Abstract

Variable latency on the Internet is a well-known problem for interactive applications. With the increase in interactive network games comes the increased importance of understanding the effects of latency on user performance. Classes of network games such as First Person Shooters (FPS) and Real Time Strategy (RTS) differ in their user interaction model and hence susceptibility to variable latency. While previous work has measured the effects of latency on FPS games, there has been no systematic investigation of the effects of latency on RTS games. In this work, we design and conduct user studies that measure the impact of latency on user performance in Warcraft III, a popular RTS game. As a foundation for the research, we separated typical Warcraft III user interactions into the basic components of explore, build and combat, and analyzed each individually. We find modest statistical correlations with latency for exploration, but very weak correlations for building and combat. Overall, the effect of even very high latency, while noticeable to users, has a negligible effect on the outcome of the game. We attribute this somewhat surprising result to the nature of RTS game-play that clearly favors strategy over the real-time aspects.

1 Introduction

Over the past decade, the Internet has grown in popularity and capability at exceptional rates. In 1997, there were 36.6 million homes with computers and only 18 million of them had Internet ac-

cess [6]. By the year 2000, the number of homes with computers had grown to 51 million, 41.5 million of which had Internet access, and many with broadband Internet connections such as cable modems and DSL lines.

This growth in popularity and capability of the Internet has led to an increasingly diverse set of applications with varying network behavior and requirements. Key metrics of latency and throughput are useful in characterizing application behavior. Traditional applications such as file transfer, Usenet news and email are primarily concerned with throughput and can tolerate delays on the order of minutes. Web browsers are also concerned about throughput, but the interactive nature of browsing demands improved latency on the order of seconds or at most tens of seconds [4]. Emerging real-time applications such as IP telephony and networked games typically have the lowest throughput requirements but are even less tolerant of latency than other applications. Knowing how these real-time applications react to latency and loss is the crucial first step in designing the next generation network hardware and software that will support their requirements. In addition, classifications of real-time applications according to latency tolerance will enable designers, developers and engineers to make informed decisions on appropriate quality for classes under such architectures as Diff-Serv [5].

The most popular real-time applications are multi-player network computer games that make

up around half of the top 25 types of non-traditional traffic on the Internet [13] and are predicted to make up over 25 percent of Local Area Network (LAN) traffic by the year 2010. Blizzard Entertainment's Battle.net¹ game service, for example, hosts tens of thousands of game sessions at one time, selected from a choice of five game titles. Knowledge of how network related issues, such as latency and packet loss, affect the usability of games can be of great use the companies that make these games, network software and equipment manufacturers, Internet Service Providers (ISPs), and the research community at large. In particular, if established latency requirements and any associated trade-offs were known, ISPs could establish tariffs based on customers' indicated maximum delays, requested Quality of service (QoS) and the ISP's ability to meet these demands.

Two of the most popular categories of real-time network games are *First Person Shooter* (FPS) games and *Real Time Strategy* (RTS) games. FPS games, first made popular by Doom,² have the player view the world through the eyes of a character (the first person). They then move the player around slaying monsters and other players, with an amalgamation of ranged weaponry (the shooter). RTS games, first made popular by Dune 2,³ are generally characterized by resource collection, unit construction, and battles that consist of large numbers of animated soldiers going through a repetitive, animated attack.

While there has been research qualitatively characterizing the effects of latency for some popular FPS games [9, 2] as well as a general awareness of latency issues [3, 10, 14], quantitative studies of the effects of latency on network games have been lacking. Moreover, it is unlikely that FPS games have the same network requirements as do RTS games. In FPS games, exact positioning and timing is required, because, for example, a target must still be at the location where the

player aimed in order for the shot to hit. In RTS games, the positioning and timing is more forgiving because, for instance, a command can be issued to attack a unit, regardless of its current location or its direction and time of movement.

This work studies the effect of latency on the usability and playability of the best selling [15] RTS game, Warcraft III.⁴ We quantify the effect of latency on user performance in Warcraft III by analyzing the results of controlled research experiments designed to measure quality of service over a range of induced latencies. As a foundation for RTS research, we divide Warcraft III up into fundamental game components of building, exploring and combat. We then develop multiple criteria for measuring user performance in Warcraft III and use these criteria in very carefully designed experiments to determine user performance over a range of latency conditions.

