### Subnet Bandwidth Manager: Admission Control over Ethernet

Raj Yavatkar, Intel Don Hoffman, Sun Ema Patki, Intel

# Goals

Step-by-step mapping of int-serv capabilities over **Ethernet infrastructure** short-term solution should work with existing bridges, hubs/switches **work with IEEE 802.1? for Level-2 support ex. traffic flow separation** Step I -- admission control for RSVP traffic and policing at end systems Step II -- traffic flow separation at hubs/switches Step III -- traffic control support in hubs/switches

# **Objectives for Step I**

 administrative control over max amount of multimedia traffic over any LAN segment
 Rely on end-system policing and rate-adaptive applications for best effort traffic
 *slow start* type congestion avoidance
 Leverage existing RSVP-signaling as much as possible

# Outline

#### **Only architectural discussion**

variations from RSVP message processing rules included protocol details, packet formats, etc. NOT included Discuss possible alternatives

intal

## Overview

SBM (Subnet Bandwidth Manager) responsible for admission control a designated SBM (DSBM) for each LAN segment an SBM may act as DSBM for many segments **SBM** is a UDP-based server soft state in SBM with refresh ala RSVP **recovery from SBM restart and failures** dynamic binding between SBM and end-systems IP multicast based

# **Overview (contd.)**

**At the start, an RSVP node discovers and binds to its DSBM using IP multicast-based protocol PATH messages sent/forwarded to the session address** (NO CHANGE) **Outgoing RESERVE over Ethernet interface unicast** to **DSBM a new LAN PHOP object specifies the PHOP DSBM** performs admission control and forwards **RESERVE** toward PHOP

# **Overview (contd.)**

DSBM processing similar to conventional RSVP processing
 merges reservations appropriately
 avoids killer reservations
 returns RESV\_ERROR or RESV\_CONFIRM (if necessary)

## **Important Notes**

NOT a centralized scheme
 Many SBMs can exist per LAN, each responsible for a separate portion of the LAN
 Does NOT require maintenance of consistent, distributed state across Hosts and SBMs
 Distribution of responsibility among SBMs allows scalability and fault tolerance

# **An Alternative Proposal**

**Assume one SBM per IP subnet PATH message sent to special SBM address** mcast to SBM group address (a new encapsulation) SBM inserts itself as a PHOP between sender and receiver **RESERVE** automatically lands up at the SBM **Presented to IEEE 801.P does not allow for multiple SBMs within a subnet** an SBM per hub/switch should be allowed

# **Supporting Mechanisms**

Discovering DSBM and binding to it
DSBM listens to a well-known UDP meast address
DSBM Election
more than one active SBM for same segment(s)
single SBM is a DSBM at any time, elected using an election protocol
Use of *I\_AM\_DSBM* declarations via IP multicast and some tiebreaking
peers step in when DSBM fails or terminates

# **Application Behavior**

Sender on a LAN not to transmit any traffic until at least one successful RESERVE reaches it **Outgoing flow to be policed to be within maximum RESERVE** made For multicast flows, receivers must leave the session mcast group in case of RESV ERR or PATH TEAR **problematic** in case of multiple senders **Best-effort traffic must be rate-adaptive** 

intal

# **Handling Complex Physical Topologies**

Multi-hop topology consisting of bridges, hubs, and switches
 data flows traverse only a subset of segments
 multiple DSBMs, each for separate portion of LAN desirable
 How to discover topology information?
 How to discover peer DSBMs and communicate with them?

# **Discovering LAN Topology**

techniques used by network management utilities
 static configuration info works only in case of non-redundant paths
 an interface to spanning tree topology info needed
 IEEE 802.1 area
 IETF hub MIB working group
 topology mapping section

## **Topology Discovery Protocol**

Placing two endpoints on a map and identifying LAN segments between them
 endpoints identified using MAC addresses
 tell managed hubs in the collision domain to watch for packets with the endpoint MAC address
 send a *PING* to the endpoint to get it to transmit
 SBM then uses hub MIB interface to read the group/port of target MAC address from managed hubs
 SBM then identifies affected segments

#### Host

#### **Peer-to-Peer DSBM Communication**

 Peers discovered using SBM\_QUERY to SBM\_GRP address
 information is cached with time-out
 After successful admission control, DSBM forwards a RESERVE to the peer on next hop towards LAN\_PHOP
 An error is sent back hop-by-hop using reservation state in intermediate DSBMs

## **Areas of Co-operation With IEEE 801.P**

definition of a standard interface for accessing spanning tree (routing) information in MAUs
 mechanisms for traffic flow separation

 ex. priority mechanism

 RSVP-based admission control combined with traffic flow separation

 a good approximation to *Controlled Load*?
