GNU Readline such as completion, line editing, and interactive history manipulation in your own programs, this section is for you.

2.1 Basic Behavior

Many programs provide a command line interface, such as `mail`, `ftp`, and `sh`. For such programs, the default behaviour of Readline is sufficient. This section describes how to use Readline in the simplest way possible, perhaps to replace calls in your code to `gets()` or `fgets()`.

The function `readline()` prints a prompt and then reads and returns a single line of text from the user. The line `readline` returns is allocated with `malloc()`; you should `free()` the line when you are done with it. The declaration for `readline` in ANSI C is

```
char *readline (char *prompt);
```

So, one might say

```
char *line = readline ("Enter a line: ");
```

in order to read a line of text from the user. The line returned has the final newline removed, so only the text remains.

If `readline` encounters an `EOF` while reading the line, and the line is empty at that point, then `(char *)NULL` is returned. Otherwise, the line is ended just as if a newline had been typed.

If you want the user to be able to get at the line later, (with `C-P` for example), you must call `add_history()` to save the line away in a *history* list of such lines.

```
add_history (line);
```

For full details on the GNU History Library, see the associated manual.

It is preferable to avoid saving empty lines on the history list, since users rarely have a burning need to reuse a blank line. Here is a function which usefully replaces the standard `gets ()` library function, and has the advantage of no static buffer to overflow:

```
/* A static variable for holding the line. */
static char *line_read = (char *)NULL;

/* Read a string, and return a pointer to it.  Returns NULL on EOF. */
char *
rl_gets ()
{
    /* If the buffer has already been allocated, return the memory
       to the free pool. */
    if (line_read)
    {
        free (line_read);
        line_read = (char *)NULL;
    }

    /* Get a line from the user. */
    line_read = readline ("");

    /* If the line has any text in it, save it on the history. */
    if (line_read && *line_read)
        add_history (line_read);

    return (line_read);
}
```

This function gives the user the default behaviour of **TAB** completion: completion on file names. If you do not want Readline to complete on filenames, you can change the binding of the **TAB** key with `rl_bind_key ()`.

```
int rl_bind_key (int key, int (*function)());
```

`rl_bind_key ()` takes two arguments: *key* is the character that you want to bind, and *function* is the address of the function to call when *key* is pressed. Binding **TAB** to `rl_insert ()` makes **TAB** insert itself. `rl_bind_key ()` returns non-zero if *key* is not a valid ASCII character code (between 0 and 255).

Thus, to disable the default **TAB** behavior, the following suffices:

```
rl_bind_key ('\t', rl_insert);
```

This code should be executed once at the start of your program; you might write a function called `initialize_readline()` which performs this and other desired initializations, such as installing custom completers (see Section 2.4 [Custom Completers], page 28).

2.2 Custom Functions

Readline provides many functions for manipulating the text of the line, but it isn't possible to anticipate the needs of all programs. This section describes the various functions and variables defined within the Readline library which allow a user program to add customized functionality to Readline.

2.2.1 The Function Type

For readability, we declare a new type of object, called *Function*. A `Function` is a C function which returns an `int`. The type declaration for `Function` is:

```
typedef int Function ();
```

The reason for declaring this new type is to make it easier to write code describing pointers to C functions. Let us say we had a variable called *func* which was a pointer to a function. Instead of the classic C declaration

```
int (*)()func;
```

we may write

```
Function *func;
```

Similarly, there are

```
typedef void VFunction ();  
typedef char *CPFunction (); and  
typedef char **CPPFunction ();
```

for functions returning no value, pointer to char, and pointer to pointer to char, respectively.

2.2.2 Writing a New Function

In order to write new functions for Readline, you need to know the calling conventions for keyboard-invoked functions, and the names of the variables that describe the current state of the line read so far.

The calling sequence for a command `foo` looks like

```
foo (int count, int key)
```

where *count* is the numeric argument (or 1 if defaulted) and *key* is the key that invoked this function.