We find that latencies up to several seconds have little effect on the final outcomes of building, exploring, and most combat. Although, the effectiveness of certain strategies, which involve precise timing of events are influenced by the amount of latency, very few such strategies prevail in typical Warcraft III games. Overall, strategy plays a much larger role in determining the outcome of the game than does latency. We conclude that Warcraft III should be placed in a different QoS class than applications with stringent latency constraints, such as FPS games or audio-conferences, since Warcraft III has latency requirements more similar to those of Web browsing.

The rest of this paper is organized as follows: Section 2 presents background information on Warcraft III; Section 3 describes our approach to measure the effects of latency on Warcraft III; Section 4 analyzes the results from our experiments; Section 5 summarizes our conclusions; and Section 6 presents possible future work.

⁴<http://www.blizzard.com/war3/>

2 Background

Warcraft III is an RTS game in which players construct buildings and fighting units, and issue commands that cause the units to move, engage enemy units in battle, and build structures. Games are played on one of many possible maps, which are either provided with the game or custom built by users. During the game, Warcraft III uses a centralized server in a client-server architecture, either over the Internet with possibly thousands of participants or in a LAN scenario with a few players. For most Internet games, the server is via Battle.net,⁵ a free service that allows Blizzard’s Starcraft, Diablo and Warcraft players to initiate multi-player games over the Internet. For a LAN game, users can have a client’s machine act as a server, too, by choosing a map and then letting other clients join the game.

At the beginning of a game, players can choose to be a member of one of four “races” (Humans, Orcs, Undead and Night Elves). Our research focuses on the Humans, but since Blizzard put great effort into making the races equivalent in power, our results should generalize to the other races. There are a number of ways in which players can be competitively grouped. In a free-for-all game, all players vie to have the last remaining army on the map. Players can also team up against each other and/or against artificially intelligent computer-controlled players in myriad ways.

Town control and unit control are two major aspects of the game. Town control consists of selecting what buildings are to be built or upgraded, what units are to be produced and what technologies are to be researched. In order to accomplish these tasks gold and lumber are required which are gathered by peasants. The Human buildings range from farms, which provide food, to town halls, which are the central building in any Human town. Buildings such as barracks produce standard army units such as footmen and knights while buildings such as the arcane sanctum produce units such as priests and sorceresses. Town

⁵<http://www.battle.net/>

Figure 1: Screenshot of Undead Army Attacking a Town.

control involves a lot of strategy in knowing when and where to build, upgrade, and research.

Unit control can be broken up into three sub-categories: building, exploration and combat. Building overlaps with town control as it is the management of peasants in harvesting gold and lumber as well as building and repairing buildings. Exploration allows players to determine geography, find creeps (neutral enemies on which to gain experience for their heroes), enemy towns or units, and neutral shops at which their heroes can buy various items. Combat allows units to kill other units, to defend towns, secure territory or gain experience points for Heroes. There are various battle strategies that can be deployed, but at a minimum the player can let the computer’s artificial intelligence handle the units. Warcraft III has special units called heroes which are more powerful than standard units, and have additional abilities.

Figure 1 shows a screenshot of a Human town under attack from an Undead army. The Undead are in the upper left area of the screen. Human peasants can also be seen carrying lumber to the town hall and other activities.

3 Approach

In order to empirically measure the effects of latency on Warcraft III, we employed the following methodology:

- Categorize user interactions in typical RTS games and construct Warcraft III campaigns that exercise each category (see Section 3.1).
- Determine criteria to quantitatively measure Warcraft III performance (see Section 3.2).
- Construct an environment for measuring the effects of latency on Warcraft III (see Section 3.3).
- Conduct pilot studies (see Section 3.4) and then numerous user studies for each RTS category over a range of latencies, recording the performance measurements.
- Analyze the results (see Section 4).

3.1 Categories of RTS Interaction

Through pilot studies, we determined there were three main user interaction components of an RTS game: *building* when players gather resources, construct defenses and recruit units; *exploring* when players send units out to determine geographic layout and location of other players' units; and *combat* when players engage their units with other units in battle. We built multi-player maps⁶ that isolated each component so we could use experiments to measure the effects of latency on that component.

For the building map (Figure 2 (left)), we divided the map into four quarters using mountain ranges that units could not cross. Each player started with a town hall and four peasants, had unlimited gold and lumber available, and had to research, build, and upgrade the complete Human technology tree as fast as possible. We added triggers to the map that disabled players' ability

⁶The maps can be downloaded at <http://perform.wpi.edu/downloads/#war3>

Figure 2: RTS Component Maps: Build (left), Explore (middle), Combat (right).

to build more than one building in order to provide consistency and reduce confusion, as well as a trigger to display the total time since the beginning of the game.