It is completely up to the function as to what should be done with the numeric argument. Some functions use it as a repeat count, some as a flag, and others to choose alternate behavior (refreshing the current line as opposed to refreshing the screen, for example). Some choose to ignore it. In general, if a function uses the numeric argument as a repeat count, it should be able to do something useful with both negative and positive arguments. At the very least, it should be aware that it can be passed a negative argument.

char * `rl_line_buffer` Variable

This is the line gathered so far. You are welcome to modify the contents of the line, but see Section 2.3.5 [Allowing Undoing], page 23.

int `rl_point` Variable

The offset of the current cursor position in `rl_line_buffer` (the *point*).

int `rl_end` Variable

The number of characters present in `rl_line_buffer`. When `rl_point` is at the end of the line, `rl_point` and `rl_end` are equal.

int `rl_mark` Variable

The mark (saved position) in the current line. If set, the mark and point define a *region*.

int `rl_done` Variable

Setting this to a non-zero value causes Readline to return the current line immediately.

int <code>rl_pending_input</code>	Variable
Setting this to a value makes it the next keystroke read. This is a way to stuff a single character into the input stream.	
char * <code>rl_prompt</code>	Variable
The prompt Readline uses. This is set from the argument to <code>readline()</code> , and should not be assigned to directly.	
char * <code>rl_terminal_name</code>	Variable
The terminal type, used for initialization.	
char * <code>rl_readline_name</code>	Variable
This variable is set to a unique name by each application using Readline. The value allows conditional parsing of the inputrc file (see Section 1.3.2 [Conditional Init Constructs], page 7).	
FILE * <code>rl_instream</code>	Variable
The stdio stream from which Readline reads input.	
FILE * <code>rl_outstream</code>	Variable
The stdio stream to which Readline performs output.	
Function * <code>rl_startup_hook</code>	Variable
If non-zero, this is the address of a function to call just before <code>readline</code> prints the first prompt.	

2.3 Readline Convenience Functions

2.3.1 Naming a Function

The user can dynamically change the bindings of keys while using Readline. This is done by representing the function with a descriptive name. The user is able to type the descriptive name when referring to the function. Thus, in an init file, one might find

Meta-Rubout: `backward-kill-word`

This binds the keystroke `META-RUBOUT` to the function *descriptively* named `backward-kill-word`. You, as the programmer, should bind the functions you write to descriptive names as well. Readline provides a function for doing that:

```
int rl_add_defun (char *name, Function *function, int key)           Function
    Add name to the list of named functions. Make function be the function that gets
    called. If key is not -1, then bind it to function using rl_bind_key ().
```

Using this function alone is sufficient for most applications. It is the recommended way to add a few functions to the default functions that Readline has built in. If you need to do something other than adding a function to Readline, you may need to use the underlying functions described below.

2.3.2 Selecting a Keymap

Key bindings take place on a *keymap*. The keymap is the association between the keys that the user types and the functions that get run. You can make your own keymaps, copy existing keymaps, and tell Readline which keymap to use.

```
Keymap rl_make_bare_keymap ()                                       Function
    Returns a new, empty keymap. The space for the keymap is allocated with malloc ();
    you should free () it when you are done.
```

```
Keymap rl_copy_keymap (Keymap map)                                  Function
    Return a new keymap which is a copy of map.
```

```
Keymap rl_make_keymap ()                                           Function
    Return a new keymap with the printing characters bound to rl_insert, the lowercase
    Meta characters bound to run their equivalents, and the Meta digits bound to produce
    numeric arguments.
```

```
void rl_discard_keymap (Keymap keymap)                             Function
    Free the storage associated with keymap.
```

Readline has several internal keymaps. These functions allow you to change which keymap is active.

Keymap `rl_get_keymap ()` Function
Returns the currently active keymap.

void `rl_set_keymap (Keymap keymap)` Function
Makes *keymap* the currently active keymap.

Keymap `rl_get_keymap_by_name (char *name)` Function
Return the keymap matching *name*. *name* is one which would be supplied in a **set keymap** inputrc line (see Section 1.3 [Readline Init File], page 4).

2.3.3 Binding Keys

You associate keys with functions through the keymap. Readline has several internal keymaps: `emacs_standard_keymap`, `emacs_meta_keymap`, `emacs_ctlx_keymap`, `vi_movement_keymap`, and `vi_insertion_keymap`. `emacs_standard_keymap` is the default, and the examples in this manual assume that.

These functions manage key bindings.

int `rl_bind_key (int key, Function *function)` Function
Binds *key* to *function* in the currently active keymap. Returns non-zero in the case of an invalid *key*.

int `rl_bind_key_in_map (int key, Function *function, Keymap map)` Function
Bind *key* to *function* in *map*. Returns non-zero in the case of an invalid *key*.

int `rl_unbind_key (int key)` Function
Bind *key* to the null function in the currently active keymap. Returns non-zero in case of error.

int `rl_unbind_key_in_map (int key, Keymap map)` Function
Bind *key* to the null function in *map*. Returns non-zero in case of error.

int rl_generic_bind (int type, char *keyseq, char *data, Keymap map) Function

Bind the key sequence represented by the string *keyseq* to the arbitrary pointer *data*. *type* says what kind of data is pointed to by *data*; this can be a function (**ISFUNC**), a macro (**ISMOCR**), or a keymap (**ISKMAP**). This makes new keymaps as necessary. The initial keymap in which to do bindings is *map*.

int rl_parse_and_bind (char *line) Function

Parse *line* as if it had been read from the **inputrc** file and perform any key bindings and variable assignments found (see Section 1.3 [Readline Init File], page 4).

2.3.4 Associating Function Names and Bindings

These functions allow you to find out what keys invoke named functions and the functions invoked by a particular key sequence.

Function * rl_named_function (char *name) Function
Return the function with name *name*.

Function * rl_function_of_keyseq (char *keyseq, Keymap map, int *type) Function
Return the function invoked by *keyseq* in keymap *map*. If *map* is NULL, the current keymap is used. If *type* is not NULL, the type of the object is returned in it (one of **ISFUNC**, **ISKMAP**, or **ISMOCR**).

char ** rl_invoking_keyseqs (Function *function) Function
Return an array of strings representing the key sequences used to invoke *function* in the current keymap.

char ** rl_invoking_keyseqs_in_map (Function *function, Keymap map) Function
Return an array of strings representing the key sequences used to invoke *function* in the keymap *map*.

2.3.5 Allowing Undoing

Supporting the undo command is a painless thing, and makes your functions much more useful. It is certainly easy to try something if you know you can undo it. I could use an undo function for the stock market.

If your function simply inserts text once, or deletes text once, and uses `rl_insert_text()` or `rl_delete_text()` to do it, then undoing is already done for you automatically.

If you do multiple insertions or multiple deletions, or any combination of these operations, you should group them together into one operation. This is done with `rl_begin_undo_group()` and `rl_end_undo_group()`.

The types of events that can be undone are:

```
enum undo_code { UNDO_DELETE, UNDO_INSERT, UNDO_BEGIN, UNDO_END };
```

Notice that `UNDO_DELETE` means to insert some text, and `UNDO_INSERT` means to delete some text. That is, the undo code tells undo what to undo, not how to undo it. `UNDO_BEGIN` and `UNDO_END` are tags added by `rl_begin_undo_group()` and `rl_end_undo_group()`.

int `rl_begin_undo_group()` Function

Begins saving undo information in a group construct. The undo information usually comes from calls to `rl_insert_text()` and `rl_delete_text()`, but could be the result of calls to `rl_add_undo()`.

int `rl_end_undo_group()` Function

Closes the current undo group started with `rl_begin_undo_group()`. There should be one call to `rl_end_undo_group()` for each call to `rl_begin_undo_group()`.

void `rl_add_undo()` (enum `undo_code` *what*, int *start*, int *end*, char **text*) Function

Remember how to undo an event (according to *what*). The affected text runs from *start* to *end*, and encompasses *text*.

void `free_undo_list()` Function

Free the existing undo list.

int `rl_do_undo` () Function
Undo the first thing on the undo list. Returns 0 if there was nothing to undo, non-zero if something was undone.