For the exploration map (Figure 2 (middle)), we designed a raised path that kept units on a general exploration course. The player had to guide a unit along the winding path and step on numerous way-points. Map triggers kept track of the player's time to complete the map.

For the combat map (Figure 2 (right)), we designed a small player versus player arena in which each player controlled a small army consisting of a level 6 Hero (a Mountain King), two Knights, four Footmen, two Riflemen, a Sorceress, and two Priests.

3.2 Warcraft III Performance Criteria

For both the building and exploration maps we recorded the game length as a measure of performance. For the combat maps, in addition to the game length, we recorded each player's unit score, number of units killed and number of heroes killed. The number of units a player starts with plus the number of units killed determines the unit score. The breakdown of points for the individual Human units used in our battle are listed in Table 1.

3.3 Experimental Setup

Figure 3 depicts our experimental testbed setup, which consisted of PCs connected on a private network subnet. Computer A was a dual-processor Pentium-2 300 MHz machine running

Unit	Score
Footman	160
Priest	170
Sorceress	200
Rifleman	270
Knight	350
Level 6 Hero	600

Table 1: Unit Score Values

Figure 3: Experimental Testbed Setup.

Mandrake Linux that routed packets with 100 Mbps connections to the Warcraft computers B, C and D. Computers B and C were Pentium-2 350 MHz machines with 256 MB of RAM, and a 64 MB Geforce 2 Ti graphics card running Windows 98. Computer D was a Pentium-4 1.3 GHz with 256 MB of memory and a 64 MB Geforce2 graphics card running Windows XP.

The recommended specifications for Warcraft III are a 400 MHz Pentium-2 or equivalent, 128 MB of RAM, and an 8 MB 3D video card (TNT, i810, Voodoo 3, Rage 128 equivalent or better) with DirectX[®] 8.1 support. Although machines C and D were only 350 MHz machines, the graphics cards and extra memory that they contained made up for this slight deficiency, and all were capable of rendering 30 frames per second⁷ even during battle. We used Warcraft III version 1.04 for all user tests and version 1.05 for the network traces due to the Battle.net requirements.

We installed NIST Net⁸ on computer A. NIST Net allows emulation of a wide variety of network conditions by giving control at the IP level, including fine tuning of latency and variation in latency (jitter). We used NIST Net to induce latency (and jitter) for one of the machines in a

game, while the others played with no induced latency. Also, in order to analyze the network footprint of Warcraft III, we ran Ethereal⁹ to capture packet traces for network analysis.

3.4 Pilot Studies

First, we conducted pilot studies to help determine the range of viable latencies on which to focus. Our first pilot studies consisted of two-player games in which one player was subjected an increasing amount of latency and the other player experienced none. Initially, each player had town halls and gold mines placed equally far away from their town hall; and second, each player had two identical units that did one point of damage per hit. We setup triggers in the maps so games could be run automatically and ran repeated tests with one player (the lagged player) having increasingly greater latency. We found both players did equally well, gaining gold and inflicting damage at exactly the same rate. In addition, both players saw exactly the same events on each screen, except the player with added latency saw events later than the player without latency.

From these pilot studies, we made two important observations about latency compensation in Warcraft III:

First, the game does not use handicapping in the game to equalize latencies across all players. Both lagged and non-lagged players see events happen at the real-time rate, regardless of the latency of the other player. The lagged player has events executed later by an amount equal to the induced latency.

Second, the game does not have inconsistent game states, which implies no dead reckoning [8]. The actions that occur on each machine are identical; there is no prediction of user actions and then correction upon some later time if the predictions are inconsistent with the actual game state.

Thus, clients must communicate any user actions to the server before executing them. Af-

⁷Tested with fraps, <http://www.fraps.com/>

⁸<http://snad.ncsl.nist.gov/itg/nistnet/>

⁹<http://www.ethereal.com/>

ter that, the commands themselves are executed identically on all machines in the game.

For the real experimental runs, the maps were not automated and we pitted one player against another player. The first player was the server with no induced latency. The second player was the client that could be subject to induced latencies from 0 to 3500 ms, a range even broader than typically found in dialup modems [11]. Hence, we concentrate our data points on ranges of more typical latencies [1] which are less than 1000 ms.