Finally, if you neither insert nor delete text, but directly modify the existing text (e.g., change its case), call `rl_modifying` () once, just before you modify the text. You must supply the indices of the text range that you are going to modify.

int `rl_modifying` (int start, int end) Function
Tell Readline to save the text between *start* and *end* as a single undo unit. It is assumed that you will subsequently modify that text.

2.3.6 Redisplay

int `rl_redisplay` () Function
Change what's displayed on the screen to reflect the current contents of `rl_line_buffer`.

int `rl_forced_update_display` () Function
Force the line to be updated and redisplayed, whether or not Readline thinks the screen display is correct.

int `rl_on_new_line` () Function
Tell the update routines that we have moved onto a new (empty) line, usually after outputting a newline.

int `rl_reset_line_state` () Function
Reset the display state to a clean state and redisplay the current line starting on a new line.

int `rl_message` (va_alist) Function
The arguments are a string as would be supplied to `printf`. The resulting string is displayed in the *echo* area. The echo area is also used to display numeric arguments and search strings.

<code>int rl_clear_message ()</code> Clear the message in the echo area.	Function
--	----------

2.3.7 Modifying Text

<code>int rl_insert_text (char *text)</code> Insert <i>text</i> into the line at the current cursor position.	Function
---	----------

<code>int rl_delete_text (int start, int end)</code> Delete the text between <i>start</i> and <i>end</i> in the current line.	Function
---	----------

<code>char * rl_copy_text (int start, int end)</code> Return a copy of the text between <i>start</i> and <i>end</i> in the current line.	Function
--	----------

<code>int rl_kill_text (int start, int end)</code> Copy the text between <i>start</i> and <i>end</i> in the current line to the kill ring, appending or prepending to the last kill if the last command was a kill command. The text is deleted. If <i>start</i> is less than <i>end</i> , the text is appended, otherwise prepended. If the last command was not a kill, a new kill ring slot is used.	Function
---	----------

2.3.8 Utility Functions

<code>int rl_reset_terminal (char *terminal_name)</code> Reinitialize Readline's idea of the terminal settings using <i>terminal_name</i> as the terminal type (e.g., vt100).	Function
---	----------

<code>int alphabetic (int c)</code> Return 1 if <i>c</i> is an alphabetic character.	Function
--	----------

<code>int numeric (int c)</code> Return 1 if <i>c</i> is a numeric character.	Function
---	----------

<code>int ding ()</code> Ring the terminal bell, obeying the setting of <code>bell-style</code> .	Function
---	----------

The following are implemented as macros, defined in `chartypes.h`.

<code>int uppercase_p (int c)</code>	Function
Return 1 if <i>c</i> is an uppercase alphabetic character.	
<code>int lowercase_p (int c)</code>	Function
Return 1 if <i>c</i> is a lowercase alphabetic character.	
<code>int digit_p (int c)</code>	Function
Return 1 if <i>c</i> is a numeric character.	
<code>int to_upper (int c)</code>	Function
If <i>c</i> is a lowercase alphabetic character, return the corresponding uppercase character.	
<code>int to_lower (int c)</code>	Function
If <i>c</i> is an uppercase alphabetic character, return the corresponding lowercase character.	
<code>int digit_value (int c)</code>	Function
If <i>c</i> is a number, return the value it represents.	

2.3.9 An Example

Here is a function which changes lowercase characters to their uppercase equivalents, and uppercase characters to lowercase. If this function was bound to ‘M-c’, then typing ‘M-c’ would change the case of the character under point. Typing ‘M-1 0 M-c’ would change the case of the following 10 characters, leaving the cursor on the last character changed.

```
/* Invert the case of the COUNT following characters. */
int
invert_case_line (count, key)
    int count, key;
{
    register int start, end, i;

    start = rl_point;

    if (rl_point >= rl_end)
        return (0);
```

```
if (count < 0)
{
    direction = -1;
    count = -count;
}
else
    direction = 1;

/* Find the end of the range to modify. */
end = start + (count * direction);

/* Force it to be within range. */
if (end > rl_end)
    end = rl_end;
else if (end < 0)
    end = 0;

if (start == end)
    return (0);

if (start > end)
{
    int temp = start;
    start = end;
    end = temp;
}

/* Tell readline that we are modifying the line, so it will save
   the undo information. */
rl_modifying (start, end);

for (i = start; i != end; i++)
{
    if (uppercase_p (rl_line_buffer[i]))
        rl_line_buffer[i] = to_lower (rl_line_buffer[i]);
    else if (lowercase_p (rl_line_buffer[i]))
        rl_line_buffer[i] = to_upper (rl_line_buffer[i]);
}

/* Move point to on top of the last character changed. */
rl_point = (direction == 1) ? end - 1 : start;
return (0);
}
```

2.4 Custom Completers

Typically, a program that reads commands from the user has a way of disambiguating commands and data. If your program is one of these, then it can provide completion for commands, data, or both. The following sections describe how your program and Readline cooperate to provide this service.

2.4.1 How Completing Works

In order to complete some text, the full list of possible completions must be available. That is, it is not possible to accurately expand a partial word without knowing all of the possible words which make sense in that context. The Readline library provides the user interface to completion, and two of the most common completion functions: `filename` and `username`. For completing other types of text, you must write your own completion function. This section describes exactly what such functions must do, and provides an example.

There are three major functions used to perform completion:

1. The user-interface function `rl_complete()`. This function is called with the same arguments as other Readline functions intended for interactive use: *count* and *invoking_key*. It isolates the word to be completed and calls `completion_matches()` to generate a list of possible completions. It then either lists the possible completions, inserts the possible completions, or actually performs the completion, depending on which behavior is desired.
2. The internal function `completion_matches()` uses your *generator* function to generate the list of possible matches, and then returns the array of these matches. You should place the address of your generator function in `rl_completion_entry_function`.
3. The generator function is called repeatedly from `completion_matches()`, returning a string each time. The arguments to the generator function are *text* and *state*. *text* is the partial word to be completed. *state* is zero the first time the function is called, allowing the generator to perform any necessary initialization, and a positive non-zero integer for each subsequent call. When the generator function returns `(char *)NULL` this signals `completion_matches()` that there are no more possibilities left. Usually the generator function computes the list of possible completions when *state* is zero, and returns them one at a time on subsequent calls. Each string the generator function returns as a match must be allocated with `malloc()`; Readline frees the strings when it has finished with them.

int rl_complete (int ignore, int invoking_key) Function
 Complete the word at or before point. You have supplied the function that does the initial simple matching selection algorithm (see `completion_matches ()`). The default is to do filename completion.

Function * rl_completion_entry_function Variable
 This is a pointer to the generator function for `completion_matches ()`. If the value of `rl_completion_entry_function` is `(Function *)NULL` then the default filename generator function, `filename_entry_function ()`, is used.

2.4.2 Completion Functions

Here is the complete list of callable completion functions present in Readline.

int rl_complete_internal (int what_to_do) Function
 Complete the word at or before point. *what_to_do* says what to do with the completion. A value of '?' means list the possible completions. 'TAB' means do standard completion. '*' means insert all of the possible completions. '!' means to display all of the possible completions, if there is more than one, as well as performing partial completion.

int rl_complete (int ignore, int invoking_key) Function
 Complete the word at or before point. You have supplied the function that does the initial simple matching selection algorithm (see `completion_matches ()` and `rl_completion_entry_function`). The default is to do filename completion. This calls `rl_complete_internal ()` with an argument depending on *invoking_key*.