From traces collected during our pilot studies, we determined that clients communicate only with the server but not directly with other clients. Servers combine data from multiple clients before distributing data. Each machine maintains a complete copy of the game state, and to an extent, all outcomes are predetermined upon initiation of the action. Data is only transferred upon the issuance of a command, and never again during the life of the event. For instance, the commands to initiate a large-scale battle are propagated to all clients once, resulting in an increase in the packet payload size, but the battle itself has no effect on traffic unless further commands are issued as the battle is carried out.

4 Analysis

Analysis of collected data was done at three levels, namely, application level analysis, network analysis and user analysis. Section 4.1 contains our analysis of the application level data we collected from our Warcraft III user studies. Section 4.2 contains our analysis of the network level traffic we collected for a LAN game and two Battle.net Internet games. Section 4.3 summarizes our observation data we collected during the user studies.

4.1 Application Layer Analysis

This section analyzes the results from each of our test maps, starting with building (Section 4.1.1),

Figure 4: Build Time versus Latency.

then exploring (Section 4.1.2) and lastly combat (Section 4.1.3).

4.1.1 Building

Figure 4 illustrates the effect of latency on the total time required to construct every building and research every upgrade (the technology tree) for the Human race from our test map. The graph shows the build time versus latency for all runs, as well as a best-fit line for the data. Under conditions with no induced latency, building the technology tree takes about 8 minutes. Latencies values of up to 3.5 seconds increase total build time by at most 14 seconds, which is less than 1% of the total time for this short game. The coefficient of determination¹⁰ is 0.05, indicating there was very little statistical correlation between latency and the building. In addition, the statistical correlation observed in a real game environment is likely to be even lower. This is due in part to a longer game time and that different numbers of buildings would be produced (such as more than one farm). In addition, in a real game, players may build their towns in a strategic layout instead of in a random pattern. Finally, time is often spent in a real game attending to other matters so that

¹⁰The coefficient of determination (R^2) represents the fraction of variability in y that can be explained by the variability in x . In the simple linear regression case, R^2 is simply the square of the correlation coefficient. An R^2 of 1 represents perfect correlation.

Figure 5: Explore Time versus Latency.

the speed of building the base is not of utmost importance. Our conclusion is that any effect latency may have on building would have no significant impact on the outcome of real Warcraft III games.

4.1.2 Exploring

Figure 5 illustrates the effect of latency on the exploration of our test map. The graph shows the exploration time versus latency for all runs, as well as a best-fit line for the data. The overall correlation between explore time and latency is modest (0.63), but can be high (0.95) for individual users. The first 8-10 games of a test typically showed a vertical component where exploration times decrease. We attribute this to the player learning the map, gaining from the knowledge in subsequent games. Once the map is known, all data show a nearly perfect linear relationships between latency and time to explore. Overall, while there is a statistical correlation for explore time versus build time, the effect of an additional 6 seconds of exploration time for every 100 ms of latency would be insignificant in a real game. In addition, it is likely that high latency players in a real game may try to adapt in various ways during exploration. For instance, high latency players may discover that they achieve better results by spending less time actively controlling their units during exploration and thus decide to send them

Figure 6: Unit Score Difference versus Latency.

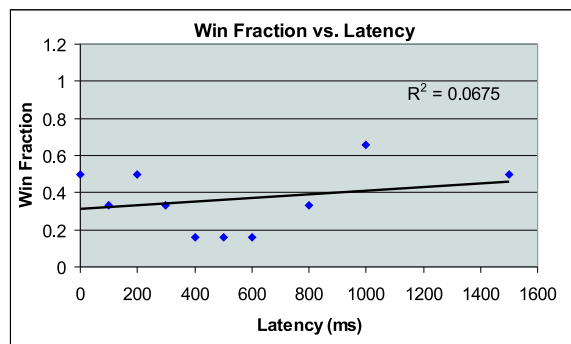

Figure 7: Games Won by Host (non-lagged) versus Latency (on the Client).

for long distances with each move command instead micro-managing them for shorter distances.

4.1.3 Combat

Figure 6 illustrates the effect of latency on combat from our test map. The graph shows the unit score difference versus latency for all runs, as well as a best-fit line for the data. The unit score difference is the non-lagged player's unit score minus the lagged player's unit score. The maximum difference (if one player loses all units and the other loses none) is +/-3020. From Figure 6, there is a slight upward trend in that the score difference increases as latency increases, but the coefficient of determination is an extremely low 0.01.

Figure 7 shows the percentage of games won by the non-lagged host versus latency of the lagged client.. Again, even though there is a slight up-

Figure 8: Unit Score Difference versus Variable Latency: Player 1 versus Player 3 (top), Player 2 versus Player 3 (bottom)

ward trend in the data, the coefficient of determination is an extremely low 0.07, indicating there is little statistical significance. Thus, we conclude that latency has little effect on the outcome of combat.