int rl_possible_completions (int count, int invoking_key) Function
 List the possible completions. See description of `rl_complete ()`. This calls `rl_complete_internal ()` with an argument of '?'.

int rl_insert_completions (int count, int invoking_key) Function
 Insert the list of possible completions into the line, deleting the partially-completed word. See description of `rl_complete ()`. This calls `rl_complete_internal ()` with an argument of '*'.

char ** completion_matches (char *text, CFunction
*entry_func) Function

Returns an array of (char *) which is a list of completions for *text*. If there are no completions, returns (char **)NULL. The first entry in the returned array is the substitution for *text*. The remaining entries are the possible completions. The array is terminated with a NULL pointer.

entry_func is a function of two args, and returns a (char *). The first argument is *text*. The second is a state argument; it is zero on the first call, and non-zero on subsequent calls. *entry_func* returns a NULL pointer to the caller when there are no more matches.

char * filename_completion_function (char *text, int state) Function

A generator function for filename completion in the general case. Note that completion in Bash is a little different because of all the pathnames that must be followed when looking up completions for a command. The Bash source is a useful reference for writing custom completion functions.

char * username_completion_function (char *text, int state) Function

A completion generator for usernames. *text* contains a partial username preceded by a random character (usually '~'). As with all completion generators, *state* is zero on the first call and non-zero for subsequent calls.

2.4.3 Completion Variables

Function * rl_completion_entry_function Variable

A pointer to the generator function for `completion_matches()`. NULL means to use `filename_entry_function()`, the default filename completer.

CPPFunction * rl_attempted_completion_function Variable

A pointer to an alternative function to create matches. The function is called with *text*, *start*, and *end*. *start* and *end* are indices in `rl_line_buffer` saying what the boundaries of *text* are. If this function exists and returns NULL, or if this variable is set to NULL, then `rl_complete()` will call the value of `rl_completion_entry_function` to generate matches, otherwise the array of strings returned will be used.

int rl_completion_query_items Variable

Up to this many items will be displayed in response to a possible-completions call. After that, we ask the user if she is sure she wants to see them all. The default value is 100.

char * rl_basic_word_break_characters Variable

The basic list of characters that signal a break between words for the completer routine. The default value of this variable is the characters which break words for completion in Bash, i.e., " \t\n\"\\' '@\$>=<;|&{(".

char * rl_completer_word_break_characters Variable

The list of characters that signal a break between words for `rl_complete_internal()`. The default list is the value of `rl_basic_word_break_characters`.

char * rl_special_prefixes Variable

The list of characters that are word break characters, but should be left in *text* when it is passed to the completion function. Programs can use this to help determine what kind of completing to do. For instance, Bash sets this variable to "\$@" so that it can complete shell variables and hostnames.

int rl_ignore_completion_duplicates Variable

If non-zero, then disallow duplicates in the matches. Default is 1.

int rl_filename_completion_desired Variable

Non-zero means that the results of the matches are to be treated as filenames. This is *always* zero on entry, and can only be changed within a completion entry generator function. If it is set to a non-zero value, directory names have a slash appended and Readline attempts to quote completed filenames if they contain any embedded word break characters.

int rl_filename_quoting_desired Variable

Non-zero means that the results of the matches are to be quoted using double quotes (or an application-specific quoting mechanism) if the completed filename contains any characters in `rl_completer_word_break_chars`. This is *always* non-zero on entry, and can only be changed within a completion entry generator function.

Function * **rl_ignore_some_completions_function** Variable

This function, if defined, is called by the completer when real filename completion is done, after all the matching names have been generated. It is passed a **NULL** terminated array of matches. The first element (**matches[0]**) is the maximal substring common to all matches. This function can re-arrange the list of matches as required, but each element deleted from the array must be freed.

char * **rl_completer_quote_characters** Variable

List of characters which can be used to quote a substring of the line. Completion occurs on the entire substring, and within the substring **rl_completer_word_break_characters** are treated as any other character, unless they also appear within this list.

2.4.4 A Short Completion Example

Here is a small application demonstrating the use of the GNU Readline library. It is called **fileman**, and the source code resides in '**examples/fileman.c**'. This sample application provides completion of command names, line editing features, and access to the history list.

```

/* fileman.c -- A tiny application which demonstrates how to use the
   GNU Readline library.  This application interactively allows users
   to manipulate files and their modes. */

#include <stdio.h>
#include <sys/types.h>
#include <sys/file.h>
#include <sys/stat.h>
#include <sys/errno.h>

#include <readline/readline.h>
#include <readline/history.h>

extern char *getwd ();
extern char *xmalloc ();

/* The names of functions that actually do the manipulation. */
int com_list (), com_view (), com_rename (), com_stat (), com_pwd ();
int com_delete (), com_help (), com_cd (), com_quit ();

/* A structure which contains information on the commands this program
   can understand. */

typedef struct {
    char *name; /* User printable name of the function. */
    Function *func; /* Function to call to do the job. */
    char *doc; /* Documentation for this function. */
} COMMAND;

COMMAND commands[] = {
    { "cd", com_cd, "Change to directory DIR" },
    { "delete", com_delete, "Delete FILE" },
    { "help", com_help, "Display this text" },
    { "?", com_help, "Synonym for 'help'" },
    { "list", com_list, "List files in DIR" },
    { "ls", com_list, "Synonym for 'list'" },
    { "pwd", com_pwd, "Print the current working directory" },
    { "quit", com_quit, "Quit using Fileman" },
    { "rename", com_rename, "Rename FILE to NEWNAME" },
    { "stat", com_stat, "Print out statistics on FILE" },
    { "view", com_view, "View the contents of FILE" },
    { (char *)NULL, (Function *)NULL, (char *)NULL }
};

/* Forward declarations. */
char *stripwhite ();
COMMAND *find_command ();

/* The name of this program, as taken from argv[0]. */
char *progname;

```

```

/* When non-zero, this global means the user is done using this program. */
int done;

char *
dupstr (s)
    int s;
{
    char *r;

    r = xmalloc (strlen (s) + 1);
    strcpy (r, s);
    return (r);
}

main (argc, argv)
    int argc;
    char **argv;
{
    char *line, *s;

    progame = argv[0];

    initialize_readline (); /* Bind our completer. */

    /* Loop reading and executing lines until the user quits. */
    for ( ; done == 0; )
    {
        line = readline ("FileMan: ");

        if (!line)
            break;

        /* Remove leading and trailing whitespace from the line.
           Then, if there is anything left, add it to the history list
           and execute it. */
        s = stripwhite (line);

        if (*s)
        {
            add_history (s);
            execute_line (s);
        }

        free (line);
    }
    exit (0);
}

/* Execute a command line. */

```

```

int
execute_line (line)
    char *line;
{
    register int i;
    COMMAND *command;
    char *word;

    /* Isolate the command word. */
    i = 0;
    while (line[i] && whitespace (line[i]))
        i++;
    word = line + i;

    while (line[i] && !whitespace (line[i]))
        i++;

    if (line[i])
        line[i++] = '\\0';

    command = find_command (word);

    if (!command)
    {
        fprintf (stderr, "%s: No such command for FileMan.\\n", word);
        return (-1);
    }

    /* Get argument to command, if any. */
    while (whitespace (line[i]))
        i++;

    word = line + i;

    /* Call the function. */
    return ((*command->func) (word));
}

/* Look up NAME as the name of a command, and return a pointer to that
   command.  Return a NULL pointer if NAME isn't a command name. */
COMMAND *
find_command (name)
    char *name;
{
    register int i;

    for (i = 0; commands[i].name; i++)
        if (strcmp (name, commands[i].name) == 0)
            return (&commands[i]);
}

```

```

    return ((COMMAND *)NULL);
}

/* Strip whitespace from the start and end of STRING.  Return a pointer
   into STRING. */
char *
stripwhite (string)
    char *string;