While the previous studies measured the effects of fixed latency on user performance, we also examined the effects of variable latency. For these tests, we set NIST Net to induce an average latency of zero¹¹ with a range of standard deviations.

Figure 8 shows games for 2 pairs of users with a standard deviation of latencies from a normal distribution with mean zero. Figure 8 (top) shows player 1 winning two games, one at 100 ms, and then again at 750 ms, while losing the games in between, all by similar margins of 1 or 2 units. Figure 8 (bottom) shows Player 3 consistently beating his opponent in every game, but by vary-

¹¹Our testbed had 1 ms of base latency from client to server.

ing margins. Neither graph shows a significant statistical relationship between the variable latency and success in battle, similar to the results with constant latency.

Overall, both from a direct conclusion from our data and with extrapolation into a complete game, we found that the effect of latency on the outcome of a Warcraft III game is negligible over a range of practical latencies.

4.2 Network Analysis

Among other things, a better understanding of network game traffic can help design networks and architectures that more effectively accommodate their traffic footprints. Furthermore, careful empirical measurements of network games can provide the data required for accurate simulations, a typical tool for evaluating network research.

We packet traced three full (20-30 minute) games, two played over Battle.net and one played over a LAN.¹² The LAN game was 1 player versus 1 player (1v1), and the Battle.net games had a 1 player versus 1 player game and a 2 player team versus another 2 player team (2v2) game. All of the games showed fairly similar overall traffic patterns that differed slightly with the number of players and outcome of the games. Unlike other popular networked games [7], Warcraft III always uses TCP as the transport protocol with port 6112 for the server. All IP traces were performed on the client machines.

Figure 9 depicts the cumulative density functions (CDFs) of the payload sizes for all packet traces (incoming and outgoing). The median payload sizes are all very small, only 9 bytes. The two most common payload sizes are 6 and 9 bytes. The Battle.net games have a little over 20% packets that are empty TCP acknowledgments. Less than 1% of the payloads for any game are over 40 bytes with the Battle.net games having slightly more larger packets. The 2v2 player Battle.net

¹²The network traces can be downloaded at <http://perform.wpi.edu/downloads/#war3>

Figure 9: Payload Distributions

game has nearly the same payload distribution as does the 1v1 player Battle.net game.

Overall, Warcraft III sends considerably smaller packets than the typical Internet traffic packet size of over 400 bytes [12]. The number of players did not have a noticeable effect on the packet sizes, either. Warcraft III packet sizes are consistent throughout the game and are not significantly influenced by the action in the game. Since current Internet routers are designed for large transfers with large packets, there may be opportunities to improve network architectures to better manage and support game traffic.

As a note, Starcraft¹³, the previous generation Blizzard Real Time Strategy game from Blizzard, has typical packet sizes of 122 and 132 bytes [7], while Warcraft III packets are most commonly 46 or 49 bytes in size (including headers).

Warcraft III's sends out packets at regular intervals. Table 2 depicts the intervals that we observed for incoming and outgoing inter-packet times during the games we traced. In our local area network game, Warcraft maintained a very steady inter-packet rate of one packet approximately every 1/10th of a second both incoming and outgoing. With our Battle.net games the timing interval was lower, down to one packet every 200 ms incoming and every 160 ms outgoing.

¹³<http://www.blizzard.com/worlds-starcraft.shtml>

	1v1 LAN	1v1 B.Net	2v2 B.Net
In Mean	104	201	201
In Std Dev	18.6	79.1	78.1
Out Mean	104	165	159
Out Std Dev	19.4	87.4	088.2

Table 2: Inter-packet Summary Statistics (ms)

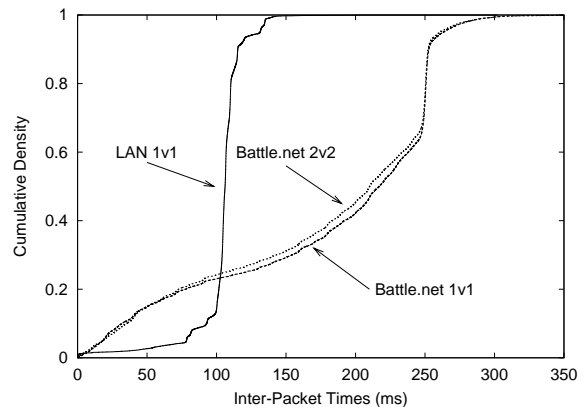

Figure 10: Inter-packet Distributions

Figure 10 depicts the CDF for inter-packet times (incoming and outgoing). The LAN game has a much more consistent data rate while the Battle.net Internet game varies considerably more. The median times for the Battle.net games are around 225 ms compared with around 100 ms for the LAN game. The 1v1 player Battle.net game exhibits about the same inter-packet times as does the 2v2 player Battle.net game.

4.3 User Analysis

While we did not provide a way to quantify player perceptions, we did note game player comments and observed trends during and after our user studies.

Players observed that it was relatively easy to adjust their strategy to compensate for latencies between 0 ms and 500 ms. The game still appeared to run smoothly, and although the delays in executing commands were perceptible, it was relatively easy to estimate this delay and react ac-

cordingly. For latencies above 800 ms, the game appeared erratic which made for a degraded game experience. Without a short response time when executing commands, gamers found it difficult to implement particular strategies.

The exact point at which a player perceived a degraded game experience was between 500 ms and 800 ms but varied from person to person based on strategy and skill level. A strategy that relied heavily on micro-management of units was more sensitive to latency than a strategy that was less focused on individual unit control. What game aspects that a player chooses to micro-manage also had an effect on how perceived latency affected the gaming experience. A player that micro-managed the town rather than the combat units was much less likely to be aggravated by latency than a player that micro-managed units in combat. Also, a mistake during combat that appeared to be the result of high latency was viewed, rightly or wrongly, as more serious than a mistake during building.

Thus, while latency does not necessarily affect the outcome of the game, if high enough, perceived latency does affect the users' gaming experience.

5 Conclusions

Understanding the effects of latency on application performance is important in order to design networks that meet application requirements. The growth in interactive network games demands better understanding the effects of latency on user performance in network games.

In this work, we investigated the effects of latency on user performance in Warcraft III, a popular Real Time Strategy (RTS) game. We divided RTS games into their fundamental components of build, explore and combat and designed experiments to isolate and measure the effects of latency on each component.

We find overall user performance is not significantly affected by Internet latencies ranging from hundreds of milliseconds to several seconds.

There is some statistical correlation between latency and the exploring game component, but the overall impact is minimal and there is even less correlation between latency and building and between latency and combat.

While these results are, at first glance, somewhat surprising they can be explained by the fact that the nature of RTS game play emphasizes strategy more than the interactive aspects. While Warcraft III is played in real-time, reaction time plays a small role compared to understanding the game, knowing a campaign map, and having a good strategy. Since RTS user strategies take seconds or even minutes to carry out, the effects of typical network latencies (less than a second) do not impact the overall outcome. This insensitivity to latency is further illustrated by Warcraft III's use of TCP as the underlying transport protocol. TCP retransmits lost packets, with the retransmissions increasing latency on the order of a round-trip time, at best, and several seconds (upon timeout) at worst. Overloading at the game server is another factor which potentially adds to game latency. The fact that Warcraft III's game play over the Internet via Battle.net is very effective further underscores the lack of significant impact of latency on game outcome.

Overall, in terms of general classification of traffic, RTS games do not have the very strict latency requirements (on the order of hundreds of milliseconds) of audio-conferencing or First Person Shooter network games, but instead have latency requirements most similar to that of Web browsing (on the order of seconds). Warcraft III exhibits network traffic characteristics with regularly-spaced small packets and modest aggregate bandwidths which make it suitable for play over a low speed modem even in the case of large-scale multi-player games.

6 Future Work

While the results in this project have focused on Warcraft III, we assume that they generalize to other RTS games (such as Age of Em-

pires¹⁴ or Command and Conquer¹⁵) as well, since most RTS games have the same fundamental components (build, explore, combat) and similar user-interaction models. Studies to confirm this through select user-studies, possibly less extensive than those presented here, would be useful to verify our assumption and help generalize our results.

The component-based studies presented here do not allow users to choose long-term strategies. Evaluating the effects of latency on how users choose what components to micro-manage, how they select and form long-range, even full-game strategies may provide insights beyond the results presented here.

The effects of latency on user performance in other game genres, such as First Person Shooters or Massively Multi-player Online Role Playing Games, is also still an open issue. However, it is clear that several network games consist of distinct phases which vary greatly in their interaction model and hence network behavior. The component-centric methodology presented here, which entails categorization of the game play and running of controlled users studies in each category, can perhaps be applied to these games as well, in order to increase overall understanding of network games.
